PREFACE TO THE NINTH EDITI

THE interval of seven years since the publication of the eighth edition of
Text-Book of Anatomy has brought some changes in the authorship o
Dr. E. B. Jamieson, who had been responsible for the *Osteology* Secti
and co-editor since 1937, has retired; and the present editor desires
grateful appreciation of a harmonious co-operation that has proved
him personally and in the maintenance of the reputation of the Text-B

The Section on *Osteology* has been taken over by Dr. R. G. Inkste
the University of Edinburgh, and he has revised in particular the ac
development and growth of bone with some new illustrations.

The untimely death of Professor D. M. Blair has caused a vacancy i
ship of the Section on *Arthrology*. This has been filled by Profe
Walmsley, University of St. Andrews, who has amplified and illustrated th
on the development of joints.

The Text-Book has suffered another severe loss by the death of Sir
not long after his appointment as Principal of the University of Edinbur
intimated that he would be unable to retain charge of the Section on
Surgical Anatomy, and his place has been taken by his successor in the R
of Clinical Surgery, Sir James Learmonth. The editor feels sure that th
association of the Section, originally contributed by the late Sir Harold
this famous Chair will be very gratifying to all former readers of the Text
in particular to graduates of the University of Edinburgh. Sir James
has revised the Section in detail, with some reduction in its length, and he h
useful Tables of the segmental innervation of the limb-muscles.

The editor, with a sense of personal loss of a friend and colleague, rec
the death of one of the contributors, Emeritus Professor Arthur B. Applet
the preparation of this edition was nearing completion. He had revised t
less Glands before his fatal illness overtook him, and his name therefore sta
author of that Section for which he had been responsible in the two previous

The editor records also with regret the death at an advanced age in
Emeritus Professor Arthur Robinson, the last surviving original contrib
editor of the fourth, fifth and sixth editions. The time has now come, t
for an alteration in the form of the Sectional headings which hitherto have
the name of the original contributor and in some instances the names of su
revisers; in this edition the name of the present contributor alone appears.

Apart from the items already mentioned, the text of this edition has ag
thoroughly revised by all the contributors and broug up to date by the in
of numerous references to new work in their several su ts. The editor
to record his appreciation of their unfailing co-operation t this has e
Special note may be made of the new material bearing the earliest st
human development incorporated in the Section on *Embryology*, Professor (
revised and illustrated account of the broncho-pulmonary segments, and t
arrangement of Professor West's Section with its w title, *The Skin and the S*
Organs.

portant innovation in this edition of the Text-Book is the provision erences at the end of each Section. Previous editions had included ımber of references to recent work, either in the text or as occasional it has been suggested that it would be much more convenient and ;o have these gathered together and amplified into brief biblio- ;ical references have not been omitted; but in general the several ; including recent scientific papers and monographs, have endeavoured ; sources which themselves provide more complete bibliographies. de also references to the sources of all borrowed illustrations, old ıddition to its character as a student's text-book, it is hoped that by ıningham's Anatomy may serve also as an up-to-date work of reference ents and others. Every endeavour has been made to ensure accuracy ;nces, both in the text and in the lists, which have been printed in th standard practice.

ıtions have again been extensively revised, and the increase of twenty- al number of text-figures does not indicate the extent of that revision. ıstrations have been omitted, some replaced and some repetitions hers, as in previous editions, have been improved by alteration, by by the addition of colour; and many have been replaced by entirely s. The number of new or altered illustrations is actually one hundred ɔne, of which fifty-five have been specially prepared, eighteen altered by addition of colour, and forty-eight borrowed or adapted from other . Special mention may perhaps be made of the new series illustrating ı development and the external form of the embryo.

jority of the new drawings have been prepared in the Department of edical Illustration Division) of the University of Edinburgh—a few of r. Clifford Shepley, but most by Miss Ann Brown, to both of whom the eatly indebted for the care and artistic skill they have brought to bear ɛ. His thanks are due also to Mrs. Yvonne Hill for a considerable number matic figures which also witness her skill as an artist. Fig. 606 has been Miss Nancy Joy of the Department of Anatomy, Toronto; Fig. 391 is . of Mr. William Cruickshank, Department of Anatomy, Aberdeen; and : M. R. Drennan, University of Cape Town, has provided Figs. 533 and e editor acknowledges also the provision of photomicrographs by Professor ısley for the Section on Arthrology, and the preparation by Dr. J. W. A. cth, of this Department, of the new photomicrographs of blood-vessels for ;ular System.

;ditor desires to thank most cordially the various authors and publishers ; so courteously granted permission to use illustrations borrowed or adapted publications. In addition to the statement of authorship and source orded with each figure and in the lists of References, acknowledgment is ;he following publishers and editors for the use of the figures mentioned: ıerican College of Chest Physicians (604, 1215); Messrs. Baillière, Tindall (827); The Blakiston Company (108 B.C.D., 109 B., 110 B.); Chicago ity Press (989); The Clarendon Press (124, 126); Edinburgh University ;, 28); MM. Hermann et Cie (1072); MM. Masson et Cie (127); and the ; and Proprietors of the *American Heart Journal* (1066); the *Anatomical* (718); *Brain* (8[illegible]; the *British Journal of Surgery* (1224); the *Bulletin of ns Hopkins Hos*[illegible]*l* (713); and the *Journal of Anatomy* (46, 733).

;cial thanks are due to Dr. George W. Corner, Director of the Department of ;ology (Carnegie Institution of Washington), Baltimore, for his very cordial ;sion, on behalf of the Department and the various authors concerned, to uce a considerable number [illegible]f illustrations from the Contributions to Embry- (Figs. 37-40, 42-44, 47,[illegible]5, 72, 112-116, 118, 119) and in particular for

providing original photographic prints for Figs. 39, 40, 42 and 43. In addition, the editor is deeply indebted to Dr. Arthur T. Hertig for his personal permission to reproduce his illustrations of the 2-cell and free blastula stages of human development (not fully published at the time), and to Dr. Corner for providing photographic prints of these beautiful specimens (Figs. A & B, p. 16) and of the perfect chorionic vesicle, with embryo in its amnion, reproduced as Fig. 121 A.

The series of Radiographic Plates, which has been a feature of the seventh and eighth editions, has again been revised and made still more complete. The total number of Plates has been increased from eighty-four to eighty-eight; and they have been rearranged and all duplicates eliminated. Twenty-three entirely new radiographs have been added and five others replaced by better examples. In addition, three Plates, reproducing, by kind permission of Messrs Faber & Faber, Ltd., nine illustrations from Professor R. D. Lockhart's *Living Anatomy*, have been added; and a classical figure from William Harvey has been included (Pl. LXXIX).

As in previous editions, the great majority of the radiographs appear in negative reproduction, only those illustrating arterial injections (Pls. LXXXI-LXXXVII) being shown as positives. Radiographs are examined clinically as negatives, and the contrast presented by these positives may enable the student to appreciate the points made in the Appendix on the technique and principles of radiography. In this connection, mention may be made also of the addition there of two simple diagrams illustrating these principles.

The editor is indebted to several colleagues for the provision of new radiographs. Dr. D. R. Maitland and Dr. J. D. Recordon of the Radiological Department, Royal Infirmary of Edinburgh, have assisted him in this way while acting as Demonstrators of Radiography in the University Department of Anatomy; and the new radiographs illustrating the paranasal sinuses were prepared by Dr. Peter Aitken. Dr. R. G. W. Ollerenshaw, Manchester Royal Infirmary, kindly prepared negative prints of his parotid and submandibular sialographs (Pl. XLIX), and Professor Norman M. Dott (through Dr. C. A. Gleadhill, Senior Registrar, Neuro-surgical Department of the Royal Infirmary) has again placed the editor in his debt by providing new ventriculographs (Pls. LXXIV, LXXVI) and cerebral arteriographs (Pl. LXXX). With the exception just mentioned (Pl. XLIX), all the prints, negative and positive, for the reproduction of the new radiographs have been prepared by Mr. John Borthwick of this Department.

With regard to nomenclature, the Birmingham Revision (B.R.) continues to be used, and the policy of eliminating synonyms in a students' text-book has been carried to its conclusion; but in a few instances latin terms have been retained (in brackets), where these may help the student to appreciate the derivation of related words.

In addition to the cordial co-operation of all the contributors, the editor h received valuable assistance in the reading of page-proofs from Dr. Helen Barret who has made numerous useful suggestions, and from Dr. R. G. Inkster who ha been responsible also for the preparation of the Index.

Lastly, the editor takes pleasure in recording that he prepares this Preface in the centenary year of his own teacher and the original editor, Daniel John Cunningham (1850–1909), and in pointing out that this ninth edition may serve, during its currency, to celebrate the Jubilee of Cunningham's *Text-Book of Anatomy*, first published in 1902.

INTRODUCTION

TO

HUMAN EMBRYOLOGY

by J. C. Brash, *M.C.*, M.A., M.D., D.Sc., F.R.C.S.Ed., F.R.S.E.
Professor of Anatomy, University of Edinburgh

Human Embryology—the study of the human embryo and its development—treats of the phenomena of the intra-uterine period of life, from the fertilization of the ovum to the birth of the child. But there is a cycle of events in the relation of succeeding generations; and so it is necessary first to consider the life-history of the germ-cells which link one generation to the next.

It has been explained in the General Introduction that all the cells of the body are the descendants of a single cell which is the starting point of each individual. The innumerable cells derived from the fertilized ovum are separable into two main groups, a larger group—the **soma-cells**—from which the body of the individual is developed, and a much smaller group—the **germ-cells**—upon which

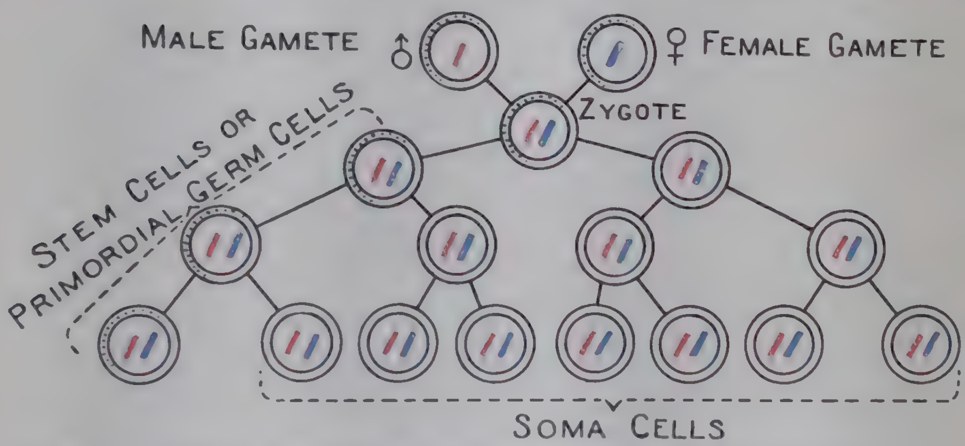

Fig. 9.—Diagram showing the Descent of Germ-cells and Soma-cells.

the life of the species depends (Fig. 9). The germ-cells are lodged in the body of the individual in the **sex-glands**—**ovaries** in the female, **testes** in the male.

The germ-cells undergo a process of ripening, known as *maturation*; and when mature they are called **gametes**. A new individual is initiated by the union of two gametes—a male gamete, or **spermatozoon**, and a female gamete, or **mature ovum.** The new cell thus formed is a **fertilized ovum** and is known as a **zygote**—a term conveniently indicating that it is formed by the yoking together of two individuals and that it contains therefore the potentialities of both (Fig. 9).

The human zygote is about 150 μ in diameter and of scarcely measurable weight. From it are produced not only a new individual and the germ-cells of the next generation, but also a series of membranes and appendages necessary for growth and development during intra-uterine life.

The **ontogenetic** or **developmental history** of the individual is usually considered to extend from the formation of the zygote to the attainment of full adult growth. The **period of development** thus defined is divided into an **intra-uterine** or **pre-natal** period and an **extra-uterine** or **post-natal** period.

The intra-uterine life of human beings lasts for about nine months, and is itself divided into three secondary periods:—(1) The **pre-embryonic period**, during which the growing zygote is *implanted* in the mucous membrane of the uterus (*endometrium*), and is differentiated into embryonic and non-embryonic portions; this period lasts rather less than two weeks. (2) The **embryonic period**, in which the rudiments of all the main organs of the adult are developed, although the embryonic part has not yet assumed a definitely human form; this period runs to the end of the second month. (3) The **fœtal period**, from the end of the second month, when the embryo begins to assume a definitely human appearance and is called, thenceforth, a **fœtus.** The fœtal period ends at birth, when the fœtus becomes a child and passes into the stage of *post-natal development.*

During the fœtal period growth proceeds rapidly. It is especially rapid during the ninth month; and at birth the child usually weighs about seven pounds.

During the first-stages of the post-natal period—**infancy, childhood, adolescence**—growth and development still proceed until the adult condition is attained; then follows a period of **maturity**, which passes insensibly into the last stage of all—**senescence**—which ends in natural death. In the following pages it is the intra-uterine period of life which will be considered and more especially the phenomena of the first two months—the pre-embryonic and embryonic periods.

The aim of this Section is to provide the student with a general account of the formation of the embryo—*embryogeny*—so that he may be in a position to understand the more detailed paragraphs on the development of organs—*organogeny*—which he will find throughout the text-book. Some account will be given also of those important extra-embryonic organs peculiar to intra-uterine life—the **fœtal membranes**—which are responsible for the protection of the embryo and fœtus and provide, by the connexion established between one of them and the uterus, for its physiological needs (Barcroft, 1946).

For further information on human development the student should consult the special works on the subject included in the list of References at the end of this Section.

Growth and Differentiation.—In the development of the embryo two main processes go hand in hand, but **growth**—increase in size by cell-division—must be carefully distinguished from **differentiation**—the specialization of cells in the formation of tissues and the rudiments of organs. Growth in general depends upon a proper supply of nutriment, and the growth of some parts of the body depends further upon special chemical factors, either derived from food-material or secreted into the blood by organs of the body itself. The differentiation of a group of cells to form the rudiment of an organ may be due to inherited potentialities located in that particular group—such rudiments of organs are said to be 'self-differentiating'; or it may depend on the situation of the group of cells and the influence of neighbouring cells and rudiments upon them. Experiments have been made by the simple excision, or the transplantation into other regions, of portions of embryos, and by the cultivation of excised portions, either as grafts on other growing tissues (such as the chorio-allantoic membrane of the chick) or inserted in suitable nutritive media (tissue-culture). It has thus been shown that the power to form parts and organs may be more widespread in the cells of an embryonic layer than is apparent, and that their development in a particular place depends on the influence of other parts already differentiated. Such 'dependent differentiation' of parts may be illustrated by two classical examples of the results obtained by the methods of *Experimental Embryology.*

The formation, and therefore the situation, of the axial structures in the embryonic area depends upon an influence, known to be chemical, exerted by the tissues in the primitive streak: these are believed to correspond with the dorsal lip of the blastopore in lower forms which, because it has this power, has been called the "Organizer" (Spemann & Mangold, 1924). The formation of the lens-vesicle of the eye from the ectoderm depends, in some species, on the presence of the underlying optic cup—a self-differentiating structure which grows out from the fore-brain; if the optic cup is removed the lens does not appear, but a lens-vesicle may be induced to form from another part of the ectoderm by transplanting the cup (Lewis, 1904).

Progressive differentiation of the cells of a region is illustrated by experiments on limb-buds. Part of a limb-bud which, if left *in situ*, would form a particular part of the limb may, if transplanted soon enough, 'regulate' so as to form a complete limb. After a time, however, the cells of the limb-bud are differentiated, chemically if not morphologically, to form a 'mosaic', any part of which has its particular destiny fixed and is incapable of 'regulating' to form a whole limb; yet, for a time, it may still be capable of producing the whole of one segment of the limb. Thus, a portion of the thigh-region of a chick-embryo, transplanted (Murray & Huxley, 1925) or grown by tissue-culture methods (Fell & Robison, 1929), will produce not a complete limb but a femur only.

For further information on the control of development see the works of Huxley & De Beer (1934), Spemann (1938) and Waddington (1935, 1940).

There are also many general chemical problems in the development of the embryo, and for information on this aspect of the subject and on the history of Embryology the student should consult Needham (1931; 1934; 1942).

GERM-CELLS

The majority of the multitudinous descendants derived from a zygote are soma-cells, which form the tissues of the body; but a minority, which inherit all the potentialities of their parents, remain as **primordial germ-cells** or stem-cells. Fresh evidence has recently been brought forward to show that the primordial germ-cells are segregated from the soma-cells at a quite early period (Fig. 9), and that they migrate from the wall of the yolk-sac to the genital ridge of the embryo (Witschi, 1948). There are three main stages in the life-history of germ-cells—multiplication, a growth-period, and maturation. Though the functions and the life-histories of germ-cells are quite different from those of soma-cells, nevertheless the structural characters of the two groups of cells are very similar; in particular they both multiply by the same process of mitotic division (p. 8). Each primordial germ-cell thus produces many descendants which are lodged in the sex-glands—female sex-cells or **oogonia** in the ovaries, male sex-cells or **spermatogonia** in the testes—where they undergo further

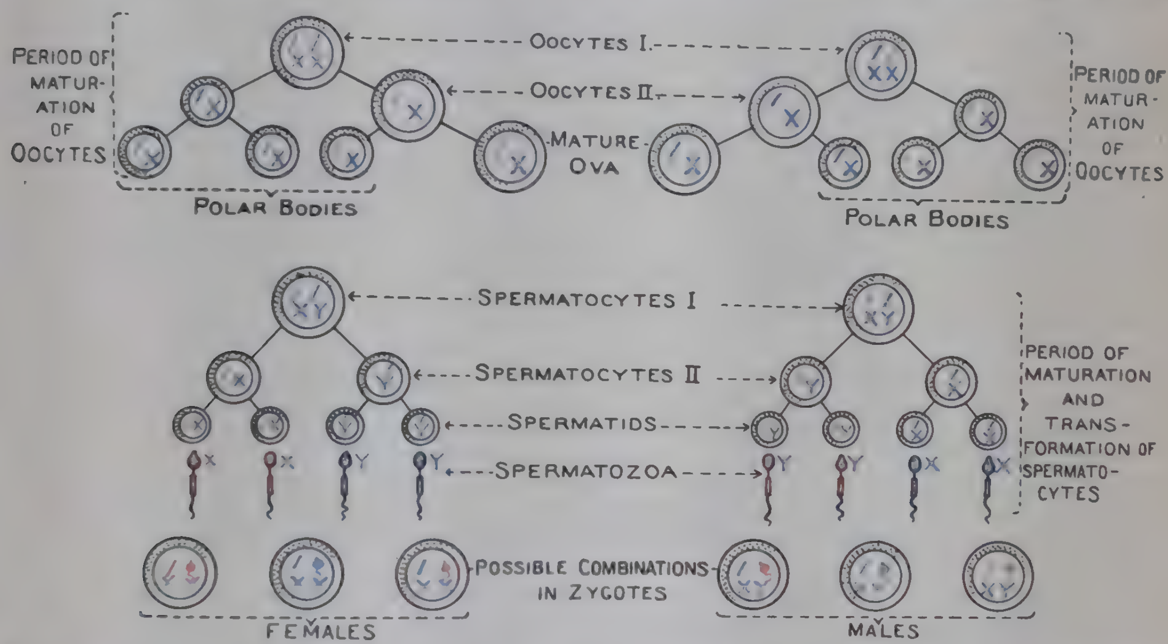

FIG. 10.—DIAGRAM OF THE BEHAVIOUR OF THE CHROMOSOMES DURING MATURATION OF THE GERM-CELLS, INCLUDING THE XY MECHANISM OF SEX-DETERMINATION.

multiplication. Eventually they cease to multiply and enter upon a period of growth; the female cells are then known as **oocytes** and the male cells as **spermatocytes.** When the growth-period is attained the power of division is not altogether lost; but each oocyte or spermatocyte is then capable of producing only four descendants by two final divisions—the **maturation-divisions.** The four descendants of an oocyte are a **mature ovum** and three small cells called *polar bodies*: the four descendants of a spermatocyte are four *spermatids* which undergo metamorphosis into **spermatozoa** (Fig. 10).

The first maturation division is *heterotypical* because the chromosomes do not split in the process, or *meiotic* [μειοῦν (meioun) = to lessen] because the result is a reduction of their number.

Heterotype Mitosis and **Meiosis.**—It has already been pointed out (p. 8) that the number of chromosomes in the dividing cells of any species of animal is always the same; the number varies greatly in different species, but is characteristically constant in each. The same number of chromosomes is found in the soma-cells and primordial germ-cells; and it is believed that they are arranged in pairs of *homologous chromosomes*, one member of each pair being derived from the male parent and the other from the female parent.

In one of the maturation divisions of the germ-cells the homologous chromosomes are separated, one of them going to one daughter-cell and the other to the other daughter-cell: this is the essence of **heterotype mitosis**; and **meiosis**, or the reduction of the number of chromosomes to half, is the result.

In Man and other mammals meiosis occurs in the first of the two maturation divisions.

During the early prophase of the reduction-division the chromatin of the nucleus passes through a special series of changes in form to which various terms have been applied. These changes, which are related to the intricate mechanism of inheritance, occur in the spermatocyte immediately before the reduction-division; but in the oocyte they may occur long before, and are then followed by a long period of rest. In other words, the prophase of the reduction-division in the spermatocyte is short, but in the oocyte it may be very prolonged. Finally, the chromosomes appear and lie side by side (Fig. 17), each pair of homologous chromosomes forming a twin-chromosome—a stage also known as *conjugation of the chromosomes*. Thus, the apparent number of chromosomes is reduced to half the original number of the ordinary chromosomes present in soma-cells and in non-maturing germ-cells.

At the end of the prophase of the heterotype division the twin-chromosomes are assembled at the equator of the spindle, where they are attached to the achromatic fibrils (see p. 8).

There is no true metaphase, since the chromosomes do not split longitudinally as in ordinary mitosis, and the anaphase begins when the homologous chromosomes separate from each other. They thus pass undivided to the opposite ends of the achromatic spindle; therefore, in the telophase, when the cell divides, each daughter-cell contains one group of chromosomes which are the homologues of the chromosomes in the other daughter-cell, and each daughter-cell has only half the number of chromosomes which were present in the mother-cell.

In other words, the heterotype division is a reduction-division by means of which homologous chromosomes are separated from one another, with the result that the mother-cell's inheritance of chromosomes is equally divided between the two daughter-cells.

Mechanism of Inheritance and Determination of Sex.—Reference has already been made to the chromosome theory of inheritance (p. 10), and the student will now realise that a reduction-division in maturation is not only necessary in order that the characteristic number of chromosomes may be maintained in each generation after fertilization, but that it is part of the mechanism for that "shuffle and deal" of the parental chromosomes upon which, according to the theory of chance, the inheritance of the offspring depends.

In Fig. 10 the behaviour of *one pair* of homologous chromosomes (paternal, red; maternal blue) in the maturation of germ-cells is represented. But in studying this diagram the student should remember that in human oocytes and spermatocytes there are 23 such pairs, in addition to a special pair in each (oocyte, XX : spermatocyte, XY) which has special relation to the inheritance of sex. The statistical study of the mode of inheritance of pairs of characters, of which one may be *dominant* and the other *recessive*—**Mendelism**—is in accord with the behaviour of the chromosomes. As it appears to be a matter of chance which daughter-cell will receive any single chromosome, it may be calculated that in the maturation and union in fertilization of any two human germ-cells there are over 281 *billions* of different possible combinations *of the chromosomes alone.*

Add to this that interchange of genes (p. 10) or groups of genes—*crossing-over*—is known to occur during the conjugation of the chromosomes in the prophase of the reduction-division, and it is abundantly clear that the chromosome theory of inheritance is consistent with the infinite variety of individual characterization.

Every normal individual must be either male or female; and there is now conclusive evidence that sex is a heritable character, that it is determined at the time of the union of the gametes and that it is dependent upon special chromosomes, which, although they bear other genes than those that determine sex, are known for that reason as *sex-chromosomes*. The relation of the behaviour of these special chromosomes to the sex of the offspring has been traced in many species of invertebrates and vertebrates. Although there are many variations of the mechanism in detail, the general principle disclosed is that one sex is characterized by the presence of a pair of similar sex-chromosomes distinguished as X-chromosomes, and the other by the presence of only one X-chromosome, which may or may not be paired with another of dissimilar form known as the Y-chromosome. The determining factor is the formation by one sex of two kinds of gametes of different chromosome-constitution. That sex (usually the male, but the female in

many invertebrates and in birds) is therefore said to be *digametic*; while the other is said to be *monogametic* since the gametes it produces are all alike.

In the determination of human sex, it is the male that is digametic. The human oocyte has 23 pairs of ordinary chromosomes and one pair of X-chromosomes—48 in all. Its chromosome-constitution may thus be written 46XX: and every mature ovum therefore possesses an X-chromosome. Its formula is 23X. The formula of the spermatocyte, on the other hand, is 46XY; when the reduction division occurs the X-chromosome passes into one spermatocyte II, the Y-chromosome to the other spermatocyte II. Therefore, of the four spermatids two will have an X-chromosome and two will have a Y-chromosome. There are thus two kinds of spermatozoa, of 23X and 23Y constitution respectively. If an X-bearing spermatozoon unites with an ovum a female results, and if a Y-bearing spermatozoon unites with an ovum a male results (Fig. 10).

The chromosome-constitution of human sex-cells stated above, including the presence of a Y-chromosome in the male, is now generally accepted on the evidence of Painter (1923) and of Evans & Swezy (1929); but the presence or absence of a Y-chromosome in the male (King & Beams, 1936) does not affect the principle of sex-determination. Male sex depends on the absence of a second X rather than on the presence of a Y-chromosome, the physiological activity of which is in some doubt.

Moreover, the student should understand, although sex is said to be 'determined' at fertilization by the chromosome-constitution of the nucleus of the zygote, that sex has to be 'developed' in the individual. The rudiments of the organs of both sexes are formed in every embryo, and the actual sex depends upon physiological factors believed to be controlled by the chromosomes. But there is evidence, experimental and otherwise, to show that the normal mechanism may be deranged, with the production of the phenomena of inter-sex and sex-reversal, by changes in the environment either external or internal.

The cytological and other evidence upon which the chromosome-theory of sex is based is confirmed by the observation that uni-ovular twins, *i.e.*, twins developed from a single ovum, are always of the same sex, whilst bi-ovular twins may be of the same or of opposite sex. It is also strikingly confirmed by the phenomena of 'sex-linkage' in inheritance. The sex-chromosomes are not solely concerned with sex; they bear genes which control other heritable characters; and these characters are linked to sex in their transmission from generation to generation. Sex-linked characters are of some importance in human inheritance, the best-known example being the condition called *hæmophilia*, in which there is an abnormal tendency to spontaneous or excessive bleeding. It is believed that the determining factor of this condition is carried on the X-chromosome, which explains its characteristic mode of inheritance; it is not transmitted from an affected father to his son, but only to a grandson through a 'carrier' daughter who remains herself unaffected (see Fig. 10).

For further information on these interesting questions, the student is advised to consult Wilson (1925); Crew (1927); Waddington (1939); and Roberts (1940).

Gametogenesis.—Gametes are the final descendants of a line of germ-cells which pass through successive stages of specialization and are finally transformed into mature ova and spermatozoa by means of the two maturation-divisions; the whole process is known as **gametogenesis** (Figs. 9 and 10).

Both ovum and spermatozoon are specialized cells, inasmuch as each possesses only half the number of chromosomes present in its grandparent; moreover, each is incapable, under ordinary circumstances, of undergoing cell-division, and must either die or unite with the other to produce a new, rejuvenated cell—the zygote.

The ovum and the spermatozoon have their own special characteristics. The phenomena of **oogenesis** and **spermatogenesis** must, therefore, be considered **separately**.

Oögenesis and the Ovum

The structure of the ovary and the relation of the oocytes to the 'germinal epithelium' are described with the Urogenital System (p. 772).

Each **oocyte** lies at first in the cortical part of the ovary, surrounded by a single layer of cells known as the stratum granulosum; and the oocyte and the stratum granulosum constitute, together, a **primary ovarian follicle** (Fig. 11).

Gradually the oocyte increases in size until it attains a diameter of 100 μ to 200 μ, and so becomes a relatively large cell. During the growth-period changes occur both in the surroundings and in the contents of the oocyte.

The changes in the surroundings include increase in number of the cells of the stratum granulosum, changes in their form, division of them into two groups

by the appearance of a cavity amidst them, and the formation of a new envelope, called the *oolemma*, around the oocyte.

At first the cells of the stratum granulosum are flat plates. Then they become cubical and increase in number by mitosis until they form several layers. Thereafter, a cavity filled with a fluid called the *primary liquor folliculi* appears amidst the cells. It increases rapidly in size and separates the cells into two multicellular parts. One part forms the boundary of the cavity and is still called the *stratum granulosum.* The other projects into the cavity; it is called the *cumulus ovaricus,* and in it the oocyte is embedded. The primary ovarian follicle is thus converted into a *vesicular ovarian follicle* (Figs. 13, 14).

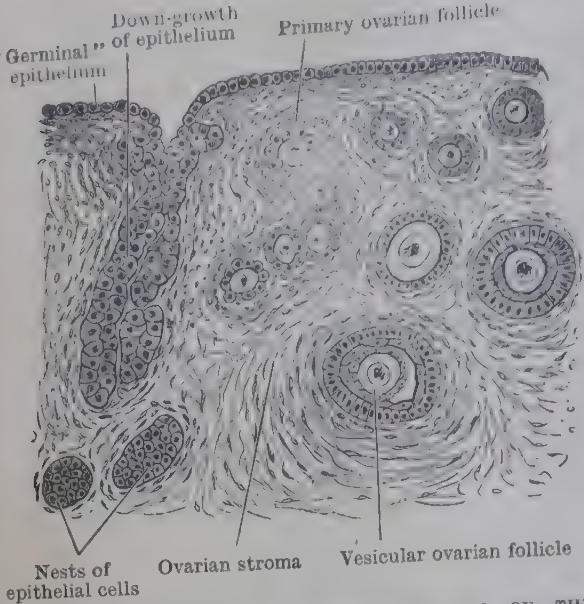

FIG. 11.—DIAGRAMMATIC REPRESENTATION OF THE MANNER IN WHICH VESICULAR FOLLICLES DEVELOP IN THE OVARY.

When the cells of the stratum granulosum have formed two layers, the **oolemma** begins to appear around the oocyte, separating it from the cells of the cumulus. It increases in thickness until the maturation of the oocyte begins, when it is an elastic, pellucid membrane (zona pellucida), sometimes faintly striated (zona striata), varying from 7 μ to 10 μ in thickness.

The oolemma is formed by the oocyte, and it appears to be traversed by processes of the surrounding cells of the cumulus, which gradually assume an elongated columnar form and constitute the *corona radiata* (Figs. 15 and 24).

It is the fine prolongations of the cells of the corona, passing through the

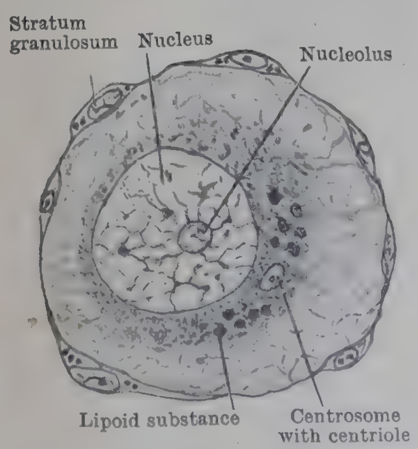

FIG. 12.—HUMAN OOCYTE AT BEGINNING OF GROWTH-PERIOD. Diameters 38 $\mu \times$ 33 μ. The small black granules in the granulosa-cells are lipoid granules.

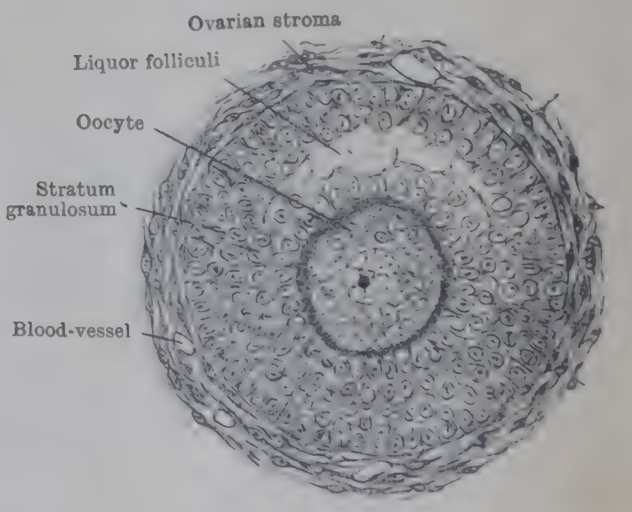

FIG. 13.—HUMAN OVARIAN FOLLICLE AT BEGINNING OF VESICULAR STAGE. Diameters of follicle 155 $\mu \times$ 155 $\mu \times$ 120 μ.

oolemma to the surface of the oocyte, which give rise to the striated appearance which has already been noted.

The changes which take place in the oocyte itself during the growth-period concern the contents of the cytoplasm, and the position and relative size of the nucleus.

At the beginning of the growth-period the oocyte (called *oocyte I* to avoid confusion with its two immediate descendants) is an almost spherical cell; but it soon becomes ovoid and it retains its ovoid form in all subsequent periods. The

cell-body contains a relatively large, eccentrically placed nucleus and a centrosome. The centrosome lies near the central pole of the nucleus and contains one or two centrioles (Fig. 12).

The nucleus possesses one or two nucleoli, and its chromatic substance is dispersed through the linin-reticulum.

Metaplasmic substance is already present in the oocyte; it lies in the cytoplasm around the nucleus, and it is most abundant at the central pole of the nucleus around the centrosome (Fig. 12). As growth proceeds, the metaplasmic substance becomes more diffused, but it is always most abundant around the nucleus in the central part of the cytoplasm.

The nucleus gradually attains a central position in the oocyte (Fig. 14), but afterwards it migrates to the periphery of the oocyte, and the centrosome may disappear before the process of maturation begins.

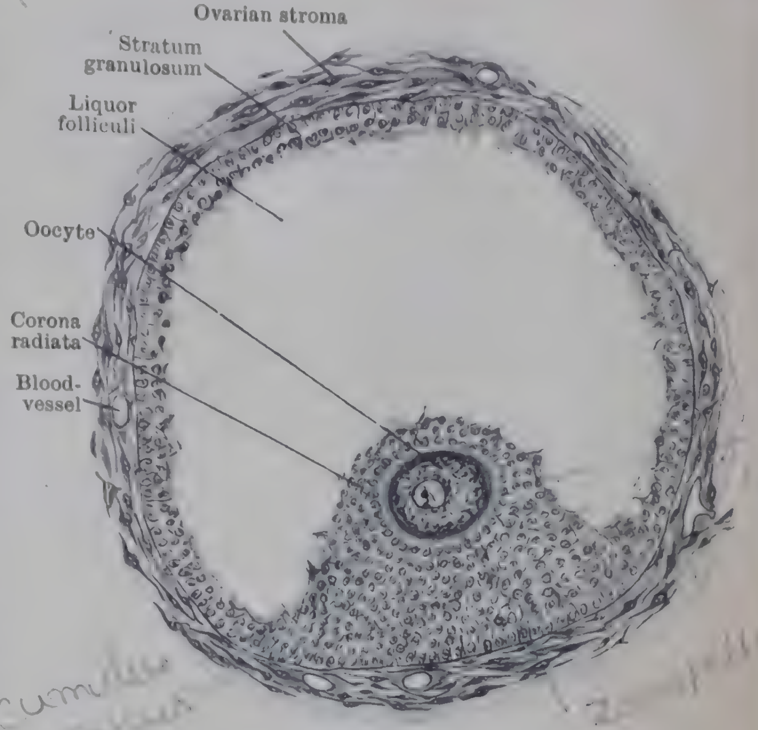

FIG. 14.—HUMAN VESICULAR OVARIAN FOLLICLE. Diameters of follicle 620 $\mu \times 465\ \mu \times 465\ \mu$.

During the period of growth the body of the oocyte grows more rapidly than the nucleus; and therefore at the end of the period the nucleus, though actually larger than it was at the beginning, is relatively smaller.

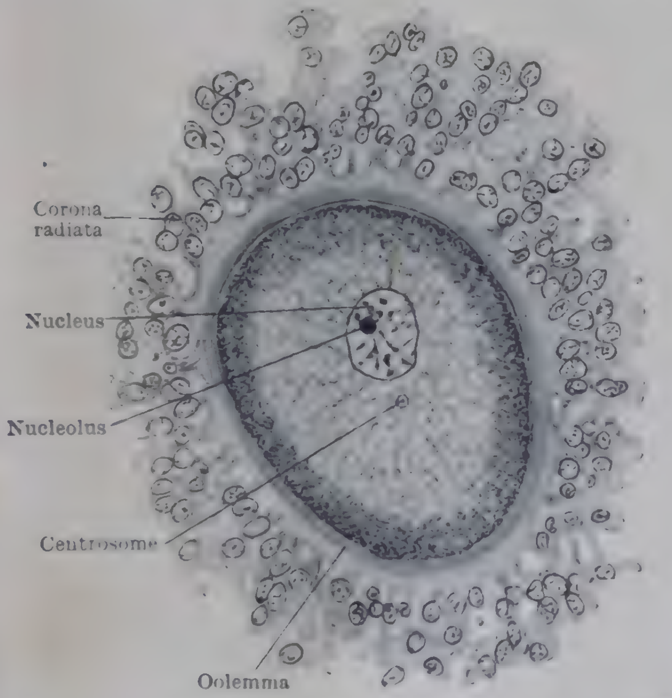

FIG. 15.—HUMAN OOCYTE NEAR THE END OF THE GROWTH-PERIOD. Diameters of oocyte exclusive of oolemma 140 $\mu \times 110\ \mu \times 84\ \mu$. Average thickness of oolemma 5 μ.

When growth is completed the full-grown oocyte I, enclosed in the oolemma, lies in the cumulus of a vesicular follicle in the cortical part of the ovary. It consists of a cell-body which contains a nucleus, mitochondria and numerous highly refractive yolk-granules; but during maturation a centrosome may not be apparent.

The diameter of the cell-body, measured along its major axis, varies from 100 μ to 200 μ, for full-grown oocytes are not all of the same size; the average diameter is 130-140 μ (Hartman, 1929). The diameter of the nucleus varies from 25 μ to 50 μ.

The amount of metaplasm or yolk-substance in human and most mammalian ova is relatively small compared with those of fishes, amphibians, reptiles, and birds. The amount of yolk determines whether the segmentation of the fertilized ovum is complete or incomplete, and special terms are employed in Comparative Embryology to denote differences in the amount and distribution of the yolk. It is sufficient here to note that the amount of yolk in the human ovum is so small that it does not in the least interfere with its complete division in segmentation.

The metaplasmic granules serve as a store of nutritive material which is utilized

during the early stages of the growth of the zygote in mammals, and until the time of hatching in oviparous vertebrates.

There is great variation in the amount of unsaturated fat (lipoid) in the ova of different mammals, as shown by osmic acid staining. It is almost absent in human ova and the ova of rats and mice; a slight but variable amount is found in the ova of rabbits; it is definitely present, as spherules of relatively large size, in the ova of guinea-pigs and cats; and there is a large amount in the ova of dogs and ferrets, in which indeed it constitutes the greater part of the volume of the ova. In the ferret it has been traced into the cells of the trophoblast, of the inner cell-mass and the ectoderm, but not into the entoderm (Robinson, 1925).

Apart from the question whether any new ova are produced in the human ovary after birth—as is apparently the case in some animals—there is evidence that a large number of developing follicles atrophy and disappear so that " radical selective elimination of ova occurs in human ovaries " (Allen *et al.*, 1930a).

Maturation of the Ovum.—Maturation is the term applied to the pheno-

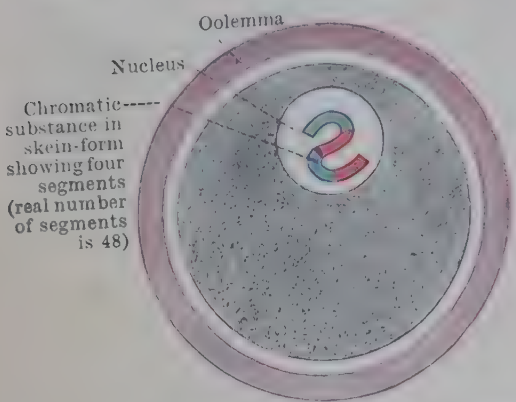

Fig. 16.—Schema of Maturation of Ovum. Early Part of Prophase of First Division.

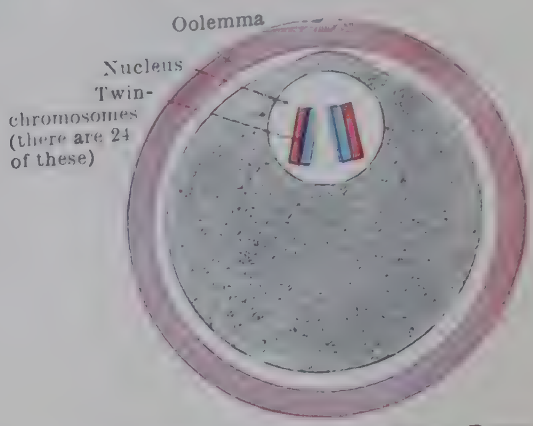

Fig. 17.—Later Prophase of First Division. The chromatic thread has divided into twin-chromosomes. Each twin may be assumed to consist of a maternal and a paternal part.

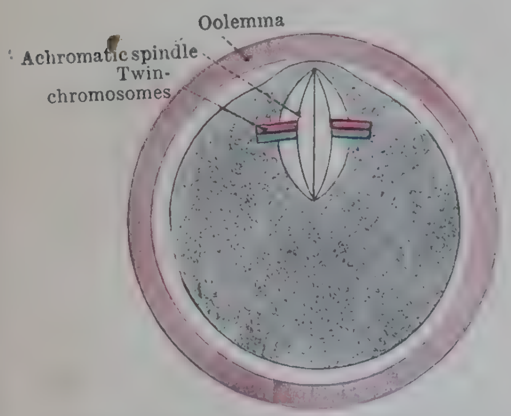

Fig. 18.—End of Prophase of First Division. The twin-chromosomes lie at the equator of the achromatic spindle.

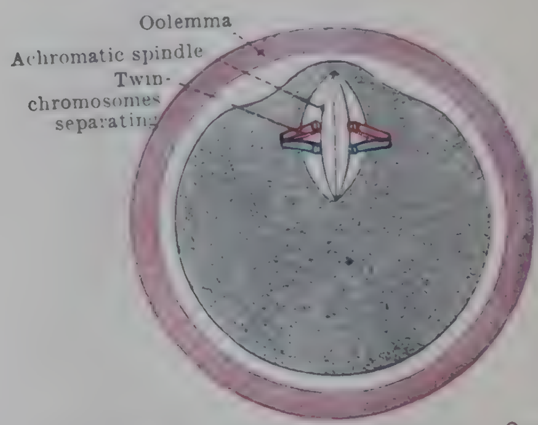

Fig. 19.—Metaphase of First Division. One pole of the spindle projects into the first polar bud, and the maternal and paternal parts of the chromosomes are separating from each other.

mena of the two cell-divisions which take place after the oocyte has attained its full growth.

Knowledge of the phenomena of maturation in human oocytes is not yet complete; but there can be no doubt that they are the same as those which have been clearly demonstrated in many other mammals.

The first of the two divisions is heterotypical and meiotic. During its progress the nuclear membrane and the nucleolus or nucleoli disappear, and an achromatic spindle appears at one pole of the oocyte, in the situation previously occupied by the nucleus.

The chromosomes are aggregated together in pairs as twin-chromosomes. They appear therefore to be only half the number of the chromosomes originally present in the oocyte; at the end of the prophase they lie at the periphery of the equator of the spindle. When this condition is attained the

spindle rotates on its transverse axis, and one pole, carrying a little cytoplasm around it, projects beyond the general surface of the oocyte, forming the *first polar projection* (Fig. 19).

During the metaphase the two halves of each twin-chromosome separate from each other, the two chromosomes thus formed being each equivalent to a whole chromosome of an ordinary cell.

In the anaphase the halves of each twin-chromosome travel to the opposite poles of the achromatic spindle, and those which travel to the peripheral pole enter the first polar projection (Figs. 19, 20).

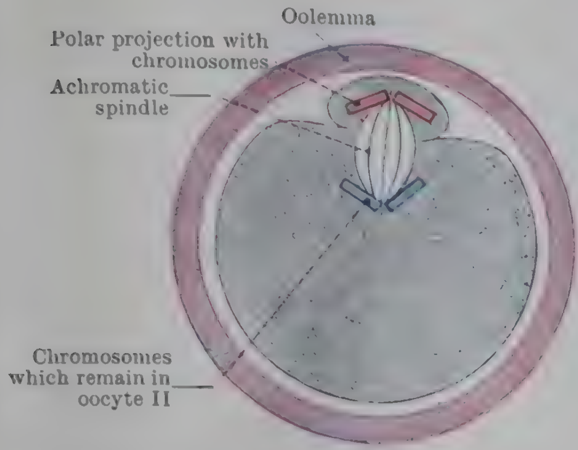

FIG. 20. — END OF ANAPHASE OF FIRST DIVISION. Two chromosomes (paternal or maternal) lie in the first polar bud and two in the larger part of the ovum which becomes oocyte II.

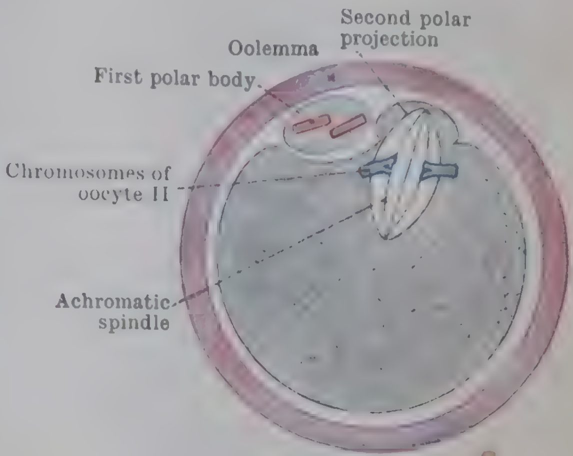

FIG. 21.—BEGINNING OF METAPHASE OF SECOND DIVISION. The chromosomes of oocyte II are dividing.

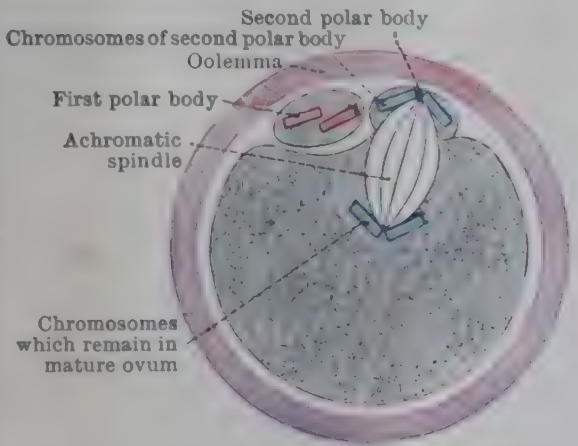

FIG. 22. — END OF ANAPHASE OF SECOND DIVISION. The chromosomes of oocyte II have separated into equal parts which have passed to the opposite poles of the spindle.

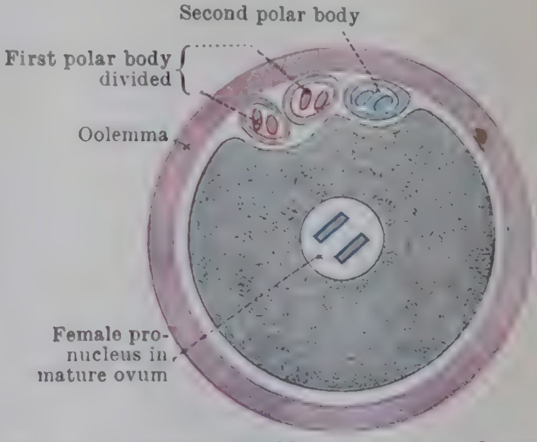

FIG. 23.—SCHEMA OF MATURATION OF OVUM. END OF TELOPHASE OF SECOND DIVISION. The four descendants of oocyte I are the mature ovum, with half the original number of chromosomes, and three polar bodies.

During the telophase the first polar projection, with its included chromosomes and a minute portion of cytoplasm, is cut off from the main part of the oocyte. The first maturation division is then completed; **oocyte *I*** being divided into a large segment (**oocyte *II***) and a small segment called the *first polar body*, both of which lie inside the oolemma and each of which contains half the number of chromosomes originally present in oocyte I (Figs. 20-26). Human ova which have attained this stage of maturation have been seen (Rock & Hertig, 1942).

After the first maturation-division is completed a nucleus may appear in the first polar body and a new achromatic spindle is formed in oocyte II. The new achromatic spindle lies at the periphery of oocyte II near the first polar body, and the chromosomes become grouped at its equator (Figs. 21, 25).

When the condition described is attained the ovarian follicle ruptures, and the liquor folliculi (which has meanwhile increased in amount by the formation of *secondary liquor folliculi* (Robinson, 1918) in spaces in the cumulus), carrying with

it the oocyte surrounded by its corona radiata, is forced through the breach in the surface of the ovary and is swept into the uterine tube. This process is known as *ovulation*; and it is now known to have a definite relation to the menstrual cycle (p. 80).

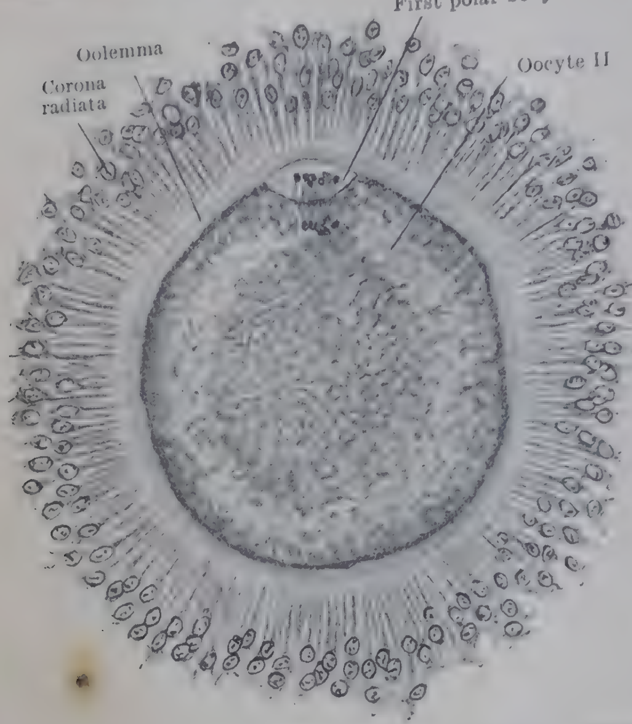

FIG. 24.—OOCYTE OF A FERRET IN THE TELOPHASE OF THE FIRST MATURATION-DIVISION. Diameters of oocyte, exclusive of oolemma, 150 $\mu \times 125\ \mu \times 110\ \mu$.

If the oocyte is penetrated by a spermatozoon it then undergoes the second maturation-division; but it is possible that the second maturation-division of the human oocyte may occur before it leaves the ovary, and therefore before the entry of the spermatozoon.

There are a few observations on record of human oocytes thought to be undergoing the second maturation-division while still in ovarian follicles (Thomson, 1919; Dixon, 1927 (Fig. 26); Hoadley & Simons, 1928; Allen *et al.*, 1930a). But other oocytes in that stage have been found in the uterine tubes (Allen *et al.*, 1930b; Lewis, 1931; Pincus & Saunders, 1937; Hamilton, 1944.); and, owing to the difficulty of obtaining such specimens, the relation of the completion of maturation to ovulation and to fertilization remains in doubt. Thomson described specimens in which he believed he had observed mature human ova in ovarian follicles (Fig. 27.)

The phenomena of the second maturation-division are those of **homotype mitosis**. One pole of the achromatic spindle, already present in oocyte II, projects beyond the surface of the oocyte, carrying with it a small amount of cytoplasm and so forming the *second polar projection* (Fig. 21). Thereafter, each of the chromosomes (which, it must be remembered, are only half as numerous as those originally present in oocyte I) splits longitudinally into equal parts. The opposite halves of the divided chromosomes then travel to the ends of the achromatic spindle; consequently, one group enters the second polar projection and the other remains in the body of the oocyte (Fig. 22).

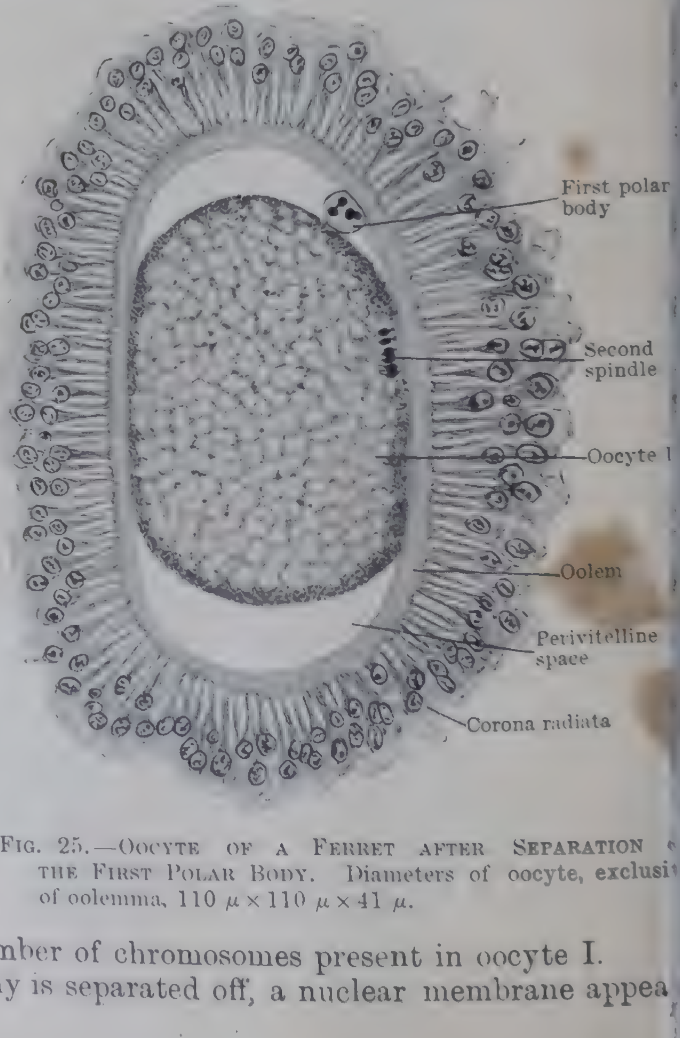

FIG. 25.—OOCYTE OF A FERRET AFTER SEPARATION OF THE FIRST POLAR BODY. Diameters of oocyte, exclusive of oolemma, 110 $\mu \times 110\ \mu \times 41\ \mu$.

When the chromosomes reach the ends of the achromatic spindle, the second polar projection is cut off from the body of the oocyte to form the *second polar body*. Thus, in the second maturation-division, oocyte II is segmented into a larger part and a smaller part (the second polar body), each of which contains half the number of chromosomes present in oocyte I.

As soon as the second polar body is separated off, a nuclear membrane appea

around the chromosomes in the body of the oocyte; a linin-reticulum is formed within the membrane, and the particles of the chromosomes are distributed along the reticulum; a nucleolus also is developed, and the maturation is completed (Fig. 27).

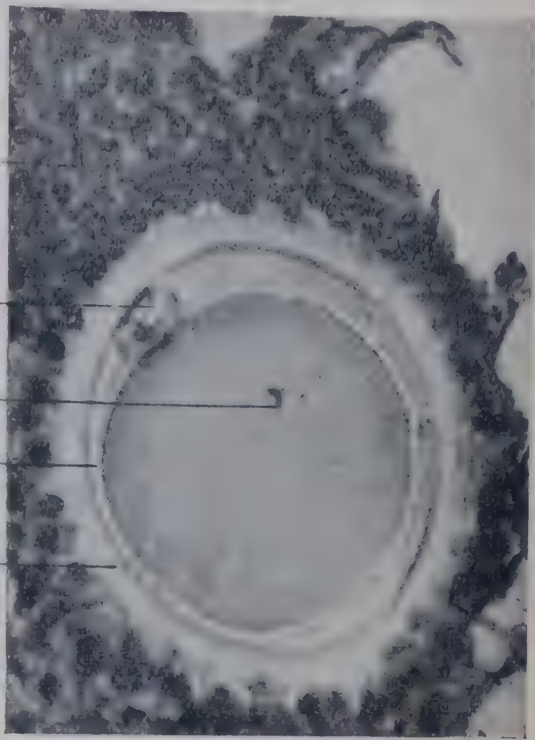

Fig. 26.—Section of a Human Ovum after the First Maturation-Division. (Dixon, 1927.)

The **mature ovum,** like the full-grown oocyte, differs from a typical animal-cell on account of its large size, and also because it is surrounded by a special protective envelope—the oolemma. An additional and important difference is the fact that the mature ovum under ordinary circumstances is incapable of further cell-division because it possesses no centrosome—a deficiency which is supplied by the spermatozoon if fertilization occurs.

The **nucleus** is frequently called the *germinal vesicle,* and the nucleolus the *germinal spot,* whilst the protoplasm of the cell-body is spoken of as the *vitellus* or *yolk.* Consequently the fine surface-layer, which appears as the polar bodies are given off (Fig. 24) and corresponds to an ordinary cell-membrane, has been termed the vitelline membrane. The space, between the body of the oocyte and the oolemma, into which the polar bodies are discharged, is called the *perivitelline space*; in fixed specimens it may appear greatly increased by retraction of the cell-body (Fig. 25).

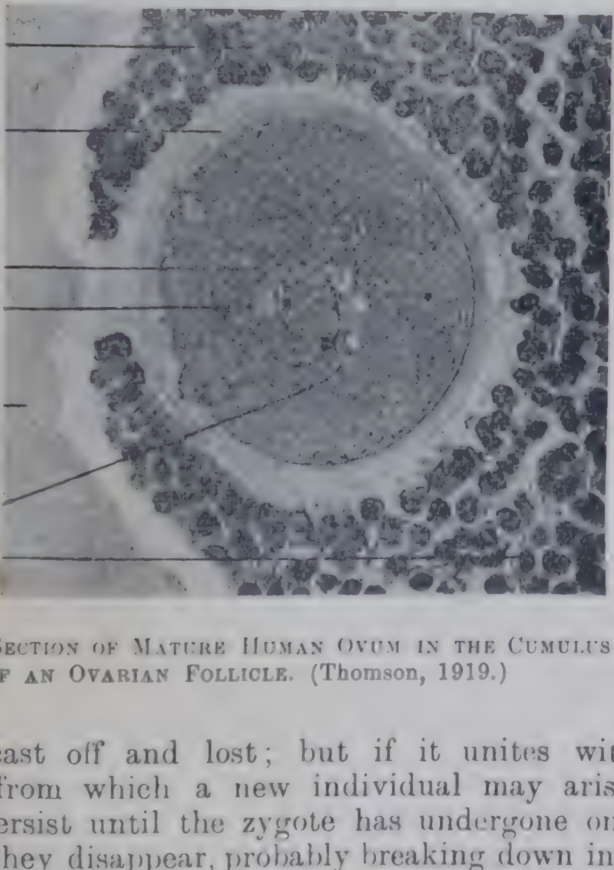

Fig. 27.—Section of Mature Human Ovum in the Cumulus of an Ovarian Follicle. (Thomson, 1919.)

As the second polar body is separated off, the first polar body not uncommonly divides into two parts. When that occurs, the result of the two maturation-divisions of the oocyte is the formation of one large cell (the mature ovum) and three polar bodies, all of which are enclosed within the oolemma (Fig. 23).

If the oocyte II does not meet with a spermatozoon it breaks down or it passes through the genital passages and is cast off and lost; but if it unites with a spermatozoon a **zygote** is formed, from which a new individual may arise, and in that case the polar bodies persist until the zygote has undergone one or two divisions; but sooner or later they disappear, probably breaking down into fragments which are absorbed by the cells of the zygote.

The polar bodies were originally so named in the belief that they indicate the line along which the first segmentation of the fertilized ovum will take place; but their exact position does not appear to be of any significance in the mammalian ovum.

Spermatogenesis and the Spermatozoon

When the male germ-cells reach the period of growth they are called **spermatocytes** I, which correspond morphologically with oocytes I (Fig. 10). The spermatogonia and the spermatocytes lie in the walls of the seminiferous tubules of the testes. There, their descendants become converted into spermatozoa (Fig. 28).

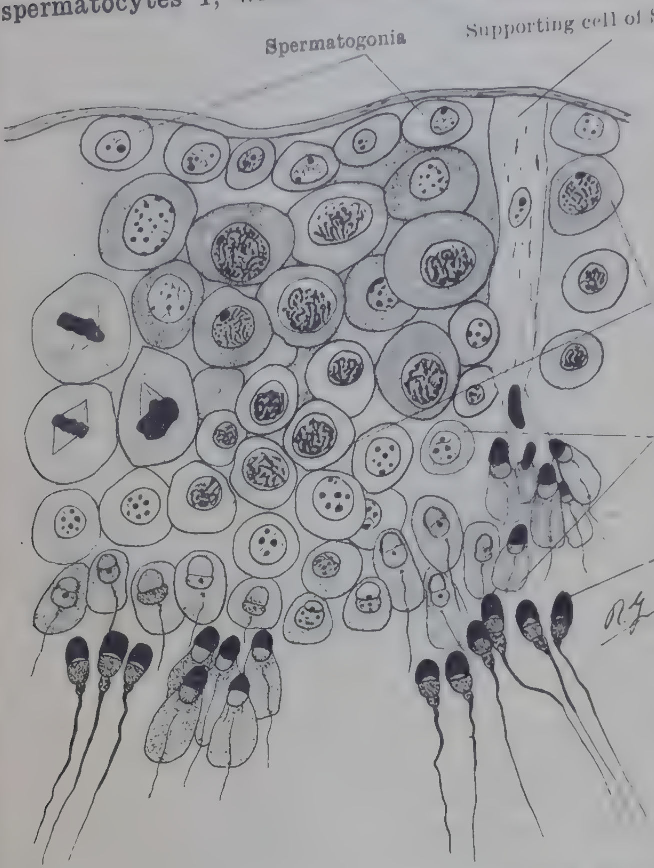

Fig. 28.—Drawing of Small Part of Transverse Section of Seminiferous Tubule of Mammal to show Stages of Spermatogenesis. (Gresson, 1948.)

Spermatocytes differ from oocytes in three important respects: (1) they have no protective membrane corresponding with the oolemma of the oocyte; (2) they are not enclosed in follicles; (3) they are not surrounded by definite encircling layers of cells similar to the cells of the stratum granulosum.

In the tubules of the testes the spermatocytes are intermingled with *supporting cells* (cells of Sertoli), amidst which they undergo their maturation-divisions; their descendants become embedded in the supporting cells, where they are converted into spermatozoa. To a certain extent, therefore, the supporting cells may be looked upon as corresponding with the cells of the cumulus ovaricus which surround the growing oocyte.

After it has reached its full growth each spermatocyte I, like each oocyte I, can produce only four descendants; the descendants, as in the case of the oocyte I, are formed by two successive mitotic divisions, of which the first is heterotypical and produces reduction of the chromosomes, and the second is homotypical.

These divisions differ from the corresponding divisions of the oocyte in the important respect that the four grand-daughter-cells are of equal size and of equal value, so that they are all capable of uniting with an ovum to form a zygote.

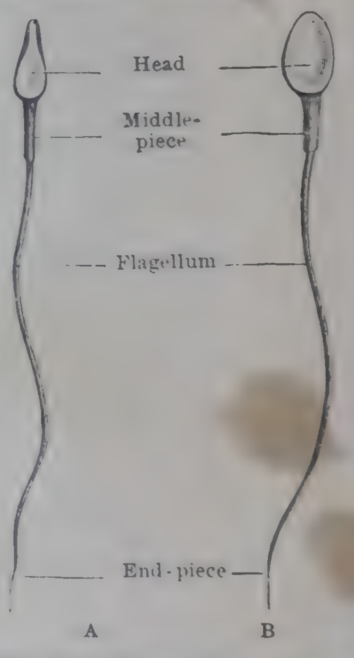

Fig. 29.—Human Spermatozoa (After Retzius.)
A, Side view; B, Front view.

In the prophase of the first or *heterotype* division the nucleus and nucleolus disappear in the ordinary way. The centrosome divides, and an achromatic spindle appears, which has the daughter-centrosomes at its poles and apparently half the typical number of chromosomes at its equator. But the chromosomes are twin-chromosomes, and during the metaphase the two segments of each twin-chromosome separate from each other. In the anaphase they travel to the opposite poles of the achromatic spindle, and consequently, when the cell divides in the telophase, each daughter-cell or **spermatocyte** II contains a centrosome and half the typical number of chromosomes (Fig. 10).

The second maturation-division, which takes place without the intervention of a resting stage, is of the *homotype* form. The centrosome divides, a new achromatic spindle appears, and the chromosomes gather at its equator. In the metaphase the chromosomes divide into equal parts, which travel to the opposite poles of the spindle during the anaphase, and when the telophase is completed each granddaughter-cell, now called a **spermatid**, possesses a centrosome and half the typical number of chromosomes (Fig. 10). In the resting stage which follows, the chromatic particles become enclosed in a new-formed nucleus, and the centriole passes to the surface of the cell and divides into two equal parts (Fig. 31 (1)). The Golgi material (p. 7), which has been scattered, reassembles close to the opposite side of the nucleus. In addition to numerous mitochondria, other particles, known as Y-granules, which may represent abortive yolk, are present, and there is also an *accessory body* which later is concerned in the formation of the neck of the spermatozoon.

The Spermatozoon.—The reader will have noted that the ova become ready for conjugation with spermatozoa directly after the first maturation-division is completed. In the case of the male germ-cells, however, the spermatids which result from the second maturation-division have still to undergo a complicated process of transformation before they become converted to spermatozoa. The process of transformation takes place in association with the supporting cells in which the developing spermatozoa become embedded.

The details of the process of transformation are difficult to follow, and knowledge regarding them has been until recently rather indefinite. Gatenby & Beams (1935), however, have provided us with an authentic account of human spermatogenesis, including very clear details of the metamorphosis of the spermatid (Fig. 31); but before these details are considered it is necessary that the student should be acquainted with the anatomy of an adult spermatozoon.

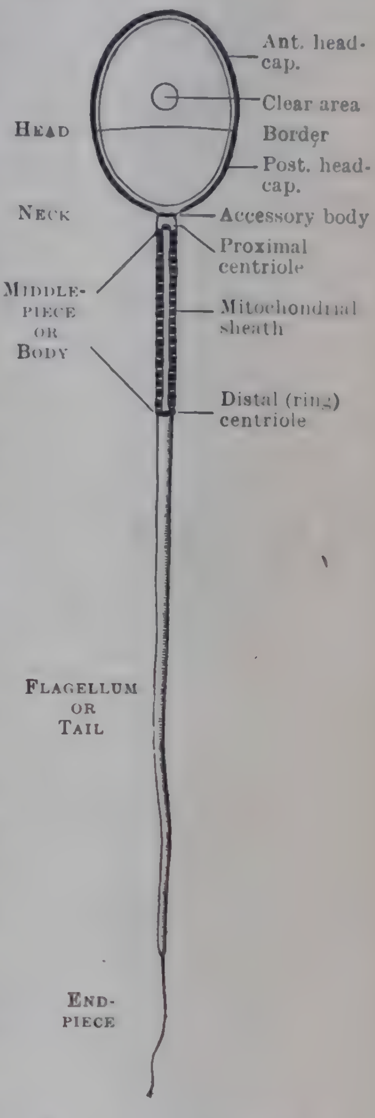

FIG. 30. — STRUCTURE OF HUMAN SPERMATOZOON. (Gatenby & Beams, 1935.)

A spermatozoon is a minute organism possessing a head, a neck, a middle-piece or body, and a flagellum or tail. Its total length is about 50 μ, that is, its length is about the same as the diameter of the nucleus of the ovum.

The **head** has the form of a compressed ovoid. It contains the nucleus of the spermatid and is completely covered by a **head-cap** which consists of two parts—an anterior part, the head-cap proper, and a posterior part, the post-nuclear cap. The length of the head is about 4·5 μ.

The **neck** is an extremely short constricted region between the head and the middle-piece. It contains a deeply staining *neck body* or *accessory body*, which may consist of Golgi material. The **middle-piece** is about the same length as the head, and its constituent parts are: (1) the proximal centriole; (2) a portion of the axial filament with its sheath; (3) the mitochondrial sheath; and (4) the distal centriole.

The **axial sheath** is a thin layer of protoplasm immediately surrounding the **axial filament**, which extends from the **proximal centriole** through the middle-piece into the flagellum. The **mitochondrial sheath** surrounds the axial sheath, and is formed by numerous fused mitochondria. The **distal centriole** is ring-shaped, and through it the axial filament and its sheath pass from the middle-piece into the flagellum.

The **flagellum** or tail is long. It consists of prolongations of the axial filament

and its sheath, and it terminates in a short thin *end-piece*, in which the axial filament appears free from the sheath.

Metamorphosis of Spermatid into Spermatozoon.—The **head** of the spermatozoon is formed from the nucleus of the spermatid, which becomes encased in a special sheath formed in two parts. The Golgi elements, which have been scattered during the maturation-divisions, assemble on the surface of the nucleus as a single apparatus which contains a bead surrounded by a small vacuole. The bead is deposited on the nucleus to form the *acrosome* from which the **head-cap** proper is derived; the vacuole enlarges to form a semilunar space over the acrosome; and the greater part

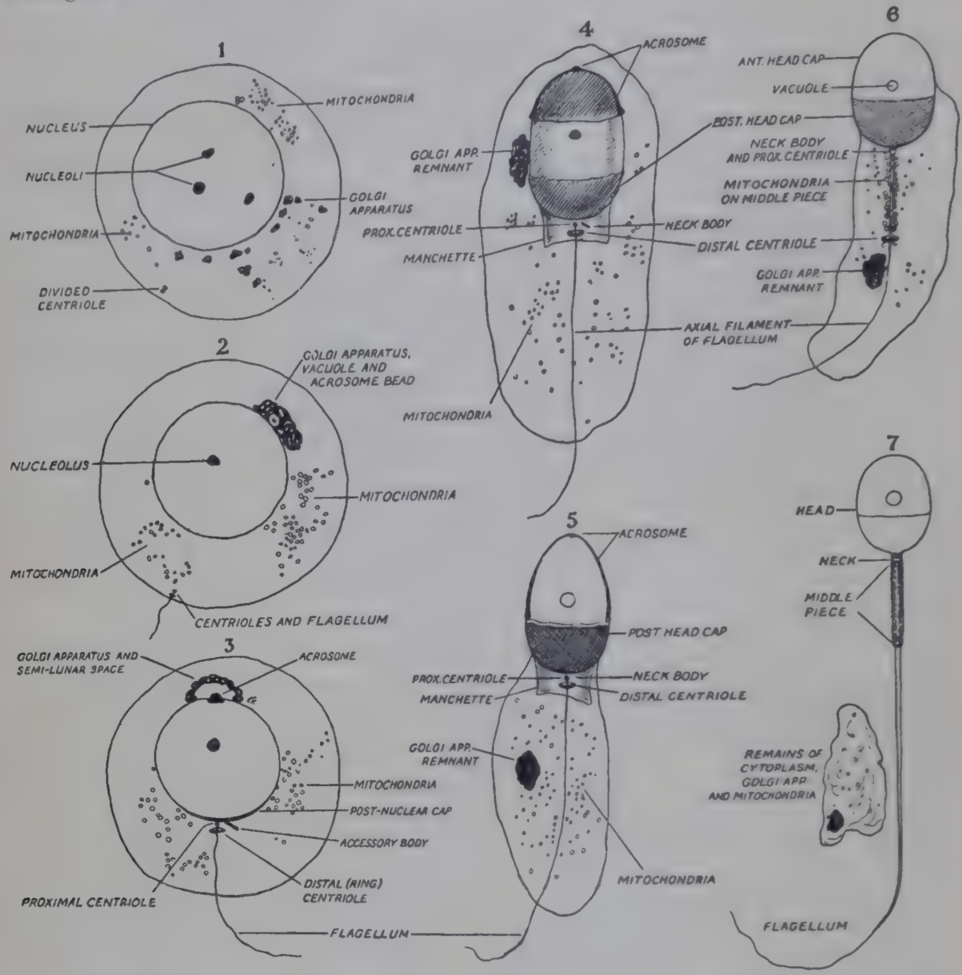

FIG. 31.—METAMORPHOSIS OF SPERMATID INTO SPERMATOZOON. (After Gatenby & Beams, 1935.)

of the Golgi material then detaches itself from the nucleus and flows down into the cytoplasm of the spermatid to be discarded later.

After the second maturation-division the centriole of the spermatid passes towards the cell-wall and divides into two; from the double centriole the **axial filament** then grows out through the surface of the cell. The double centriole moves inwards again, and can then be seen to consist of two separate parts—a **proximal centriole** (nearer the nucleus) which is granular and gives rise to the axial filament of the flagellum, and a **distal centriole** which appears as a *ring* threaded on the filament. The two centrioles continue to move in together and become applied to the nucleus on the side opposite the attachment of the acrosome-bead. The distal centriole grows very considerably and becomes a conspicuous object.

A new membranous structure has meanwhile appeared between the centrioles and the nucleus. This is the rudiment of the **post-nuclear cap**, which begins to grow upwards to meet the down-growing head-cap proper, which is derived from the rapidly spreading acrosome. A clear area or vacuole (probably of nucleolar origin) has meanwhile appeared in the nucleus, and when the two parts of the head-cap meet, the head of the sperm is complete.

While the acrosome and the post-nuclear cap are spreading to form the complete head-cap, and before the separation of the two centrioles, the *accessory body* has been taken

into the neck-region, between the proximal centriole and the head, and becomes the *neck-body*; and a collar-like structure (*manchette*) grows down from the nucleus and encloses the two centrioles. The manchette soon disappears, and its significance, like that of the neck-body, is not known.

The **middle-piece** has still to be formed and the **flagellum** completed. The distal ring-centriole slips down the axial filament for a distance about the length of the head, and leaves a space on to which most of the mitochondria crowd to form the **mitochondrial sheath**. The remains of the cytoplasm of the spermatid, carrying other mitochondria and the remnant of the Golgi material, are then stripped off, and the spermatozoon is complete (Fig. 31 (7)).

Fertilization

The process of union of the male and female gametes to form a zygote is known as *fertilization of the ovum*. It begins when a spermatozoon enters an

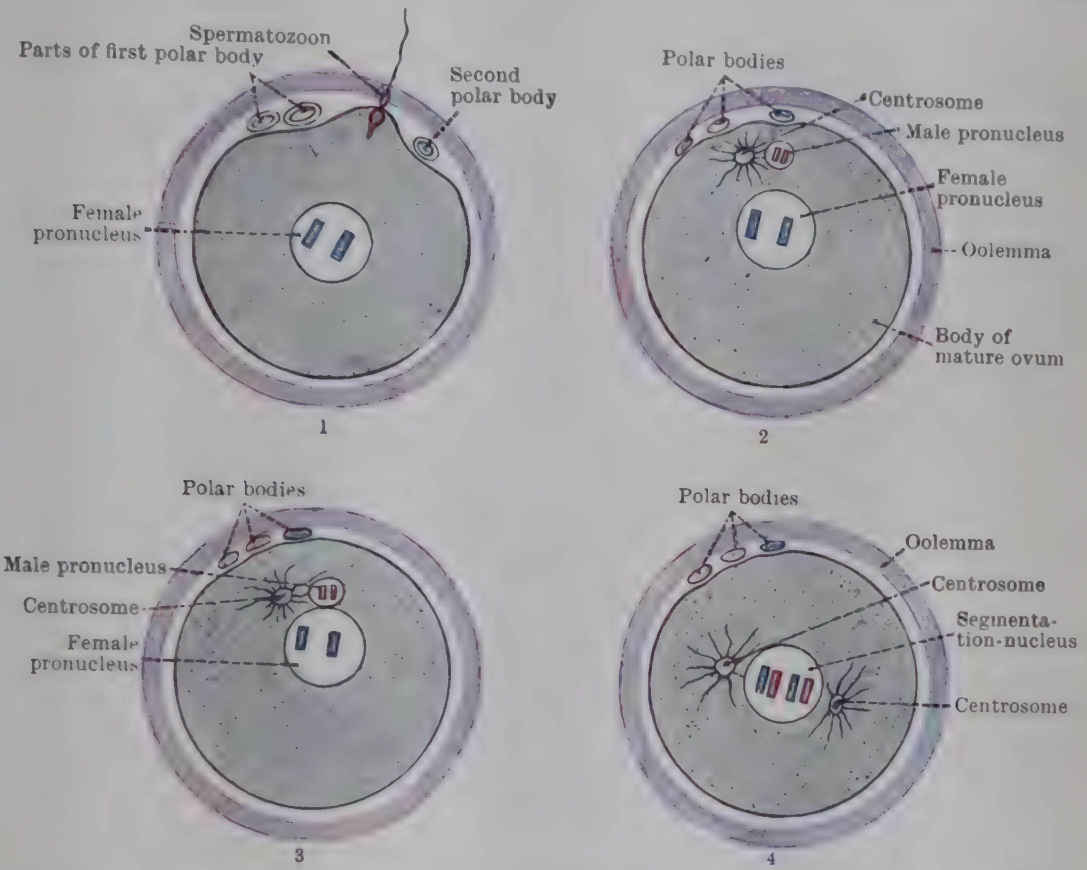

FIG. 32.—SCHEMA OF FERTILIZATION OF MATURE OVUM AND FORMATION OF ZYGOTE.

ovum (either mature or in the last stage of maturation), and it is completed when the nuclear elements of the two have combined.

Fertilization of the human ovum has not been observed, but it is certain that all its essential features are the same as those which have been found to occur in other mammals. The stages of fertilization will probably be observed before long in human ova recovered from the uterine tubes (Hamilton, 1944); but experimental observation of fertilization and segmentation *in vitro* has not so far been very successful, although 2-cell and 3-cell stages have been obtained (Menkin & Rock, 1948). It is believed that fertilization takes place in the ampulla of the uterine tube, and that the entry of one spermatozoon causes some change in the surface of the ovum that prevents the entry of others (Fig. 34).

It has already been pointed out that maturation of the oocyte is usually not completed until after the spermatozoon has entered; thereafter, the second polar body is extruded and the nucleus of the mature ovum, now called the **female pronucleus**, takes up a central position. It contains half the number of chromosomes present in the nucleus of the oocyte before the maturation began. As the female pronucleus forms, the tail of the spermatozoon disappears, the head is transformed into the **male pronucleus**, and two centrosomes arise from the middle-

piece. The male pronucleus is smaller than the female pronucleus, and it also contains only half the number of chromosomes present in the spermatocyte I from which it descended.

As soon as the female and male pronuclei are established they approach each other (Fig. 32), meet, and fuse together to form a single nucleus (Figs. 32, 33) called the *segmentation-nucleus*, which contains the full number of chromosomes.

When fertilization is completed, therefore, a new structure—the **zygote**—is formed. It lies, together with the polar bodies, inside the oolemma, and it consists of a cell-body containing the segmentation-nucleus, and two centrosomes which lie at opposite poles of the nucleus. The only essential difference in appearance between an oocyte I and a zygote is the presence of two centrosomes in the zygote. But oocyte I is a cell almost at the end of its life-period. It can have only one capable descendant and its chances of life are small, whilst the zygote is a rejuvenated cell, endowed with the potentialities of its parents and capable of producing a new member of the species.

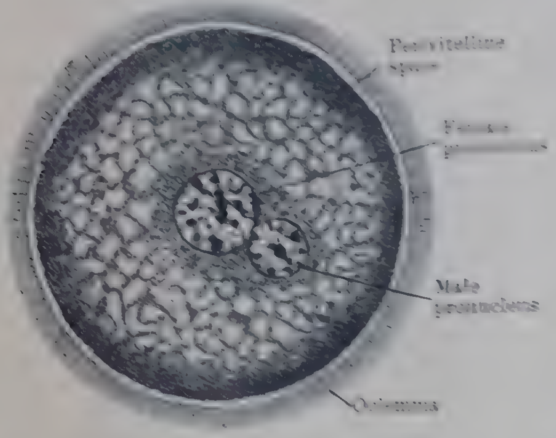

FIG. 33.—ZYGOTE OF A FERRET JUST BEFORE THE FUSION OF THE PRONUCLEI. Diameters of zygote, exclusive of oolemma, 100 μ × 93 μ × 90 μ.

There are therefore two factors in fertilization. The first is the reconstitution in the segmentation-nucleus of the number of chromosomes that is typical for the cells of the species to which the zygote belongs, half of them derived from the female parent and half from the male. The second factor is the stimulus to division which the spermatozoon provides—a stimulus that is due to the physico-chemical influence exerted by the centrioles.

In the phenomena of natural parthenogenesis among invertebrates there are many interesting variations in the chromosome-mechanism. Loeb (1913) and others have also shown experimentally—*artificial parthenogenesis*—that it is possible, in the case of invertebrates like the sea-urchin, and even in the frog, to replace the stimulus normally supplied by the spermatozoon by chemical or mechanical means. Further information on the interesting cytological problems of parthenogenesis will be found in the works of the authors already cited (p. 21).

PRE-EMBRYONIC PERIOD

Segmentation.—Immediately after its formation the zygote segments, by a series of consecutive mitotic divisions, into a large number of cells or blastomeres

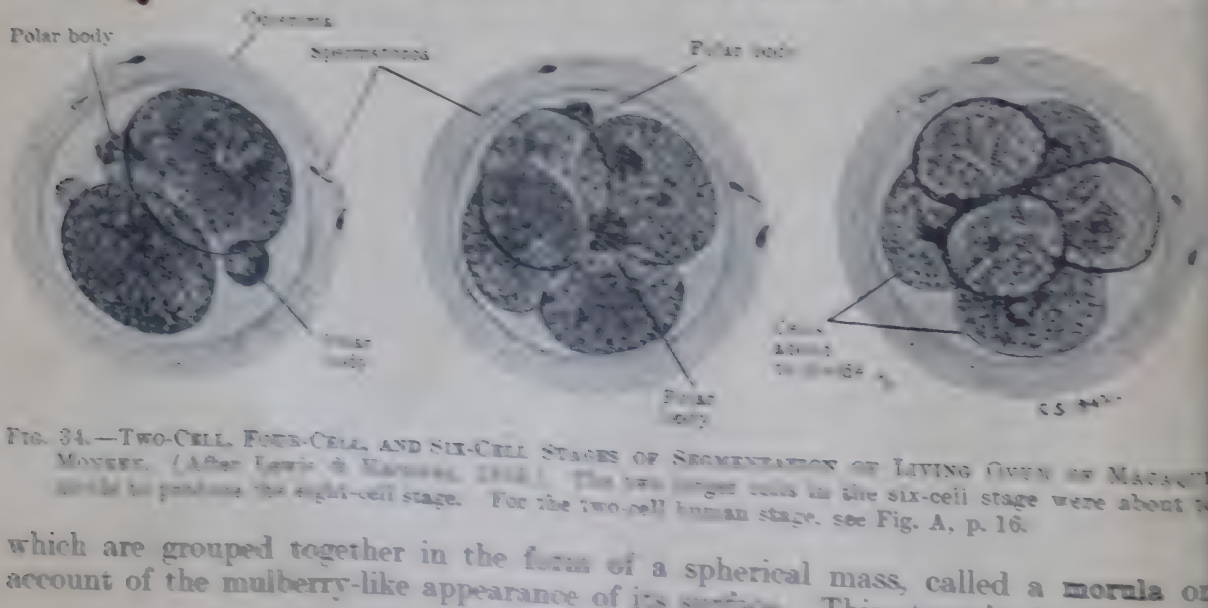

FIG. 34.—TWO-CELL, FOUR-CELL, AND SIX-CELL STAGES OF SEGMENTATION OF LIVING OVA OF MACAQUE MONKEY. (After Lewis & Hartman, 1933.) The two larger cells in the six-cell stage were about to divide to produce the eight-cell stage. For the two-cell human stage, see Fig. A, p. 16.

which are grouped together in the form of a spherical mass, called a **morula** on account of the mulberry-like appearance of its surface. This stage in development

TEXT-BOOK OF ANATOMY

INTRODUCTION

ANATOMY is a comprehensive term, for it includes several closely related branches of knowledge. It originally meant the cutting up of the body [ἀνατομία from ἀνά (ana) = up, τέμνειν (temnein) = to cut] for the purpose of examining the characters and arrangement of its parts; thus, it is primarily equivalent to **dissection** [dis = asunder, secāre = to cut] but comes secondarily to mean knowledge of the form and relations of the parts into which the body may be resolved by that fundamental method of study.

As the body is dissected region by region or is studied by means of sections taken in different planes, and as the knowledge so acquired is formulated in descriptions of all the features of each region taken together, such basic anatomical knowledge is known as *Regional* or *Topographical Anatomy*, which is a kind of "descriptive geography" of the body [τόπος (topos) = a place or locality].

But in the course of dissection it soon becomes evident that all regions of the body are built up of the same kinds of structures (bones, muscles, nerves, blood-vessels, etc.), and that the viscera are related to one another in special ways. The idea of **systems** of structures therefore arises, and the description of the same kinds of structures found throughout the body is known as *Systematic Anatomy*. The observation that there are different kinds of structures in the body inevitably leads to enquiry (speculative at first and then experimental) about what they do; and thus the idea of a community of **function** is inherent in the description of a 'system' of parts or organs. *Functional Anatomy* may therefore be considered in a sense equivalent to Systematic Anatomy; but it has in fact a wider range and merges insensibly into Physiology, which is the study of the normal functions of the body.

Closely related to the study of the functions of the body is the use of the microscope for resolving still further the structure of its parts. The topography of the body as learned by the method of dissection is often referred to as *Gross* or *Macroscopic Anatomy*: the finer structure is, in contrast, known as *Microscopic Anatomy*. It will be easily understood by the student that there is no essential difference between the two—only one of method of study—and that even this difference may be bridged to some extent in the dissecting-room by the habitual use of magnifiers of moderate power, by means of which many important details of the finer structure of organs may be readily observed. Microscopic Anatomy includes not only the minute structure of the organs and parts but also the still finer details of the **tissues** of which they are composed. The study of the minute structure of the tissues is called *Histology* [ἱστός (histos) = a web]; and it includes *Cytology* [κύτος (cytos) = a receptacle, a cell], *i.e.*, the study of the cells which, although far from simple, may be taken as the ultimate units of the body.

But the structure of the body is not the same at all stages of life. All the cells of the body are the descendants of the single cell—formed by the union of ovum and spermatozoon—which is the starting-point of each individual. This single-cell stage is obviously a very different thing from the finished organism represented by the adult; and the series of changes through which the organism passes until its structure is perfected constitute the phenomena of **development** and **growth**.

The general term 'development' is not restricted to the various and striking structural changes which occur during the intra-uterine life of the individual, to the study of which the term *Embryology* is more specially applied; it includes also—in addition to alterations in proportions—many developmental and growth processes which occur after birth, such as the adjustment of the vascular system to its new requirements, the later stages in the ossification and growth of the bones, the eruption of the two sets of teeth, and the changes in the sex-organs and the appearance of secondary sex-characters at puberty. 'Development', indeed, in the wider sense continues throughout the natural span of life, and includes all changes in the body which are due to age.

In the mind of the thoughtful student, the study of Embryology in particular raises questions of the origin of Man and, indeed, helps to answer them. Human Anatomy from this point of view is but part of a larger subject; Man as a vertebrate and a member of the mammalian Order of Primates takes his place in the wider studies of *Comparative Anatomy* and *Comparative Embryology* with all the evidence that they have to offer in support of the theory of evolution. The broader conceptions of anatomy, which are obtained by a general survey of the structural aspects of the vertebrate animal-kingdom, constitute *Vertebrate Morphology*. The morphologist investigates the laws of form and structure, and he gives attention to detail only in so far as this is necessary for his argument.

The knowledge of anatomy which is required by the student of medicine is different. Though his education is incomplete without some appreciation of these wider issues, it is essential for him to be familiar with details of the structure of the human body; and many details that are important from the practical point of view have little or no morphological interest. Moreover, his knowledge is of little value if he is incapable of transferring it from the dissecting-room to the bedside, and of applying it in the examination and treatment of his living patients. Hence the importance of having his attention directed to the study of the anatomy of the living body. This may be done in several ways. One is the consideration of the relation of organs and other structures to the superficial features of the body—*Surface Anatomy*; or the living body may be examined in the revealing light of the X-Rays—*Radiographic Anatomy*. By X-Ray examinations not only may the student's impressions of the form and position of organs obtained from the embalmed cadaver be suitably corrected, but his attention may also be drawn to many interesting observations which are important from the growth and functional points of view.

Finally, it should be understood that what is called *Applied Anatomy* is not a separate division of the subject at all; it is merely the application of every kind of anatomical knowledge to practical problems of diagnosis and treatment in Medicine, Surgery, and other departments of clinical study, as exemplified in the classical work of Hilton (1863). It should, indeed, be the aim of the student of medicine during his anatomical studies to obtain such a knowledge of the anatomy of the living human body that he will find no difficulty in applying it later in practice with understanding and confidence.

Topographical Anatomy

As already explained, Anatomy is primarily a descriptive science founded on observation, and in order that precision and accuracy may be attained it is necessary to have well-defined **descriptive terms**. It is in dissecting-manuals that the regional or topographical method is followed; but such terms are just as necessary in a systematic text-book. It must therefore be clearly understood that all topographical descriptions are framed on the anatomical convention that the body is in the erect position, with the arms by the side and held so that the palms of the hands look forwards. An imaginary plane of section, passing longitudinally through the body and dividing it accurately into a right and a left half, is called the **median plane**, Fig. 1 (M.P.). When the right and left halves of the body are studied it will be found that both are to a large extent formed of similar parts. The right and left limbs are alike; the right and left

Fig. 1.—Horizontal Section through Trunk at Level of First Lumbar Vertebra.
M.P.-M.P.', median plane; S-S', sagittal plane; C-C', coronal plane; A B, points relatively lateral and medial; D E, points relatively ventral and dorsal.

halves of the brain appear the same; there are a right and a left kidney and a right and a left lung; and so on. Many organs are therefore **symmetrically** arranged. But still a large amount of **asymmetry** may be observed. Thus, the chief bulk of the liver lies to the right side of the median plane, and the spleen is an organ which belongs wholly to the left half of the body. Indeed, it is well to state that perfect symmetry never does exist. There always will be, and always must be, a certain want of balance between symmetrically placed parts of the body. Thus, the right upper limb is, as a rule, constructed upon a heavier and more massive plan than the left, and even in those organs where the symmetry appears most perfect, as for instance the brain and spinal cord, it requires only a closer study to reveal many points of difference between the right and left halves.

The line on the front of the body along which the median plane reaches the surface is termed the **anterior median line**; and the corresponding line behind is called the **posterior median line**.

It is convenient to employ other terms to indicate other imaginary planes of section through the body. The term **sagittal** is used to denote any plane which

cuts the body parallel to the median plane (S S′); and the term **coronal** is given to any vertical plane which cuts the median plane at right angles (C C′). These two terms are derived from the names of two of the sutures of the skull. The term **horizontal**, as applied to a plane of section, requires no explanation.

Any structure which lies nearer to the median plane than another is said to be **medial** to that other; and any structure placed farther from the median plane than another is said to lie **lateral** to it. Thus, in Fig. 1, A is lateral to B; and B is medial to A. The term **intermediate** may be employed to indicate the position of a third structure lying between two others that are medial and lateral.

The terms **internal** and **external** express relative distance from the centre of an organ or a cavity; thus, the ribs have external surfaces, that is, surfaces away from the cavity of the thorax, and internal surfaces adjacent to the cavity. The terms **superficial** and **deep** also are used to denote relative distance from the surface of the body, especially in the limbs.

The terms **anterior** and **ventral** are synonymous, and are used to indicate a structure (D) which lies nearer to the front or ventral surface of the body than another structure (E) which is placed nearer to the back or dorsal surface of the body and is thus said to be **posterior** or **dorsal**. The terms 'anterior' and 'posterior' belong strictly to human descriptive anatomy, since they are applicable only to man in the erect attitude and cannot be applied to a four-footed animal; the terms 'ventral' and 'dorsal' belong rather to the language of morphology, as they are independent of habitual position.

Similar pairs of terms are **superior** or **cephalic** and **inferior** or **caudal**, which are employed to indicate the relative levels at which two structures lie with reference to the head or upper end of the trunk, and the lower end or tail.

The term **middle** may be used to indicate the position of a third structure that lies between two others that are either 'superior' and 'inferior' or 'anterior' and 'posterior'.

In the hand we commonly speak of **dorsal** and **palmar** instead of 'posterior' and 'anterior'; and in the foot the corresponding surfaces, though 'superior' and 'inferior' in the anatomical position, are usually called **dorsal** and **plantar**.

The terms **proximal** and **distal** denote relative distance from some central point agreed upon. They are commonly employed only in the description of the limbs, and then denote relative nearness to or distance from the root of the limb. Thus, the hand is distal to the forearm, and the upper arm is proximal to the forearm.

The terms **preaxial** and **postaxial** also are useful in relation to the axis of a limb in considering its development or the distribution of its nerves (see p. 325 and the Section on the Peripheral Nervous System).

Systematic Anatomy

The description of the several systems of organs of which the human body is composed, separately and in logical order, constitutes 'Systematic Anatomy', and is the plan upon which this treatise is based. The several parts of each system not only present a certain similarity of structure but are also associated in specialized functions. As already pointed out, 'Functional Anatomy' merges insensibly into Physiology. It begins with simple ideas, such as that the skeleton has the primary function of a supporting framework of the body, and the muscles the primary function of moving the parts of the framework in relation to each other and the external world: it advances by deductions about the function of parts from their anatomical arrangement (such as Harvey's famous discovery of the Circulation of the Blood (1628), from observations and simple experiments on the

valves of the veins and of the heart): but it is also concerned with the wider field of the interrelations of parts belonging to different systems—for example, the anatomical localization in the Central Nervous System of the origin of nerve-fibres concerned with the regulation and control of the functions of different organs. Anatomy and Physiology are indeed but two different aspects of one subject, separated as a matter of convenience for investigation and study. Structure and function are in reality indissolubly associated; and that is the basis of Systematic Anatomy. Thus there are—

1. The *Locomotor System*, which includes

A. The *Skeletal System*, composed of the bones and certain cartilaginous and membranous parts associated with them, the knowledge of which is known as **osteology**.

B. The *Articulatory System*, which includes the joints or articulations, the knowledge of which is termed **arthrology**.

C. The *Muscular System*, comprising the muscles, the knowledge of which constitutes **myology**. With the muscles are usually included fasciæ, synovial sheaths of tendons, and synovial bursæ.

2. The *Digestive System*, which consists of the alimentary canal and its associated glands, and parts such as the tongue, teeth, liver, pancreas, etc.

3. The *Respiratory System*, in which we place the nasal passages, larynx, windpipe, and lungs.

4. The *Urogenital System*, composed of the urinary organs and the genital organs—the latter differing in the two sexes.

5. The *Ductless Glands*, which, though heterogeneous in their origin, structure, and particular functions, are conveniently grouped together as a 'system', as they share the common functional feature of '**internal secretion**' and together have a profound influence on the functioning of the body as a whole: they include the thyroid and parathyroid glands, the thymus, the hypophysis cerebri and pineal body (these two are attached to the Brain), the suprarenal glands, and the spleen.

The term **splanchnology** denotes the knowledge of the organs included in the digestive, respiratory, and urogenital systems, and the ductless glands.

6. The *Nervous System*, which is divided into—

A. The *Central Nervous System*—the brain and the spinal cord.

B. The *Peripheral Nervous System*—the cranial and the spinal nerves and their ganglia.

C. The *Autonomic Nervous System*, comprising the Sympathetic and Parasympathetic Systems of nerves and ganglia.

The knowledge of all these is included in the term **neurology**.

With the Nervous System may be included

D. The *Organs of the Special Senses* (Sight, Hearing, Smell, Taste) and also

E. The *Common Integument* (skin, nails, hair, etc.), which is also a great sense-organ.

7. The *Blood-Vascular System*, including the heart and blood-vessels (arteries, veins, and capillaries).

8. The *Lymphatic System* of lymph-vessels and lymph-glands.

Microscopic Anatomy and Histology

The organs which form the various systems of the body are themselves built up of **tissues**. Their intimate structure can be resolved only by the use of the microscope and is thus known as *Microscopic Anatomy*. The tissues themselves

are built up of elements comprising **cells** and their products; and the study of these tissues constitutes *Histology*. These two together form an important branch of Anatomy requiring special technical methods for its study; and, since it involves finer description in great detail, special text-books are devoted to it. In a general text-book of Anatomy it is only the outlines of this aspect of the subject that can be presented; and in this text these outlines will be found in relation to the systematic description of the organs in the several Sections. It is, however, necessary to give the student an introduction (1) to the general structure of the ultimate units of the body—the cells—including their methods of reproduction, and (2) to the kinds of tissues which they build up and which in turn form the basis of the microscopic anatomy of the organs.

Structure of the Cell

The human body is an aggregate of innumerable microscopic units called **cells**. The cells vary in size and shape, but all are very minute, the largest—apart from ova (p. 21)—rarely exceeding 80 μ in diameter (a μ = a micron, which is 1/1000 of a millimetre). In some tissues, as will be explained, the cells lie side by side, but in others they are separated from one another by a varying amount of intercellular substance. Each cell is a minute mass of the living substance called **protoplasm**, which is the "physical basis of life".

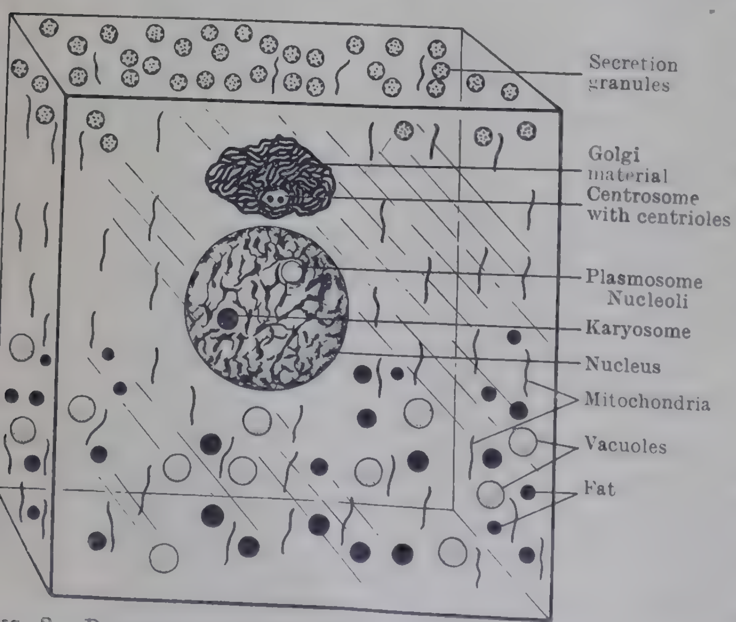
Protoplasm is a colourless, semi-transparent, mobile, irritable substance. It is a colloidal mixture of proteins and nucleo-proteins, with carbohydrates, fats, lipoids, inorganic salts, and water. Different kinds of protoplasm, containing different proportions of these constituents, are recognizable by their reactions to various staining agents.

Every typical animal cell has a **cell-body**, which contains the following structures:—

Nucleus with its **nucleolus** or nucleoli.
Centrosome with its **centriole**.
Mitochondria.
Golgi material.

In addition, the cell-body may contain a number of substances, more or less constant in different cells but not essential parts of their structure. They are products of the activity of the living protoplasm and are known collectively as **metaplasm**. They include:—(1) *Fats* and *Lipoids*, in the form of globules of varying sizes; (2) *Carbohydrates*, including *Glycogen*; (3) *Vacuoles*, filled with fluid; (4) *Secretion granules*; (5) *Pigment granules*; (6) *Protein crystals*, etc.

Much light has recently been thrown on the structure of the cell and the physical nature of its parts by the method of **microdissection** (Chambers, 1940); and microchemical methods also have been applied to the study of the cell.



IG. 2.—Diagram of Animal-Cell. (After Gresson, 1948.)

Cell-Body.—The proto-lasm of the cell-body is called **cytoplasm**. It is probable that the living cytoplasm as no special structural arrangement other than that due to its colloidal nature, and hat the apparent structure, which has been variously described in the dead cell, is ue to the action of fixing and staining chemicals.

The peripheral part of the cytoplasm forms a definite, clear film called the **plasma-membrane**, outside which a definite **cell-membrane** may or may not be present. These act as a semi-permeable membrane through which exchanges take place between the cell and its surroundings.

Nucleus.—The protoplasm of the nucleus is called **nucleoplasm**, and it is surrounded by a *nuclear membrane.* Contained within it there are:—(1) the substance known as *chromatin*; (2) a network of *linin*; and (3) one or more *nucleoli*, which are either (*a*) plasmosomes or (*b*) karyosomes, or both. The nucleus controls the metabolic changes in cells, and it is also concerned with their reproduction by mitotic division.

The **chromatin** is present in the form of granules and owes its name to the fact that it is very readily stained by basic dyes. In fixed cells it generally forms a beaded network, and during cell-division it is aggregated into the specific bodies known as **chromosomes**.

The **linin** or 'thread' material may be seen in fixed cells as a fine reticulum with which the chromatin-network, though independent, may be connected. It has an affinity for acid dyes, but it is not easily stained. It is probably an artifact due to fixation.

The **nucleoli** are small spheres of two kinds. (*a*) The *plasmosomes*, or true nucleoli, lie in the karyoplasm and stain, like cytoplasm, with acid dyes. (*b*) The *karyosomes* appear as knots in the chromatin-network, and they stain, like chromatin, with basic dyes.

The **nuclear membrane** is the outer layer of the nucleus and stains like the chromatin, with which it is connected. It disappears when cell-division begins.

Centrosome.—The essential part of this structure is a minute particle called the **centriole**. It is usually seen densely stained at the centre of a homogeneous sphere, which is different in appearance from the surrounding cytoplasm and placed near the nucleus. The centriole is the structure that appears to initiate cell-division; it is present in all cells that have retained the power of division, and is absent only in those so highly specialized (*e.g.*, nerve-cells) that they have lost that power.

Mitochondria.—These minute bodies are believed to play an important part in cell-function, for example, in the production of *enzymes* (ferments). They occur as minute granules, rods, or filaments, and they may be scattered throughout the cell or collected in groups. When a cell divides, the mitochondria are distributed between the two daughter-cells.

Golgi Material.—This remarkable intracellular 'apparatus' is seldom visible in living cells but is displayed after the cell has been treated by special chemical reagents—silver and osmium. It varies greatly in shape and in size, according to the activity and function of the cell; it often appears beside the nucleus as a network (Figs. 2, 31), but it has no definitely fixed place in the cytoplasm. Like the mitochondria, it seems to be very important in the functioning of the cell and is believed to be concerned with metabolism and the formation of secretions. Like the mitochondria also, the Golgi material is shared between the two daughter-cells when a cell divides.

Life-History of Cells

Necessities for Cell-Life.—In order that an animal-cell may live and perform its work, certain conditions are necessary:—(1) a temperature which varies only within narrow limits; (2) a certain amount of moisture in the form of water; (3) oxygen; and (4) a supply of food from which it can obtain the other chemical elements of its substance, more especially carbohydrates (in the form of sugar), fats, and proteins which contain the necessary nitrogen.

Reproduction of Cells.—Every animal-cell is formed by the division of a pre-existing cell called the *mother-cell*. The mother-cell divides into two equal parts—*the daughter-cells*—each of which, under ordinary conditions, possesses all the capabilities of its mother. Every new cell has a definite life-history. It grows and performs its proper functions; it then ceases to exist either by dividing into two daughter-cells, or by dying and breaking up into fragments which disappear.

Any tissue or organ grows so long as the multiplication-rate of the cells exceeds the death-rate. When the multiplication-rate and the death-rate are equal, the tissue or organ is in a state of equilibrium. As soon as the death-rate exceeds the multiplication-rate, decay and atrophy set in; and, when the decay and atrophy have proceeded to such an extent that an important tissue or organ can no longer perform its proper functions, general death ensues. Cell-division is therefore a vital necessity, and it takes place in two ways—(1) by **amitotic division**, and (2) by **mitotic division.**

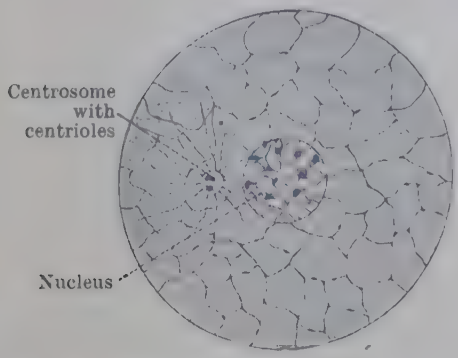


FIG. 3.—SCHEMA OF ANIMAL-CELL IN RESTING STAGE.

Amitotic Division.—The amitotic division of cells is an apparently simple process. First the nucleus is divided by an advancing constriction; thereafter, the cell-body is constricted and divided; and so two similar daughter-cells are produced.

The nucleus of some cells (epithelium of urinary bladder, giant cells of bone-marrow) may divide in this manner, so that the cells become bi-nucleated; but complete amitotic division occurs rarely, if at all, in the human body, and it is not known whether the daughter-cells produced can live and, in their turn, divide. Amitosis may be a degenerative process; and in any case, in comparison with mitosis, it is certainly unimportant.

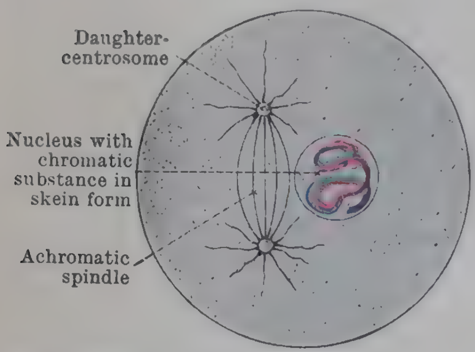

FIG. 4.—SCHEMA OF ANIMAL-CELL IN EARLY PART OF PROPHASE OF MITOSIS.

Mitotic Division.—Mitosis (so-called from the thread-like formation of the chromosomes) or *karyokinesis* (from the activity of the nucleus) is the more common, the more important, and by far the more complicated method of cell-division.

The phenomena of mitosis occur in four phases termed (1) the prophase, (2) the metaphase, (3) the anaphase, and (4) the telophase.

Prophase.—During the prophase the centrosome and the nucleus undergo very obvious changes.

The centrosome divides into two daughter-centrosomes, of which one passes to one side and the other to the opposite side of the nucleus.

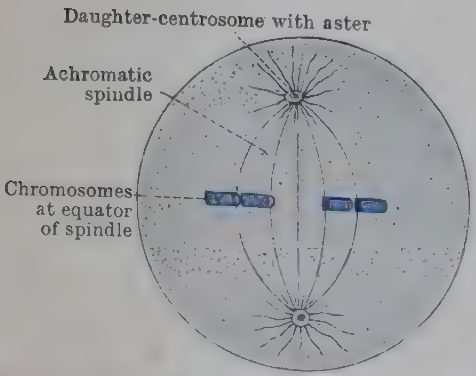

FIG. 5.—SCHEMA OF ANIMAL-CELL AT COMPLETION OF PROPHASE OF MITOSIS.

At the same time a spindle of achromatic fibrils appears and extends from one daughter-centrosome to the other; and fibrils radiate also from each centrosome into the surrounding cytoplasm with star-like figures known as *asters* (Fig. 4). In some cases the *achromatic spindle* is formed entirely outside the nucleus; but more often it passes through the nucleus and may then appear to be derived from the reticulum of linin. It is thought that the fibrils represent a physical change in the cytoplasm, and they appear to guide the movements of the chromosomes in the anaphase of division.

The nuclear transformation affects also the nuclear membrane, the nucleoli, and the chromatin. The nuclear membrane disappears, as also do the nucleoli—sometimes after passing from the nucleus into the cytoplasm, but more commonly without such migration.

The chromatin, during the resting period, is dispersed in the nucleus in an apparently irregular and inconstant manner. As the prophase begins, it is aggregated into small nodules, called *chromomeres*, which are strung together to form a series of nodulated filaments called **chromosomes**. In each species of animal the number of chromosomes

found during cell-division is constant and characteristic. The number of chromosomes in human cells is now definitely known to be 48 (p. 21).

The filamentous chromosomes of the early prophase are bent, twisted, and intimately intermingled, so that, for a time, they simulate a convoluted *skein* (Fig. 4), and, indeed, the individual filaments are sometimes united to one another end to end. Such a condition is, however, but a transitory connexion of the individual chromosomes, and they soon reassert their independence. Gradually the thread-like chromosomes become shorter until the chromomeres are so compressed together that they are no longer distinguishable from one another.

When the shortening is completed the chromosomes appear in the form of rods, hooks, or V-shaped bars, of varying size, which are gathered together at the equator of the achromatic spindle, where they form collectively the *equatorial plate* of the completed prophase (Fig. 5). At this period, each chromosome is attached to one or more of the fibrils of the achromatic spindle.

Metaphase.—During this phase each chromosome divides longitudinally into two equal daughter-chromosomes (Fig. 6).

The division begins at the point where the chromosome is attached to the achromatic spindle; and, as it proceeds, it becomes evident that one daughter-chromosome is attached by one or more of the fibrils of the achromatic spindle to one centrosome and the other to the opposite centrosome.

When the division of the chromosomes is complete the metaphase is ended, two equatorial daughter-plates are present, and the number of chromosomes is doubled.

Anaphase.—In the anaphase the chromosomes of each equatorial daughter-plate move along the fibrils of the achromatic spindle towards the corresponding centrosome. As they approach the centrosome, the body of the cell begins to be divided by a circular constriction which appears at the level of the equator of the achromatic spindle. The appearance of the constriction indicates the end of the anaphase and the commencement of the telophase (Fig. 7).

Telophase.—In the telophase, the terminal period of mitosis, the constriction of the cell-body deepens until the cell is divided into two daughter-cells.

As the division of the cell-body proceeds, the changes which occurred in the chromatin to form the chromosomes are reversed, so that first a skein and then a network are formed. A nuclear membrane is formed again and nucleoli reappear. A new daughter-nucleus is thus formed in each daughter-cell; and as it is formed the greater part of the achromatic figure disappears.

The result of mitotic division is therefore the formation of two daughter-cells from a mother-cell. Each daughter-cell is necessarily smaller than the mother-cell, but has the same constituent parts and the same number of chromosomes in its nucleus as the mother-cell had (Fig. 8).

Heterotypical and Homotypical Mitosis.—The mechanism of mitosis just described applies to all **somatic cells** or **body-cells**; but in the maturation of the **germ-cells** two special cell-divisions occur which are known as 'heterotypical' and 'homotypical'.

In **heterotypical mitosis** the number of chromosomes is reduced to half the characteristic number; in **homotypical mitosis** the ordinary mechanism of cell-division is applied to the daughter-cells with the reduced number of chromosomes (see pp. 19 and 26).

Periods of Growth and Function.—After cell-division there is a variable period during which the daughter-cells grow until they attain the adult size. Thereafter, until division again occurs, they perform the functions of the group of cells to which they belong.

The capability of cells to perform functions depends upon their chromatin contents as well as upon proper nutriment, warmth, and moisture, upon their relative positions in the body of which they form a part, and the provision of means whereby the products of the cell-activity can be removed.

Function of Chromosomes.—As the chromosomes of the mother-cells are split longitudinally during mitosis, each daughter-cell receives exactly the same number of

chromosomes and presumably the same number of chromomeres as the mother-cell from which it was derived, and in the case of cells in fully differentiated tissues it seems probable that the chromosomes carry with them the same possibilities for functional capacity that the mother-cell possessed. This, however, cannot always be the case in the early stages of development before the different tissues of the body are differentiated from one another, for in those stages some cells take part in the formation of one tissue, and others in the formation of other tissues which ultimately perform quite different functions. It must be assumed, whilst the number of the chromosomes in all the cells of the body is the same, that the qualities of their chromomeres may be different.

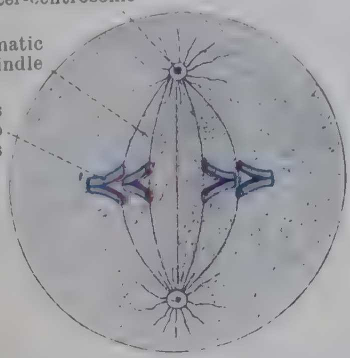

FIG. 6.—SCHEMA OF ANIMAL-CELL IN METAPHASE OF MITOSIS.

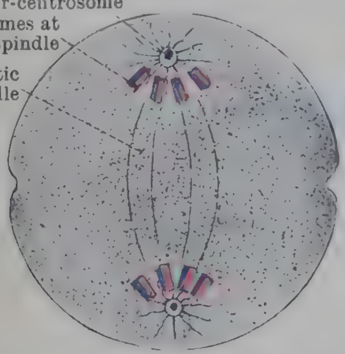

FIG. 7.—SCHEMA OF ANIMAL-CELL AT END OF ANAPHASE OF MITOSIS.

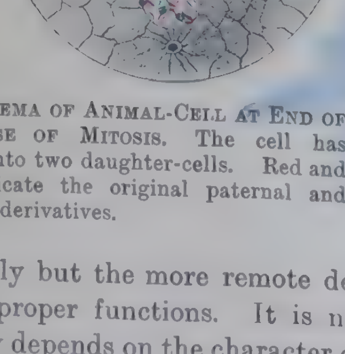

FIG. 8.—SCHEMA OF ANIMAL-CELL AT END OF TELOPHASE OF MITOSIS. The cell has divided into two daughter-cells. Red and blue indicate the original paternal and maternal derivatives.

The function of the chromosomes is therefore to transmit potentialities from one generation of cells to the next. This function has its supreme expression in the transmission through male and female germ-cells of heritable characters from two parents to their offspring. The chromosomes are thus "the material basis of inheritance".

It is believed that the chromomeres of the chromosomes consist of innumerable ultra-microscopic particles, called **genes,** in which, in some manner unknown, determinants of heritable characters are located, and that the capabilities and tendencies of each new individual depend upon the paternal and maternal genes which come together in a new combination in the fertilized ovum.

Further, the evidence available points to the conclusion that the chromomeres and their genes derived from the father never fuse with those derived from the mother, although they lie in close juxtaposition (Fig. 8).

Period of Cell-Life.—As already pointed out, every new cell has a definite life-history. The period of cell-life varies, but it always ends in death; for a time comes when cells no longer transmit to their descendants the power of division, or the capability of growth and function. If it were not so, growth and function, or at least maintenance and function, would continue uninterruptedly, and, in the absence of accident or disease, individual life would continue for ever, and 'old age' would be unknown.

It appears therefore that the ancestors of some cells are capable of producing only a certain number of descendants that can grow to the normal size and perform their proper functions for a more or less fixed period, whilst in other cases the power of division appears to be transmitted continuously but the more remote descendants become less and less capable of performing their proper functions. It is not known how the period of cell-life is fixed; but it probably depends on the character of the genes and their rearrangement in the fertilized ovum. When favourable combinations occur the human individual may live for a hundred years or more. If the combinations of the genes are unfavourable the ova may die immediately after they are fertilized; or they may survive and develop for a time, only to die later at any stage of the intra-uterine period. Eventually all individuals

must die—some killed by accident, others by microbic disease; but most because they have reached the limit originally determined by their inheritance.

There is evidence that the prenatal death-rate is high (Robinson, 1921). For example, it has been shown that about 30 per cent of pig embryos " are abnormal, and that one-third of these are already defective in the phase of segmentation ". In the case of the Hertig-Rock series of early human embryos (p. 38), almost 40 per cent of the twenty-three implanted specimens found in nine years " show some abnormality, often of such a serious nature that it is incompatible with normal continuation of the pregnancy " (Corner, 1947).

Tissues of the Body

There are only four main tissues in the body—**epithelial**, **connective**, **muscular**, **nervous**—and all parts of it are made up of combinations of varieties of these four in different proportions. All the tissues originally consist of cells; and the differences between the tissues are due to (1) changes in the cells in accordance with specialized functions, and (2) the formation of different kinds of extra-cellular materials—**intercellular substance**—which may surround the cells and separate them in varying degree.

The contents of the cells of some tissues are, however, not entirely separate, as in the germinative zone of the epidermis in which protoplasmic bridges pass between contiguous cells. Cell-walls may even be absent so that the 'cells' form a mass of multi-nucleated protoplasm known as a **syncytium** or a **plasmodium**, as in the outer layer of the 'ovum' in early stages of development (p. 81).

In **epithelial tissue**, extra-cellular material is at a minimum, and the varieties of the tissue depend upon the form of the comparatively simple cells according to their situation and function. *Epithelium* provides a covering for the surfaces of the body, external and internal, and is represented also by the secreting cells of glands. It is derived from all three germ-layers of the embryo (p. 55). The epidermis of the skin with its derivatives (skin-glands, hairs, nails) is ectodermal in origin; the epithelium that lines the alimentary and respiratory tracts and composes the secreting parts of the glands associated with them is entodermal; and the epithelial lining of the greater part of the urogenital tract is derived from the mesoderm.

The epithelial cells that line the cavities of the heart, blood-vessels, and lymph-vessels, and of the serous cavities of the body, also are mesodermal in origin. They are specially named *endothelium*; but those that line the serous cavities (pericardium, pleura, and peritoneum) are sometimes distinguished as *mesothelium*.

In **connective tissue**, intercellular substance is at a maximum, and its varieties depend mainly upon the nature of the intercellular substance and the appearance of different kinds of fibres in it. Connective tissues in general form the framework of the body, including the skeleton. The main varieties are areolar, adipose, fibrous, elastic, and reticular tissue, cartilage and bone; they are all derived from the mesoderm or the mesenchyme of the embryo (p. 52). *Areolar tissue* is the most widespread connective tissue in the body, and also the least specialized, as it contains a mixture of the white, collagenous (gelatin-producing) fibres and the yellow elastic fibres, which preponderate respectively in fibrous and elastic tissues. It is a loose tissue which receives its name because spaces or 'areolæ' are easily produced in it; and it is found wherever a slightly elastic connexion that will accommodate itself to movements of parts is required, *e.g.*, in the superficial fascia (p. 410) and in the submucous coat of the alimentary tract.

Adipose tissue is areolar tissue in which the cells are loaded with fat. It is found notably in the superficial fascia, in the mesentery and greater omentum in the abdomen, and around the kidneys, where it acts as a packing-material adapting these organs to the bed in which they lie (p. 728).

Fibrous tissue is composed mainly of bundles of collagenous fibres, and it is the basis of dense, strong structures such as the deep fascia (p. 410), ligaments, and tendons.

Elastic tissue owes its name to the property of the elastic fibres which are its chief constituent. It is found where strong, highly elastic connexions are required by the nature

of the movements that take place, *e.g.*, in the yellowish ligaments (ligamenta flava) of the vertebral column (p. 346), and in the ligamentum nuchæ (p. 345) of quadrupeds which relieves the muscles in the support of the head. Elastic tissue is an important element in the walls of blood-vessels, especially of the larger arteries.

Reticular tissue is a special kind of areolar tissue in which the collagenous fibres are arranged as a fine-meshed framework for the support of the proper substance of various organs. It is typically seen as the supporting element of the lymphoid tissue in lymph-glands, in the tonsils and other lymphoid structures in the alimentary tract, and in the spleen; and it is found also in the liver and the bone-marrow. Associated with reticular tissue there are special phagocytic cells called *macrophages* which are capable of ingesting particles and readily take up certain dyes in the process of vital staining. These cells, with others of similar property in the blood and elsewhere, are collectively known as the *reticulo-endothelial system* (p. 831).

Cartilage is the more or less translucent, resilient tissue that occurs mainly in relation to the skeleton. There are three varieties—hyaline, white fibro-cartilage, yellow or elastic fibro-cartilage—differing in respect of the inclusion of fibres in the ground-substance; they are described on p. 112.

Bone is the highly specialized connective tissue that forms the skeleton. It is described in the Section on Osteology (p. 106).

Bone-marrow (p. 109) and the *blood* and *lymph* (in which the fluid corresponds to inter-cellular substance in other varieties) are usually reckoned also as connective tissues.

Muscular tissue consists of highly specialized cells which have been converted into *muscle-fibres.* Muscle-fibres exhibit a supreme degree of contractility in response to stimulus—a property inherent in all protoplasm—and are of different kinds according to their situation and function and the nature of their control by the nervous system. There are three structural varieties of muscular tissue (p. 403):—(1) *Plain muscle*, the simplest kind, which is the contractile element in the walls of hollow viscera and of blood-vessels. (2) *Striated muscle*, the fibres of which are more specialized and exhibit under the microscope a characteristic cross-striation; the ordinary skeletal muscles are composed of this tissue arranged in bundles. (3) *Cardiac muscle*, which is intermediate in structure and functionally specialized in relation to the rhythmic contraction of the heart. With certain exceptions (plain muscle of sweat-glands and of the iris of the eye, which are ectodermal) all muscular tissue is derived from the mesoderm or the mesenchyme.

Nervous tissue (p. 835), consists of *nerve-cells* and their processes, including *nerve-fibres* which are the essential element in ordinary nerves. A nerve-cell with all its processes constitutes a unit called a *neuron*, and the whole of the nervous system, both central and peripheral, is built up of these units (p. 840); their relation to each other in the central nervous system is extremely complex. Neurons are the most highly specialized cells in the body, exhibiting in supreme degree irritability and conductivity which, like contractility, are inherent properties of protoplasm. Nervous tissue, including most of the elements, known collectively as *neuroglia*, which take the place of ordinary connective tissue in the central nervous system, is derived from the ectoderm of the embryo.

For a general account of the tissues, emphasizing their functions and the parts they play in the building-up of the body, the student is strongly recommended to consult Le Gros Clark (1945).

Embryology and Morphology

The study of the processes by which the parts of the body are gradually formed, and of the structural arrangements by means of which a temporary connexion, for the purpose of an interchange of nutritive and other materials, is established between the ovum and the mother, renders Embryology one of the most interesting of all the branches of Anatomy. Moreover, the early stages in the development of the embryo, and the mode of development of its organs, are of great morphological importance. The term **ontogeny** also is used to denote the

development of the individual. There is, however, another form of development, slower but just as certain in its progress, which has affected all the members of the animal-group to which the individual belongs. The theory of **evolution** leads us to believe that the wide structural gap between Man of the present day and his remote ancestors would, if the geological record were perfect, be completely occupied by long-lost intermediate forms. In the process of descent by evolution, structural changes have gradually taken place which have modified the entire race. The evolutionary phases through which it has passed constitute the ancestral history or **phylogeny** of the race. Ontogeny and phylogeny, moreover, are intertwined in a remarkable manner. The ancestral evolutionary development appears to be so stamped upon an individual that it repeats certain of the phylogenetic stages with more or less clearness during the process of its own ontogenetic development. Thus, at an early period in the development of Man evanescent gill-pouches appear which are comparable with those of a fish, and a study of the development of his heart shows that it passes through transitory structural conditions similar, in many respects, to the permanent conditions of the heart in certain of the lower animals. Thus has arisen the picturesque phrase that every animal during its individual development climbs up its own genealogical tree—a saying which, taking it even in the broadest sense, is only partially true.

Speaking broadly, it may be said that during ontogeny only so much of the phylogenetic history is recapitulated as may be necessary to lay the foundation for further stages of development. Thus, although the embryos of the higher mammals have long since ceased to depend upon the storage of yolk in the egg for their nourishment, even in the human embryo a yolk-sac is well-developed, since it is intimately related to the formation of the alimentary canal and to the early appearance of blood-vessels and blood.

Certain terms employed in morphology require some explanation. The same organ repeated in two different animals is said to present a case of **homology**. But the morphological identity between the two organs must be proved beyond dispute before the homology between them can be allowed. The great and essential test is that the two organs in question should have a similar developmental origin. Thus, the fore-limb of a quadruped is homologous with the human upper limb; the puny collar-bone of a tiger, the fibrous thread which is the only representative of this bone in the horse, and the strongly marked clavicle of the ape or Man are all, strictly speaking, homologous with one another. Homologous organs in different animals usually occupy a similar position and possess a similar structure, but not invariably so. It is not uncommon for a muscle to wander slightly from its original position, and many cases could be quoted in which parts have become completely transformed in structure, either from disuse or for the purpose of meeting some special demand in the animal economy. In the study of the muscles and ligaments instances of this will be brought under the notice of the reader.

The term **homoplasy** is sometimes used to express a form of correspondence between organs in different animals which cannot be included under the term homology. Two animal groups, which originally have sprung from the same stem-form, may exhibit convergence in evolution by developing independently a similar structural character which is altogether absent in the ancestor common to both. Thus, the common ancestor of man and the carnivora in all probability possessed a smooth brain, and yet the human brain and the carnivore brain are both richly convoluted. Correspondence of this kind is included under the term 'homoplasy'. Another example is afforded by the heart of the mammal and that

of the bird. In each of the[illegible] [illegible]ups the ventricular portio[illegible] [illegible]eart consists of a right and a left chamber, and yet the ventricular septum in [illegible] [illegible] not strictly homologous with the corresponding septum in the other, because the common ancestor from which both have sprung possessed a heart with a single ventricular cavity, and the double-chambered condition has been a subsequent and independent development in the two groups.

Often organs which perform totally [illegible] [illegible]unctions are yet perfectly homologous. Thus, the wing of a bat or [illegible] [illegible] a bird, both of which are subservient to flight, are homologous with the human upper limb, the office of which is the different one of prehension. Identity or correspondence in the function performed by two organs in two different animals is not taken into consideration in deciding questions of homology. The gills of a fish and the lungs of a higher vertebrate perform very much the same physiological office, and yet they are not homologous. The term **analogy** is often used to express functional correspondence of this kind.

In the construction of vertebrates and certain other animal groups a series of similar parts are repeated along a longitudinal axis, one after the other. Thus, the series of vertebræ which build up the backbone, the series of ribs which gird round each side of the chest, the series of intercostal muscles which fill up the intervals between the ribs, the series of nerves which arise from the brain and spinal cord, are all examples of this. Parts thus repeated are said to be **serially homologous**. An animal in which similar structures are thus repeated is said to present the **segmental type** of organization. In the early stages of development this segmentation is much more strongly marked, and it is to be seen in parts which subsequently lose all trace of such a division. But there are other instances of serial homology besides those which are manifestly produced by segmentation. The upper limb is serially homologous with the lower limb: each is composed of parts which, to a large extent, are repeated in the other, and the correct adjustment of this comparison between the several parts of the upper and lower limbs constitutes one of the most difficult and yet interesting problems of morphology.

No student of Anatomy can proceed far without becoming aware that the human body, like all living things, is subject to **variation**. Many structural variations are recorded in the following pages. Apart altogether from **malformations**—due to aberrations in the course of the development of parts or organs of the body—most of them can be explained on morphological, genetic, or developmental grounds. But there are other kinds of variations in the human body that are not 'structural' in the usual sense, and that are notably subject to the laws of **inheritance.** Even the chemistry of the body varies, and such variation may be inherited. There are constitutional variations in body-build [illegible] [illegible] habitus which have been described and classified in numerous ways (S[illegible] [illegible] The proportions of the body, the stature, the form of the skull and [illegible] the texture and colour of the hair, the colour of the eyes and of the sl[illegible] [illegible] these and many other variable characters, in the skeleton and soft parts alike, make up in infinite variety the genetic constitution of individuals; and in characteristic combinations they are the hall-marks of the varieties or races of mankind.

Such variations are the subject-matter [illegible] *Physical Anthropology*, which not only deals with comparative racial ana[illegible] [illegible]ut is also concerned with the fascinating problems of the evolutionary origin and the early history of Man.

The appended list of References [illegible] [illegible]udes special works on the different aspects of Anatomy mentioned in this Introd[illegible] [illegible], and also books on the history of Medicine from which the enquiring student ca[illegible] [illegible] information on the history of Anatomy

itself. A list … ces will be found … of each Section of the Text Book for the … of those who may wish to st…y any topic more fully. These references include some classical books and papers; but in general they have been selected from recent papers which themselves provide lists that will lead the senior student to all the original sources.

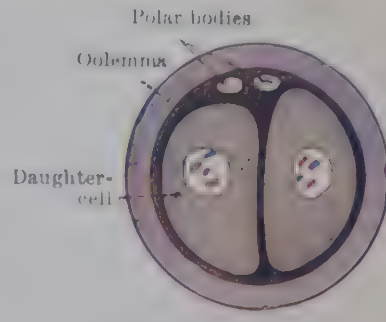
(a) The nuclei are in focus. (b) The two polar bodies are seen, the upper one in focus.

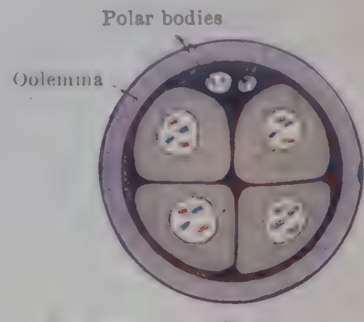
FIG. A.—TWO SECTIONS OF TWO-CELL STAGE OF SEGMENTATION OF HUMAN OVUM, FROM UTERINE TUBE. Photomicrographs × 500. (Carnegie No. 8698; by special permission of Dr. Arthur T. Hertig.)

FIG. B.—SECTION OF FREE HUMAN BLASTULA, 5-6 DAYS OLD, FROM UTERINE CAVITY. Photomicrograph × 600. Note the arrangement of the inner cell-mass in relation to the expanding trophoblastic wall and the segmentation cavity. (Carnegie No. 8663; by special permission of Dr. Arthur T. Hertig.)

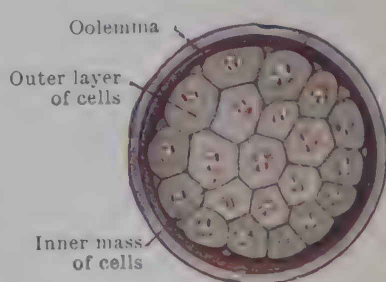
s *the period of segmentation* (Figs. 34, 35). The segmentation of the human ovum has
not yet been followed in detail, but again there can be no doubt that it occurs in
he same manner as the segmentation of the ova of
other mammals (Fig. 34); a perfect 2-cell stage (Fig. A,
p. 16) and at least three other segmenting human ova,
with 8, 9, and 12 blastomeres respectively (Corner,
1947) have been obtained, and the 8-cell stage has
been figured (Rock & Hertig, 1948).



A. Two-Cell Stage.



B. Four-Cell Stage.



C. Morula Stage.

Fig. 35.—Diagrams of Segmentation of Zygote.

The morula is formed inside the oolemma, so that its total size does not exceed that of the mature ovum; consequently, the proportion of cytoplasm to nucleus in the individual cells becomes progressively reduced during segmentation. That proportion is very high in the ovum, and its reduction within the normal range of the soma-cells appears to be an essential preliminary to the next stage of development. Before the segmentation-divisions are completed the polar bodies disappear, and at the end of segmentation the oolemma itself disintegrates as the zygote enlarges with the intake of fluid and structural differentiation begins.

There is evidence which tends to the conclusion that the earliest segmentation-divisions, by which the zygote is divided first into two and then into four parts are qualitatively equal. After a time, however, the divisions result in the formation of cells of different sizes and different capabilities, definite and circumscribed functions being allocated to certain groups of cells and their descendants, according to the position they assume in the morula; that is, the divisions become qualitative as well as quantitative. Some of the cells retain all the potentialities derived from their male and female ancestors and become stem-cells—that is, primordial germ-cells; and there is some evidence that they migrate in the developing embryo to the site of formation of the sex-glands (Witschi, 1948). To others only parts of the chromatic inheritance are transferred, and they become the soma-cells whose descendants become the tissue-cells of the body (Fig. 9).

Trophoblast and Inner Cell-Mass.—The first structural change that occurs in the morula is the differentiation of its cells into an outer layer and an inner cell-mass (Fig. 35 C).

The cells of the outer layer constitute the **trophoblast** or trophoblastic ectoderm, which, by its active proliferation (Figs. 39-48), plays a most important part in the implantation of the ovum in the mucous coat of the uterus and in the nutrition of the embryo and fœtus. It enters into the formation of the **chorion** or outermost envelope of the growing zygote. The chorion, part of which later forms the placenta, serves, in the first instance, as both a protective and a nutritive covering. The relation of the trophoblast to the site of implantation and its differentiation into outer syncytial and inner cellular layers—*plasmoditrophoblast* and *cytotrophoblast*—will be described with the fœtal membranes and placenta (p. 81).

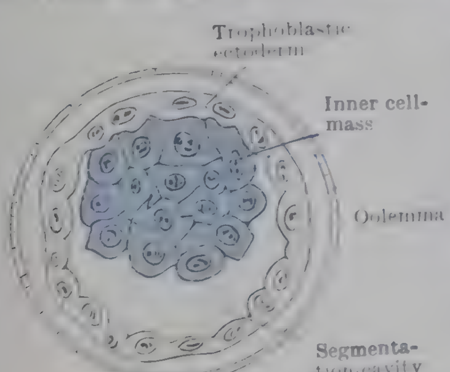


Fig. 36.—Diagram of Mammalian Blastula as Segmentation-Cavity begins to form.

The **inner cell-mass** contains the cells from which the embryo itself will be developed; but it is concerned also with the formation of the other extra-embryonic organs—amnion, yolk-sac, and allantois—which, with the chorion, constitute the fœtal membranes.

In all mammals—it is now known that human development is no exception (Figs. B, p. 16, 39)—a cavity appears in the zygote before the differentiation of the inner cell-mass takes place. As soon as this **segmentation-cavity** appears, the zygote becomes a **blastula** or **blastocyst**. The segmentation-cavity fills with

fluid and enlarges until it separates the inner cell-mass from the outer layer except at one pole of the zygote, where the inner cell-mass and the outer layer remain in contact (Fig. 36). By this time the oolemma has disintegrated and the blastula is free to expand with the further intake of fluid so that the trophoblastic cells are flattened out into a thin membrane, except where the inner cell-mass is attached (Figs. B, p. 16, 37). At this stage—the zygote having entered the uterus as a morula, probably on the 4th or 5th day from ovulation—the blastula becomes attached to the uterine epithelium (Fig. 38) and implantation begins. It is probable that this occurs on the 6th or 7th day, as the earliest implanting human zygote yet observed (Fig. 39) was recovered 7½ days after the presumed date of fertilization; it is still in the blastula stage.

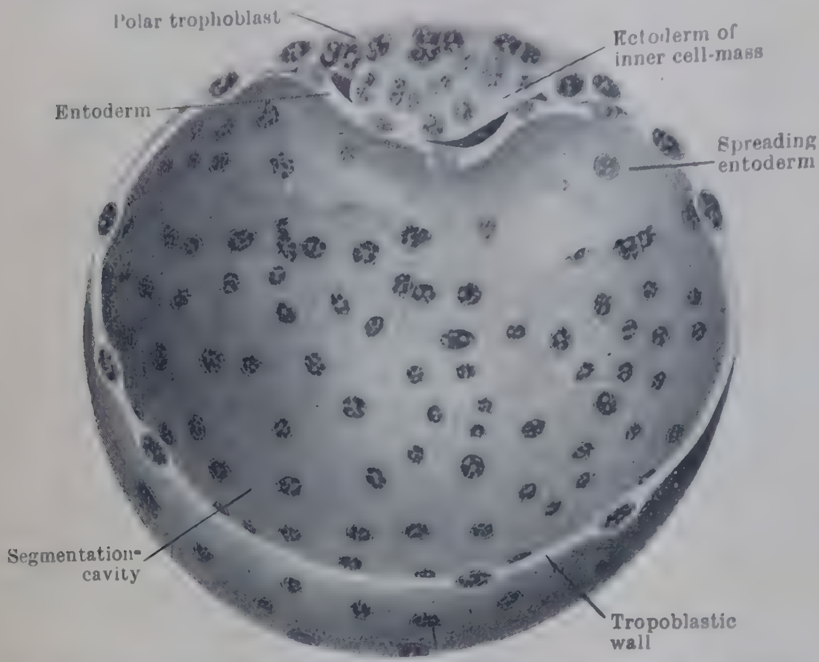

FIG. 37.—RECONSTRUCTION OF 9-DAY OLD BLASTULA OF MACAQUE MONKEY. The entodermal part of the inner cell-mass is flattened and its cells are spreading over the inner surface of the trophoblast. × 280. (After Heuser & Streeter 1941.)

Differentiation of Inner Cell-Mass.—As the blastula begins to attach itself to the endometrium and to be implanted, the fate of the cells of the inner cell-mass is already indicated by the relative positions they occupy (Figs. 39, 40, 51). The group that adheres for a time to the trophoblast, itself of ectodermal origin (p. 76), produce the **ectoderm**, destined to take part in the formation of both the embryo and its amnion; the remainder, projecting at first into the segmentation cavity but rapidly flattening out into a plate of single cells, constitute the **entoderm**, which takes part, too, in the formation of the embryo, and, in addition, of its yolk-sac. The appearance of the inner cell-mass in the blastocysts of the macaque monkey—in which the whole process has been observed (Heuser & Streeter, 1941)—makes it probable that the cells destined to form extra-embryonic parts are segregated at a very early stage from others which remain relatively large and will form the embryo itself.

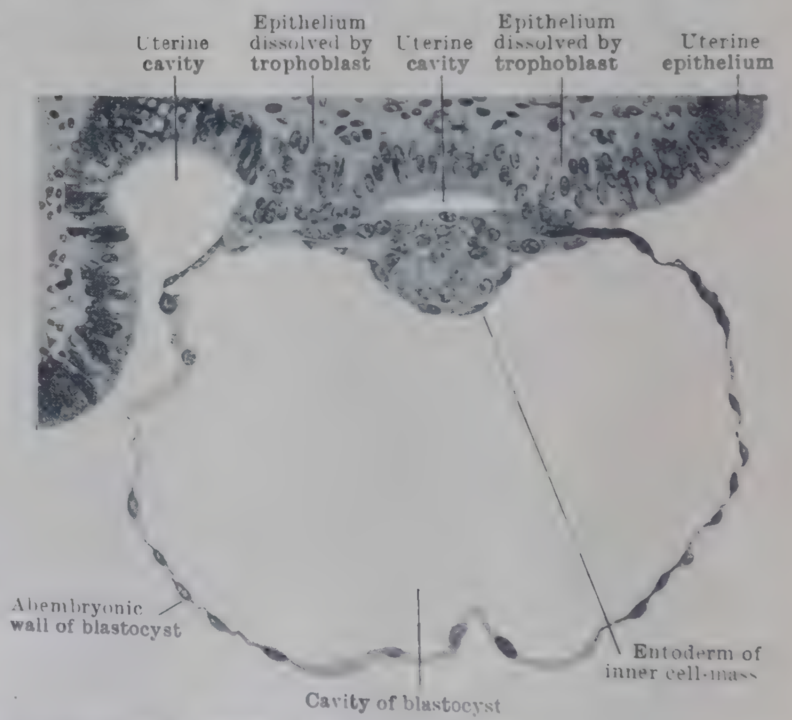

FIG. 38.—EARLY STAGE OF ATTACHMENT OF MACAQUE BLASTULA (ABOUT 9 DAYS) TO THE UTERINE EPITHELIUM. Note the dissolution of the endometrial cells in contact with the trophoblast and the spread of the entoderm from the inner cell-mass. Photomicrograph × 185. (After Heuser & Streeter, 1941.)

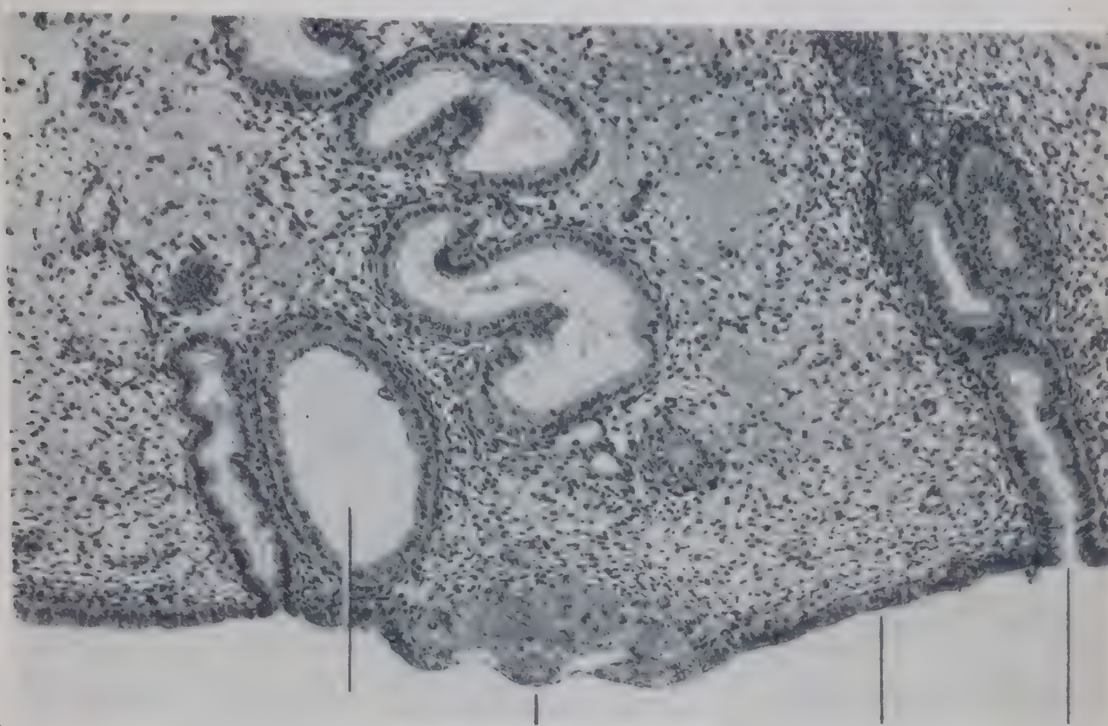
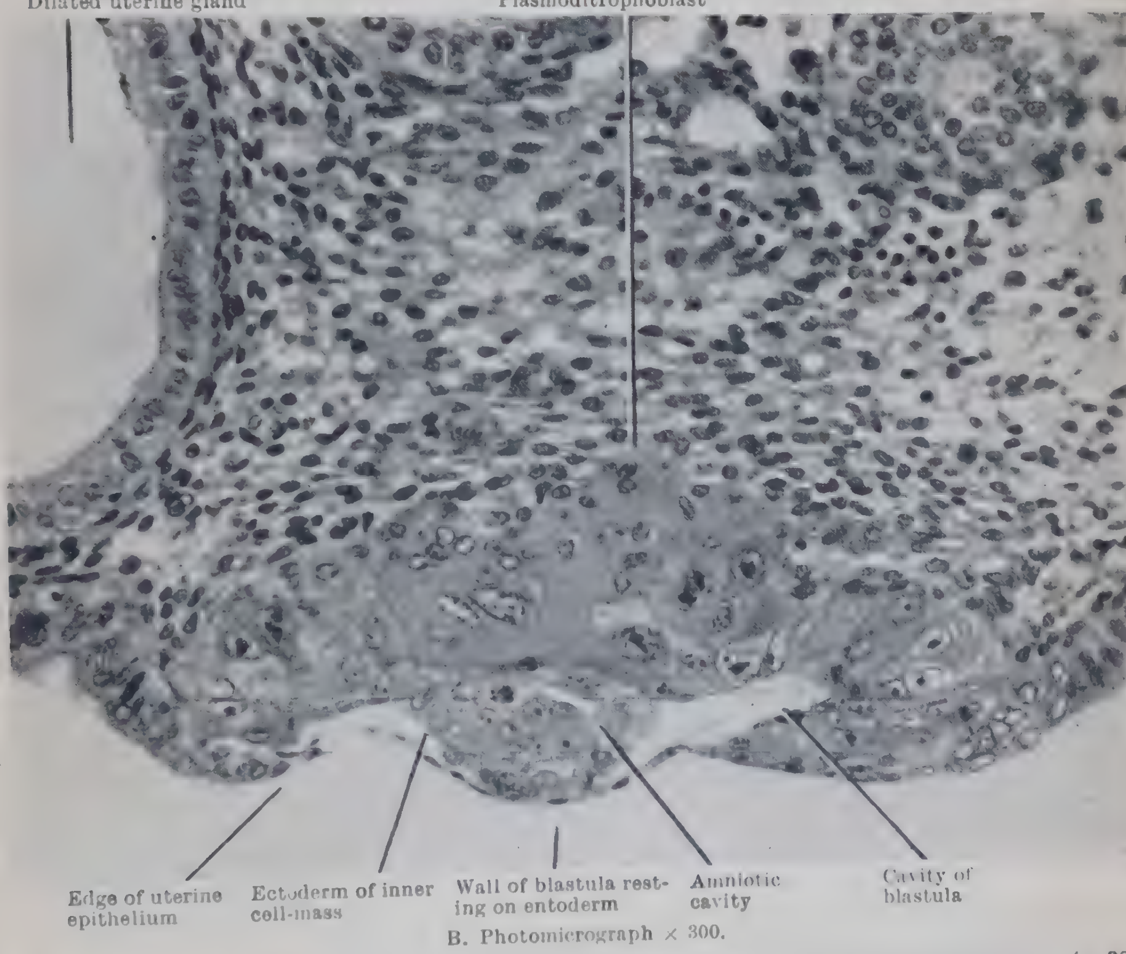
The delimitation of the ectodermal and entodermal elements of the inner cell-mass is followed by the formation of two vesicles, one from each group of cells.



A. Photomicrograph × 100.

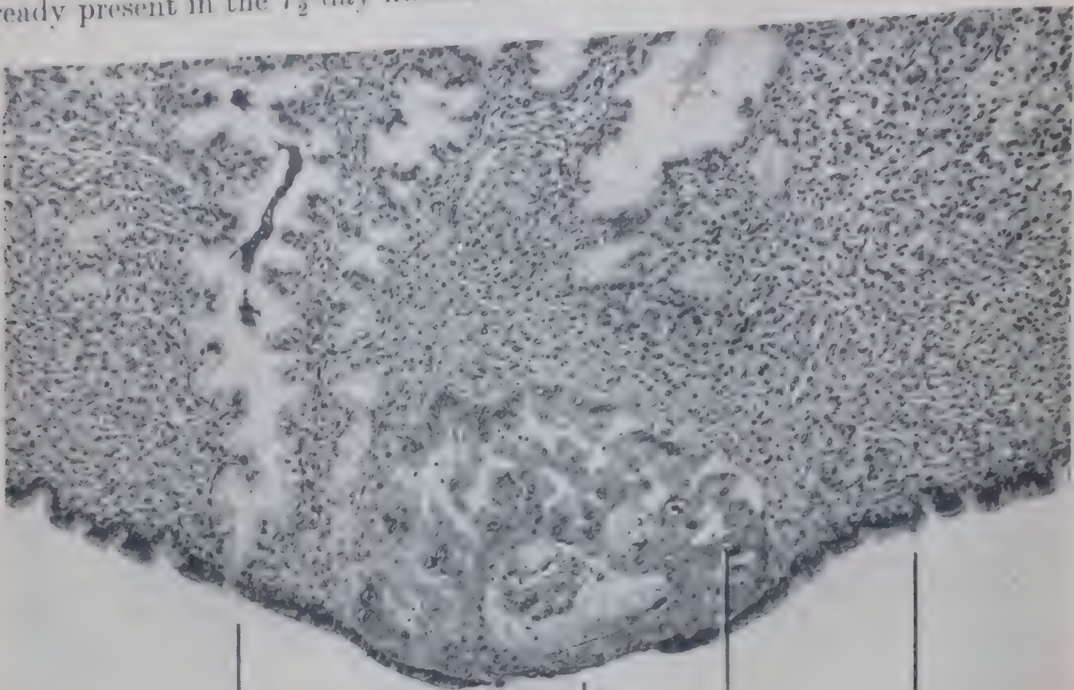


B. Photomicrograph × 300.

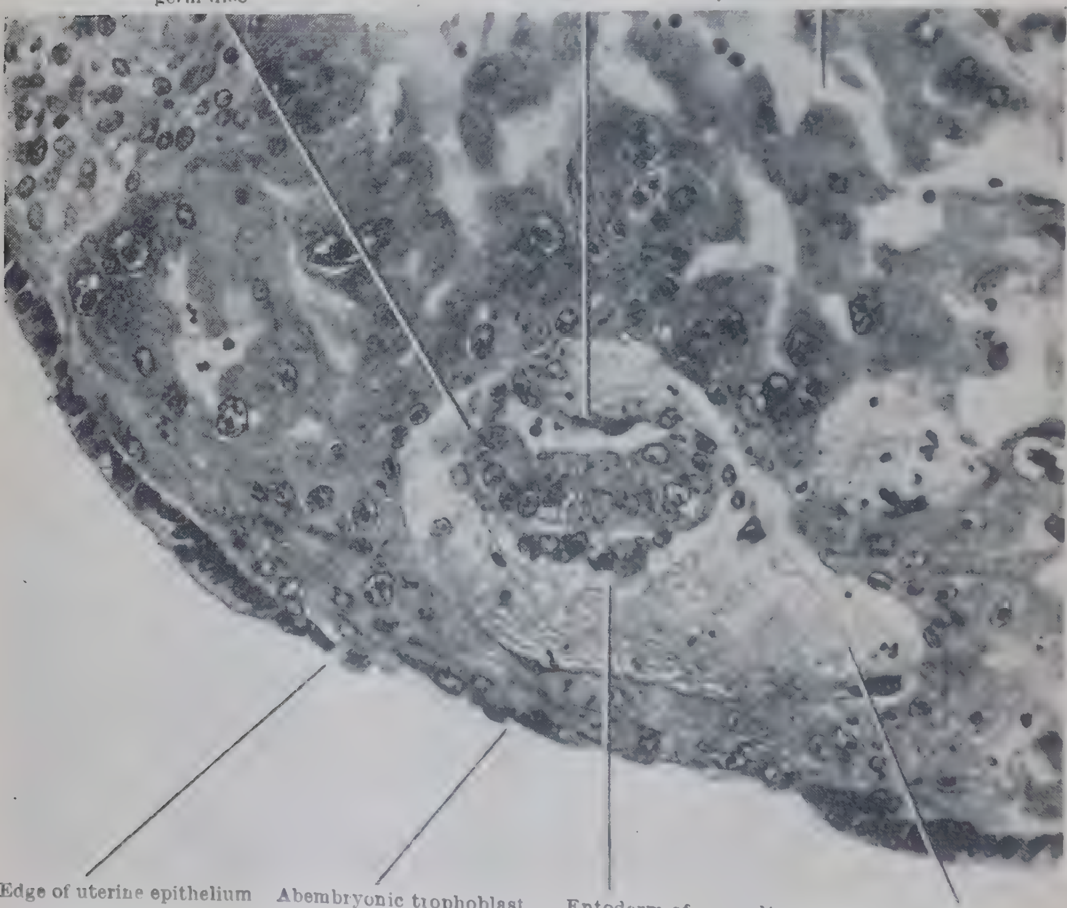
FIG. 39.—SECTION OF HUMAN ZYGOTE, 7½ DAYS OLD, IN EARLY, SUPERFICIAL STAGE OF IMPLANTATION (p. 38). The trophoblast is proliferating wherever it is in contact with the endometrium, and the thin, abembryonic wall of the blastula, still exposed to the uterine cavity, is collapsed on the inner cell-mass. (Hertig & Rock, 1945.)

There is some doubt whether the cavity in the ectodermal group is formed by a loosening of the cells in the middle of the group or by the partial separation of a layer of 'amniogenic' cells from the overlying trophoblast; but in either case the layer of 'amniogenic' cells from the overlying trophoblast ; but in either case the

cells are re-oriented around a space in which fluid accumulates. This *amniotic cavity* is already present in the 7½-day human blastula (Fig. 39).



A. Photomicrograph × 100.



B. Photomicrograph × 300.

FIG. 40.—SECTION OF HUMAN ZYGOTE, 9½ DAYS OLD (p. 38), MORE DEEPLY IMPLANTED THAN THE 7½-DAY SPECIMEN SHOWN IN FIG. 39.

Only a small portion of the trophoblastic wall is still exposed and the uterine epithelium is beginning to regenerate over it. There are numerous anastomosing lacunae in the plasmoditrophoblast. (Hertig & Rock, 1945.)

The precise mode of formation of the entodermal vesicle also is not quite certain. It is at first very much larger than the ectodermal vesicle and the question of its origin is complicated by the simultaneous appearance of the loose, semi-fluid tissue known as the *primary mesoderm*.

The entodermal portion of the inner cell-mass appears in the $7\frac{1}{2}$-day human blastula as a simple layer of cells (Fig. 39), and in a $9\frac{1}{2}$-day specimen (Fig. 40) there is little change in this layer beyond a possibly significant appearance of extending at its edges, although the ectodermal plate has grown thicker, the amniotic cavity is better defined and the implantation of the whole zygote has advanced considerably. Yet in quite a number of slightly older specimens recently described (p. 38) a complete 'entodermal' vesicle is present, larger than the ectodermal vesicle with its amniotic cavity, and occupying a varying but considerable part of the original cavity of the blastula itself now filled with 'primary mesoderm' (Figs. 41-44, 51). In mammals in general, the entoderm grows round the inside of the trophoblastic shell before any mesoderm—which arises later from the primitive streak of the embryonic disc—is present. It is known that the entoderm spreads in this way in the blastula of the macaque monkey (Fig. 37), (Heuser & Streeter, 1941); and it seems highly probable that this happens in human development also.

There is however an obvious difference between the cuboidal cells that form the 'roof' of the vesicle in contact with the ectodermal plate and the extremely tenuous remaining part of the wall of the vesicle. The thin, drawn-out cells that form it are of mesothelial character and are indeed indistinguishable from the cells of the primary mesoderm that now lines the trophoblastic shell and occupies the rest of the cavity in wisps of mesenchymatous tissue. For this reason, on the view that the thin part of the wall of the vesicle is derived from the primary mesoderm, the cavity was originally considered to be the first indication of the *extra-embryonic cœlom* (p. 42) and its wall was named the *exocœlomic membrane* (Heuser, 1932*b*, 1938). But, apart from any doubt as to the origin of the vesicle, its subsequent relation to the formation of the 'yolk-sac' (see below) suggested that it should be named the 'primary yolk-sac' (Heuser & Streeter, 1941), a designation now generally adopted (Figs. 41-44).

Origin of Yolk-Sac.—The vesicle known as the primary yolk-sac is the characteristic feature of the remarkable series of young human zygotes recently described (p. 38). Its origin has given rise to much discussion, but the balance of opinion is that the whole of the wall is of entodermal origin, in spite of the fact that the greater part—the so-called exocœlomic membrane—is composed of cells which appear to be derived from those of the primary mesoderm. But the whole of this vesicle does not participate in the formation of the 'yolk-sac' of later stages. The primary yolk-sac reaches its final state of development about the 12th day, when it is much larger than the ectodermal vesicle (Figs. 43, 44): thereafter, it is quite rapidly reduced in size—actual, not relative size—so that in a $13\frac{1}{2}$-day embryo (Fig. 47) it is not much larger than the ectodermal vesicle and soon, by the growth of that vesicle, the yolk-sac appears about the same size or even for a time relatively smaller (Fig. 48-50). It may now be called the **secondary yolk-sac.**[1]

There is some doubt, moreover, about the process by which the reduction is effected; but again it seems probable that the entodermal plate in the roof of the primary yolk-sac either delaminates with the formation of a cavity or extends at its edges to enclose the upper part of that vesicle. There is no doubt, however, that a considerable portion of the primary yolk-sac is cut off and disintegrates. In several young specimens small detached vesicles, sometimes connected by strands, can be recognized as degenerating portions of the primary yolk-sac (Figs. 46, 47). The earliest record of the stage of constriction of the primary yolk-sac, with a suggestion of its evolutionary significance, is in the description of the "Teacher-Bryce II" embryo by Bryce (1924). Stieve (1931) figured hypothetical stages in the reduction in size of the yolk-sac; and his interpretation is borne out by the 14-day specimen (Fig. 46) recently described by Morton (1949). The primary yolk-sac appears to correspond to the yolk-sac of lower mammals, and its replacement by the secondary yolk-sac is a specialized developmental process in Man and other Primates.

[1] The term *definitive yolk-sac* is better retained for the yolk-sac after separation from the alimentary canal, when it is known also as the 'umbilical vesicle' (p. 77).

Pre-Villous Human Embryos.—In the last edition of this text-book it was possible to make only preliminary reference to the accumulating wealth of new material that has revolutionized our knowledge of early human development. Some of these numerous specimens of recently implanted zygotes—they have been called " a perfect galaxy of new stars in the uterine firmament "—are now illustrated; and it may be well to summarize the features exhibited by this remarkable series, with references to the original descriptions.

No fewer than *eight* specimens in the pre-villous stage of development, i.e., before the formation of chorionic villi (p. 81), have been recorded since 1939. Five of them belong to the beautiful Hertig-Rock series (from the Carnegie Department of Embryology in Baltimore) which includes a number of other early human zygotes, all likewise embedded in the endometrium but described as " abnormal in respect of the state of the trophoblast and thought to have been destined to abort " (Hertig & Rock, 1944). Four of these 'abnormal' specimens, ranging in age from 11½ to 13½ days, show the same essential features of the embryonic rudiment as the eight normal zygotes.

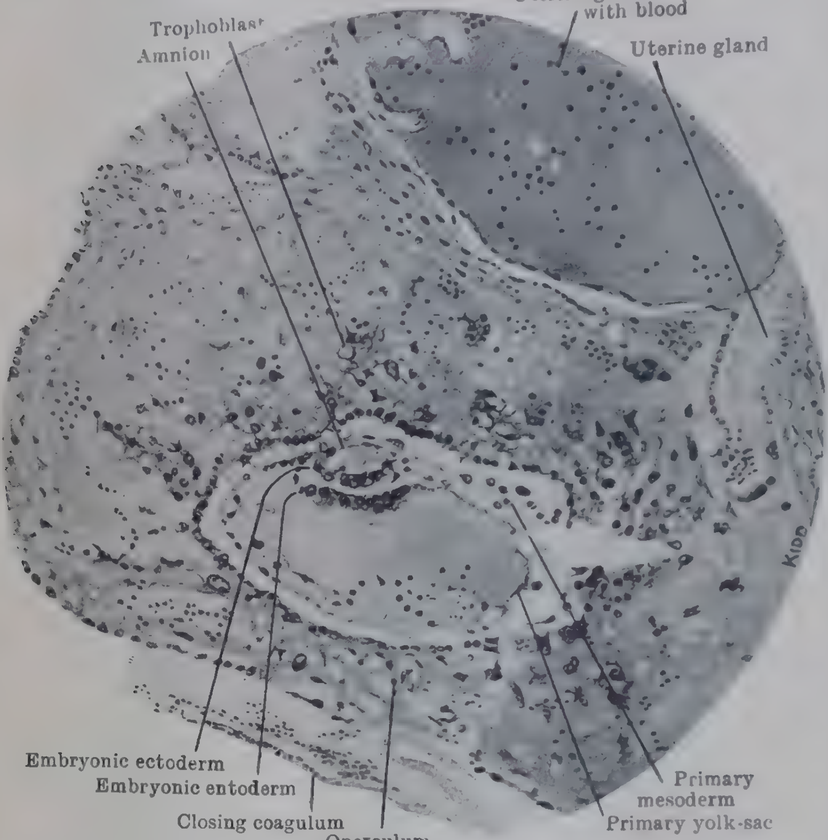


FIG. 41.—SECTION OF DIBLE-WEST EMBRYO TO SHOW THE EMBRYONIC RUDIMENT AND ITS RELATION TO THE PRIMARY MESODERM. × 75. (Dible & West, 1941.)

Carnegie No. 8020 (7½ days).—This is the earliest implanting human zygote yet recorded (Fig. 39). Its striking feature is the proliferation of the trophoblast wherever it is in contact with uterine tissues (p. 81). The implantation is quite shallow; the uterine epithelium shows a wide gap through which the thin abembryonic wall of the blastocyst, though collapsed on to the inner cell-mass, still projects into the uterine cavity. The inner cell-mass, attached to the advancing portion of the trophoblastic wall, shows a commencing amniotic cavity and a flattened plate of entodermal cells. There is no primary mesoderm in the segmentation - cavity; and this specimen provided the first proof—see Fig. B, p. 16—that there is a true blastula stage in human development (Hertig & Rock, 1945).

Carnegie No. 8004 (9½ days). This specimen (Fig. 40) shows the same general features but it is more deeply implanted, there are numerous *lacunae* in the plasmoditrophoblast (p. 81). the abembryonic pole of the trophoblastic shell has begun to proliferate and the uterine epithelium to regenerate over it. The embryonic rudiment is slightly more advanced with a better-defined amniotic cavity, and the entodermal plate shows signs of extending at its edges—an indication possibly of commencing formation of the primary yolk-sac. But there is as yet no primary mesoderm and the cavity appears to be filled with coagulum only (Hertig & Rock, 1945).

" *Davies-Harding* " (9-10 days).—The implantation is similar to the preceding, but there is no regeneration of the uterine epithelium and the aperture is plugged by a 'closing coagulum' (p. 80). The embryonic rudiment is in a definitely more advanced stage; although there is not much difference in the amniotic cavity, a complete primary yolk-sac is present, much larger than the ectodermal vesicle. It occupies a considerable part of the cavity and the rest of the cavity is filled with primary mesoderm. This is the important feature (see p. 37) which is characteristic also of the remaining specimens in this series. (Davies, 1944.)

" *Barnes* " (10-11 days).—Implantation appears to be more superficial than in the preceding specimen—the abembryonic trophoblast is quite thin and there is no regeneration of the uterine epithelium—but the embryonic rudiment is more advanced. The ectodermal plate projects with a convex surface into a well-defined amniotic cavity, the primary yolk-sac is smaller in proportion, and the cavity is filled with primary mesoderm and coagulum. (Hamilton, Barnes & Dodds, 1943.)

" *Dible-West* " (11½ days).—The descriptions of this specimen (Fig. 41) and of the next two were published in the same year, and they share the distinction of demonstrating the now well-known 'primary yolk-sac stage' of human development. The features are very similar to those of the " Davies-Harding " specimen, but the primary yolk-sac occupies a rather larger part of

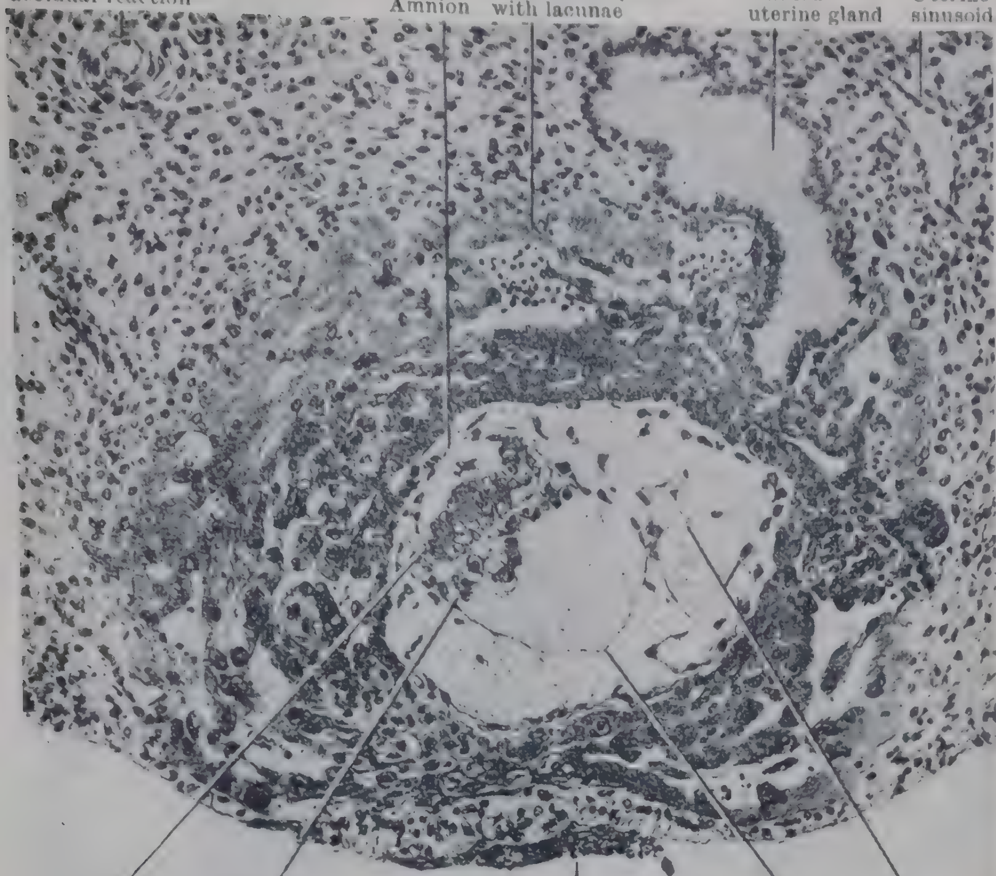

FIG. 42.—SECTION OF HUMAN ZYGOTE, 11½ DAYS OLD (p. 40).

The implantation is advanced to the stage of regeneration of the uterine epithelium, and the abembryonic trophoblast is proliferating. The 'germ-disc' is clearly defined; and the amniotic cavity, the primary yolk-sac and primary mesoderm are evident. Photomicrograph × 125. (Hertig & Rock, 1941.)

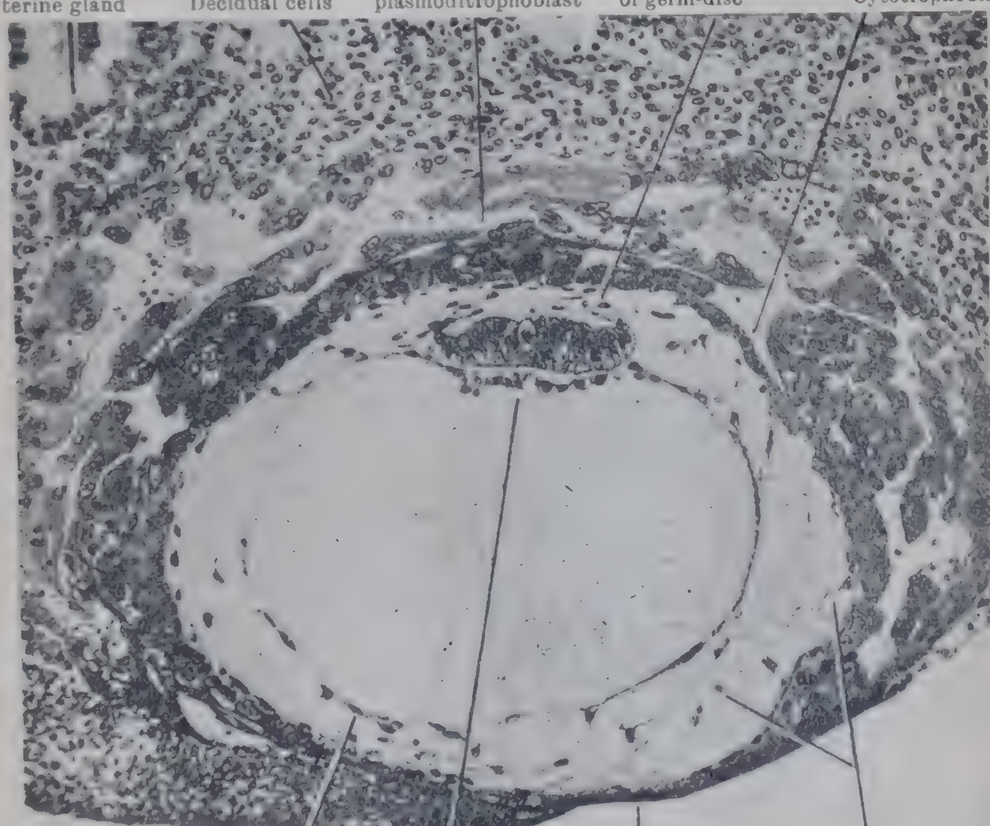

FIG. 43.—SECTION OF HUMAN ZYGOTE, 12½ DAYS OLD (p. 40).

The general features are the same as in the 11½-day specimen (Fig. 42); but the primary yolk-sac is much larger and the 'germ-disc' more advanced. The implantation, however, is more superficial. Photomicrograph × 125. (Hertig & Rock, 1941.)

the cavity, and there is a trophoblastic 'operculum' (p. 80) as well as a closing coagulum. (Dible & West, 1941.)

Carnegie Nos. 7699 ($11\frac{1}{2}$ days) and *7700* ($12\frac{1}{2}$ days).—These two specimens, described together

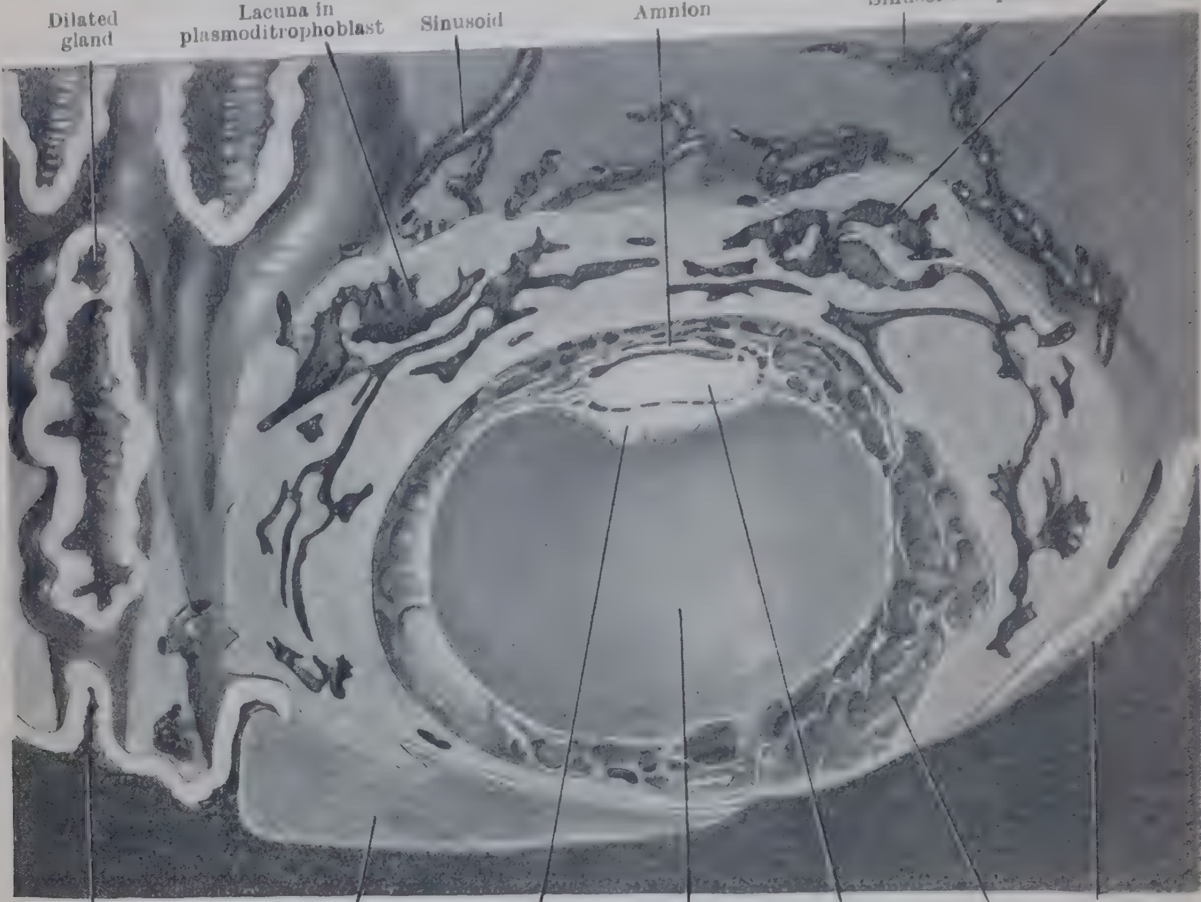

FIG. 44.—SECTIONAL RECONSTRUCTION OF THE $12\frac{1}{2}$-DAY HUMAN ZYGOTE IN FIG. 43.
The reconstruction shows the main features of the embryonic rudiment and of the trophoblast, in particular its relation to the endometrium. ×125. (After Hertig & Rock, 1941, from a drawing by James F. Didusch.)

in the same publication, are the most beautiful examples of the primary yolk-sac stage. They exhibit all the characteristic features and differ, like the others, in detail only, notably in the size of the primary yolk-sac. The ectodermal plates and the amniotic cavities are very similar but the primary yolk-sac is very much larger in the older specimen and indeed occupies nearly the whole of the chorionic cavity (Figs. 42-44). The younger specimen is more deeply implanted with regenerated uterine epithelium and a small closing coagulum (Fig. 42); the older one is more superficial and not so completely covered by abembryonic trophoblast and regenerating epithelium (Figs. 43, 44). (Hertig & Rock, 1941.)

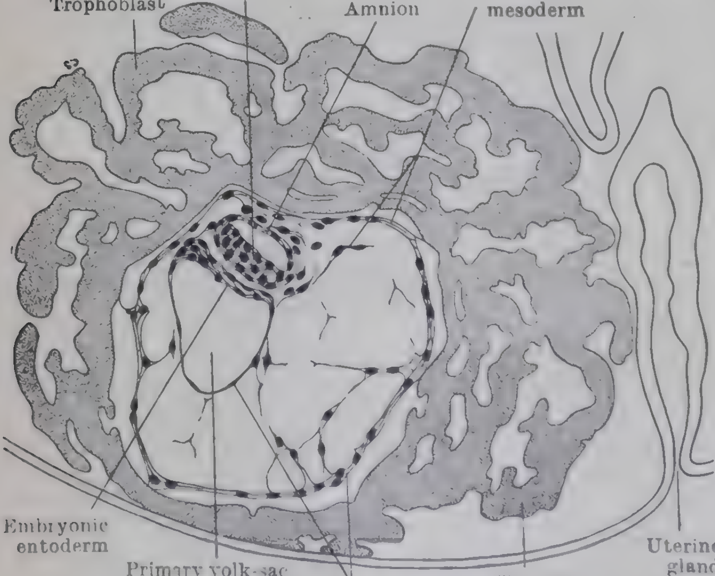

FIG. 45.—RECONSTRUCTED SECTION OF THE MILLER EMBRYO TO SHOW THE EMBRYONIC RUDIMENT AND ITS RELATION TO THE PRIMARY MESODERM AND THE TROPHOBLAST. × 100. (After G. L. Streeter, 1939.)

Carnegie No. 7950 (12 days).—This specimen is very similar to No. 7700 both in respect of the more superficial implantation and the size of the primary yolk-sac. The main difference is the slightly asymmetrical development of the ectodermal plate (Hertig & Rock, 1944).

To this account of these recent pre-villous specimens there should be added a note on two others previously described and now recognized to be examples of the primary yolk-sac stage.

"*Miller*" (11 days).—Originally described by J. W. Miller (1913) and re-described by G. L. Streeter (1926), it was reconstructed by Streeter (1939) (Fig. 45). The "Miller Ovum" supplanted, as the youngest-known human zygote, the well-known 12-13 day "Teacher-Bryce I Embryo" (Bryce & Teacher, 1908; Bryce, 1924), now recognized to be abnormal.

"*Werner*" (11½ days).—Described by Stieve (1931, 1936), it is the first on record to illustrate the 'primary yolk-sac', and the author put forward the proposition, now known to be true, that the 'yolk-sac', as previously understood, is secondarily derived from the larger vesicle.

It may be added that a 10½-day chimpanzee embryo demonstrates an essential similarity to the young human specimens now available in the method of implantation, in the differentiation of the inner cell-mass and in the proliferation of primary mesoderm (Elder, Hartman & Heuser, 1938; Heuser, 1940).

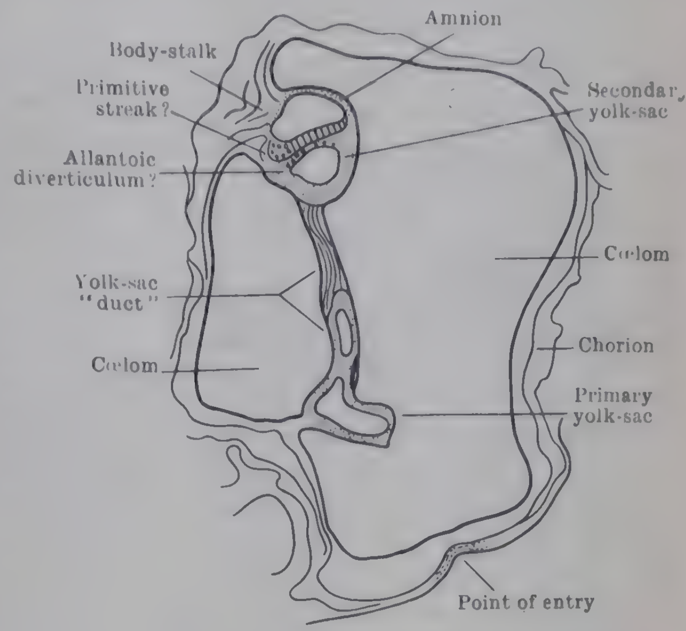

FIG. 46.—DIAGRAMMATIC RECONSTRUCTION OF HUMAN EMBRYO ABOUT 14 DAYS OLD.

This embryo is in the stage of reduction of the yolk-sac; the secondary yolk-sac is still connected by a tubular stalk to a degenerating portion of the primary yolk-sac. × 70. (After Morton, 1949.)

Primary Mesoderm, Extra-Embryonic Cœlom and Body-Stalk.—The mesoderm is one of the three *germ-layers* (p. 52) which co-operate in the building of the tissues and organs of the embryo, and most of it—in the majority of mammals, the whole of it—is formed at a later stage within the developing embryo itself. The *primary mesoderm* of human and other primate zygotes is precocious in its appearance, and this is probably to be associated with early implantation and the mode

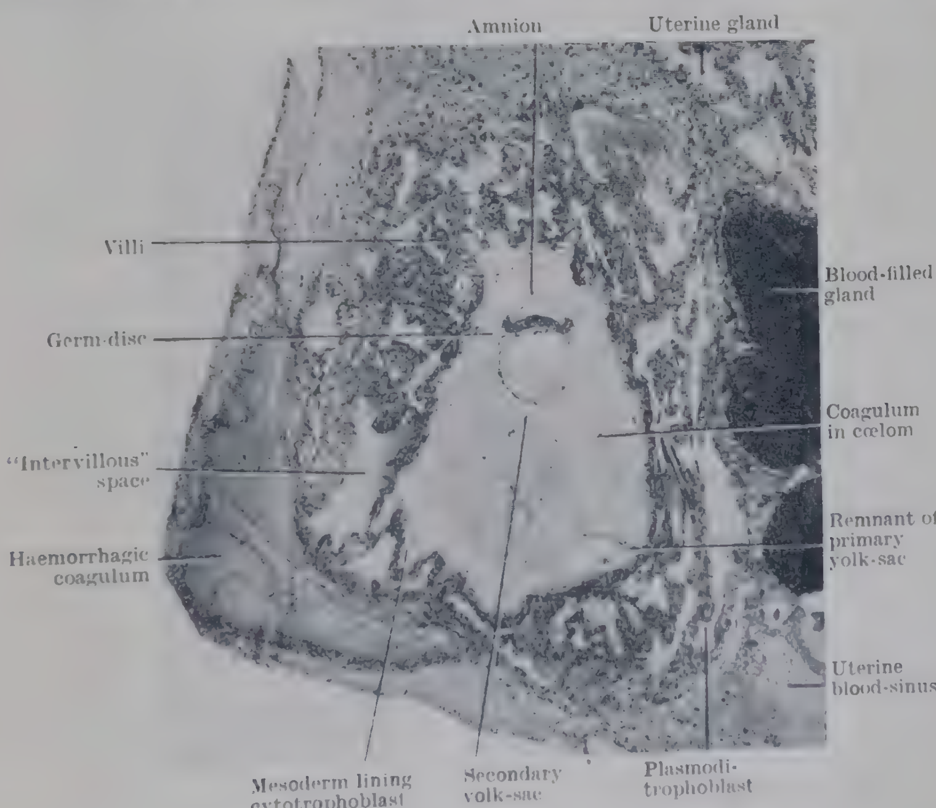

FIG. 47.—SECTION OF HUMAN ZYGOTE, 13½ DAYS OLD.

The embryonic rudiment is clearly defined with amnion and secondary yolk-sac, and a remnant of the primary yolk-sac is seen. There is an unusually large 'closing coagulum', and chorionic villi have begun to form. Photomicrograph × 30. (Heuser, Rock & Hertig, 1945.)

of formation of the ectodermal and entodermal vesicles. The primary mesoderm is extra-embryonic in origin, and indeed it is concerned with the formation of the foetal

membranes which, as already noted, are extra-embryonic organs. It is akin to the special kind of mesoderm formed later within the embryo and known as *mesenchyme* (p. 52).

It is probable that the primary mesoderm, which appears simultaneously with the primary yolk-sac, is derived from the inner surface of the trophoblastic shell. It soon lines the trophoblast as a distinctive layer, fills the space between the trophoblast and the primary yolk-sac in a loose, semi-fluid reticulum and attaches the ectodermal vesicle to the region of the trophoblast from which the 'amniogenic cells' (p. 35) may be derived (Figs. 40, 41, 45).

When the secondary yolk-sac is formed and the remnants of the primary yolk-sac disintegrate, clefts begin to appear in the primary mesoderm and presently run together to form a new cavity. That cavity expands rapidly until the mesoderm is reduced to two thin layers, one of which lines the inner surface of the trophoblast while the other covers the outer surface of the ectodermal and yolk-sac vesicles (Figs. 48-50). This space is the **extra-embryonic cœlom.**

The extra-embryonic cœlom, however, never completely separates the amnio - embryonic and yolk-sac vesicles from the inner surface of the trophoblast; it is obvious that continuity must be maintained at some point to provide a pathway for blood-vessels between the placental area of the chorion and the embryo. The basis of that pathway is provided by the primary mesoderm, which continues to connect the inner surface of the trophoblast with the vesicles in the region that will become the caudal end of the embryonic area. This mesodermal connecting-link is called the **body-stalk** (Figs. 50, 59, 61, 69, 71); the *allantois* grows into it from the yolk-sac; and it takes part, as will be seen later, in the formation of the umbilical cord which connects the fœtus with the placenta (p. 79).

FIG. 48.—SECTION OF HUMAN ZYGOTE, 16½ DAYS OLD. The secondary yolk-sac is fully formed with an outer covering of primary mesoderm. The 'germ-disc' is more advanced than in the 13½-day specimen (Fig. 47) with a primitive streak, early formation of intra-embryonic mesoderm, and a head-process. There is an indication of an 'amnion-stalk' in the condensation of mesoderm that attaches amnion to chorion, and an allantoic diverticulum was present. The chorionic villi with their mesodermal cores are branching freely. Photomicrograph × 30. (Heuser, Rock & Hertig, 1945.)

The word 'cœlom' means 'body-cavity'; and the apparent paradox that part of the body-cavity should be outside the body of the embryo and at one stage should even surround it (Fig 62)—is explained by its relation to the evolution and development of the fœtal membranes (Fig. 89). The *intra-embryonic* part of the cœlom—the body-cavity proper—is developed independently (p. 49) and becomes continuous for a time with the extra-embryonic part at the margin of the embryonic area and the umbilical orifice (Figs. 64 B, 65 B).

Embryonic Area.—When the extra-embryonic cœlom is developed, the zygote then consists of three vesicles, one large and two small. The large **chorionic vesicle** is bounded by the trophoblast lined with primary mesoderm; it contains the two small vesicles projecting into the cœlom and connected to the part of the chorion farthest from the uterine cavity by the mesodermic stalk only. The **ectodermal** or **amnio-embryonic vesicle** and the **entodermal** or **yolk-sac vesicle** remain in contact where the primary mesoderm has not penetrated between the original ectodermal

and entodermal elements of the inner cell-mass; and they form a bilaminar plate known as the **embryonic area** or **germ-disc**—the rudiment of the embryo itself. The ectodermal lamina is *embryonic ectoderm*—it will take part in the formation of the embryo; the *amniotic ectoderm* completes the ectodermal vesicle. Similarly, the entodermal vesicle consists of a lamina of *embryonic entoderm* and extra-embryonic or *yolk-sac entoderm* (Figs. 48, 51 F). The embryonic area is indicated as soon as the amniotic cavity is formed; it is well-defined in the classical Peters embryo of 13 days (Fig. 49), and is clearly demarcated in all young embryos in which the secondary yolk-sac is formed, for example, the 13½-day embryo (Fig. 47), and the embryos of 15 ays (Fig. 50) and 16½ days (Fig. 48) in which the primitive streak (see below) is already in evidence.

FIG. 49.—SECTION OF PETERS EMBRYO SHOWING THE EMBRYONIC AREA BETWEEN THE CAVITIES OF AMNION AND SECONDARY YOLK-SAC. (After Peters, 1899.)

With the formation and spread of the intra-embryonic mesoderm from the primitive streak (p. 48), the embryonic area becomes trilaminar.

Differentiation of Embryonic Area and Formation of Primary Axial Structures.—As the embryonic area is the area of contact between the ectodermal and the entodermal vesicles it is, at first, circular in outline. As growth continues the area becomes oval, and a linear thickening of the ectoderm, called the **primitive streak**, appears in that part of the oval which becomes the caudal part of the area (Figs. 53, 58, 63, 111). Bilateral symmetry is thus impressed upon the embryonic area and the line of the axial structures of the developing embryo is laid down. From this point in development we can speak of **cephalic** and **caudal** ends of the embryonic area. The growth of the area is most rapid at the caudal end so that it becomes elongated and for a time assumes a pear-shaped outline (Figs. 53, 111).

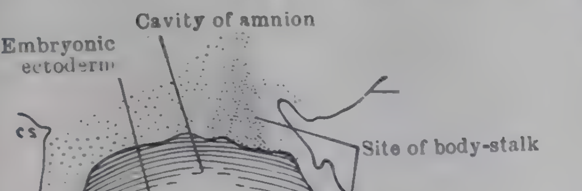

FIG. 50.—MEDIAN SECTION OF 15-DAY HUMAN EMBRYO (RECONSTRUCTION) TO SHOW THE EARLIEST STAGE OF THE PRIMITIVE STREAK AT THE CAUDAL END OF THE EMBRYONIC AREA. (After Brewer, 1938.)

The primitive streak is produced by a downgrowth of the ectoderm which projects as an inverted ridge against the entoderm in the caudal part of the embryonic area, pushing aside any primary mesoderm which may have intervened between the adjacent parts of the walls of the two vesicles. The deeper cells of the ridge adhere to the entoderm, and, by proliferation laterally into the interval between the ectoderm and entoderm of the embryonic area, they form the **intra-embryonic** or **secondary mesoderm**; they also give rise, after a series of remarkable developmental events, to the **notochord**—an axial structure characteristic of all vertebrates.

Immediately after the formation of the primitive streak a groove, called the

neural groove, appears in the cephalic part of the embryonic area (Figs. 60, 62, 68, 113). It is formed by the longitudinal folding of a thickened plate of ectoderm—

B. Differentiation of inner cell-mass, growth of entodermal plate, and proliferation of plasmoditrophoblast (Figs. 39, 40).

C. Formation of amnion, germ-disc defined, primary yolk-sac developing, primary mesoderm spreading, lacunæ with maternal blood in plasmoditrophoblast.

D. Amnion and primary yolk-sac fully formed, primary mesoderm lines the trophoblastic shell and anchors the yolk-sac. There may be an amnion-stalk (Figs. 41-44).

E. Secondary yolk-sac is forming but still connected with degenerating remains of primary yolk-sac by tubular stalk. Chorionic villi are forming from cytotrophoblast (Figs. 46, 47).

F. The secondary yolk-sac is fully formed; the primary mesoderm lines the trophoblast, extends into the branching chorionic villi and forms the body-stalk which supports the embryonic vesicles in the cœlom (Figs. 48-50).

the **neural plate**—which is the rudiment of almost the whole nervous system, the only exceptions being the olfactory nerves, some parts of the ganglia of the cranial

nerves, and the end-organs of the sensory nerves. From it also are derived the cells of the primitive sheaths of the nerve-fibres and the chromaffin cells of the suprarenal glands and other chromaffin structures. The side-walls of the neural groove form the **neural folds.** Almost from the first the cephalic ends of the neural folds are united together a short distance behind the head-end of the embryonic area. Their caudal ends, which remain separate for a time, embrace the cephalic part of the primitive streak. For the further development of the neural groove and the central nervous system, see p. 59.

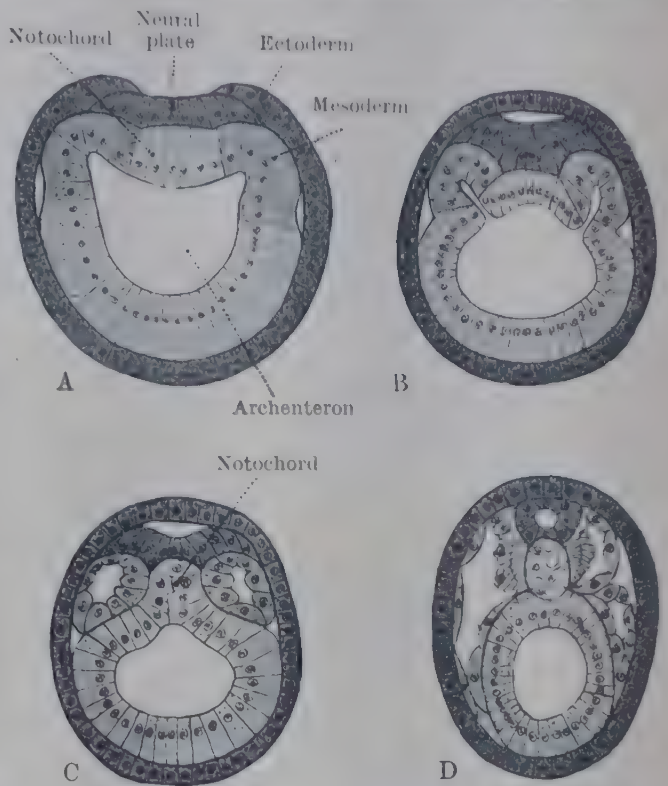

FIG. 52.—TRANSVERSE SECTIONS OF YOUNG *AMPHIOXUS* ILLUSTRATING THE ORIGIN OF THE NOTOCHORD AND THE MESODERM FROM THE ENTODERMIC LAYER OF THE GASTRULA. (After Hatschek.) (J. Graham Kerr, *Text-Book of Embryology: Vertebrata.* Macmillan & Co.)

In the meantime, however, a depression—the **primitive groove**—has appeared on the surface of the primitive streak. The headward end of the primitive groove deepens, until it forms a perforation which passes through the cephalic end of the streak and the subjacent entoderm into the cavity of the entodermal vesicle. As this perforation passes from the floor of the caudal part of the neural groove into that part of the entodermal vesicle which afterwards becomes the primitive alimentary canal or enteron, it is called the **neurenteric canal** (Figs. 59-61). The explanation of this remarkable phenomenon must be deferred until the formation of the notochord

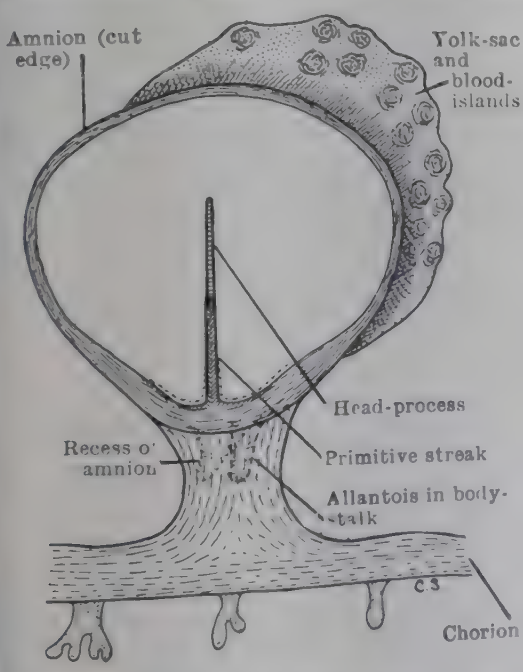

FIG. 53.—RECONSTRUCTED SURFACE VIEW OF EMBRYONIC AREA OF YOUNG HUMAN EMBRYO OF 18 DAYS TO SHOW POSITION OF HEAD-PROCESS AND ITS RELATION TO PRIMITIVE STREAK. × 50.

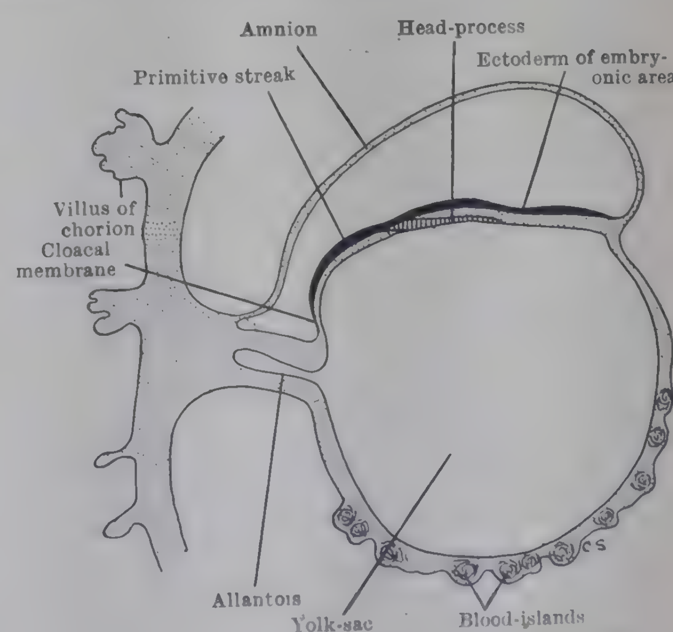

FIG. 54.—RECONSTRUCTED MEDIAN SECTION OF SAME YOUNG HUMAN EMBRYO AS IN FIG. 53. × 50. (Thompson & Brash, 1923.)

is considered; the neurenteric canal as such is but a transitory passage, and it disappears in Man and other mammals before the neural groove is converted into a closed neural tube.

After the appearance of the primitive groove and the neurenteric canal, the caudal ends of the neural folds converge across the cephalic part of the primitive streak and fuse together caudal to the neurenteric canal. The primitive streak is thus divided into two portions: (1) A cephalic portion, which lies at first in the floor of the neural groove, and later in the floor or ventral wall of the caudal end of the spinal cord; and (2) a caudal portion, which remains on the surface and takes part in the formation of the median portion of the tail-end of the body, forming the perineum and the median part of the ventral wall of the body from the perineum to the umbilicus. It is through the perineal section of the caudal part of the primitive streak at a later period of embryonic life, when it is known as the *cloacal membrane* (Figs. 54, 70, 71) that the anal and uro-genital orifices of the body are formed.

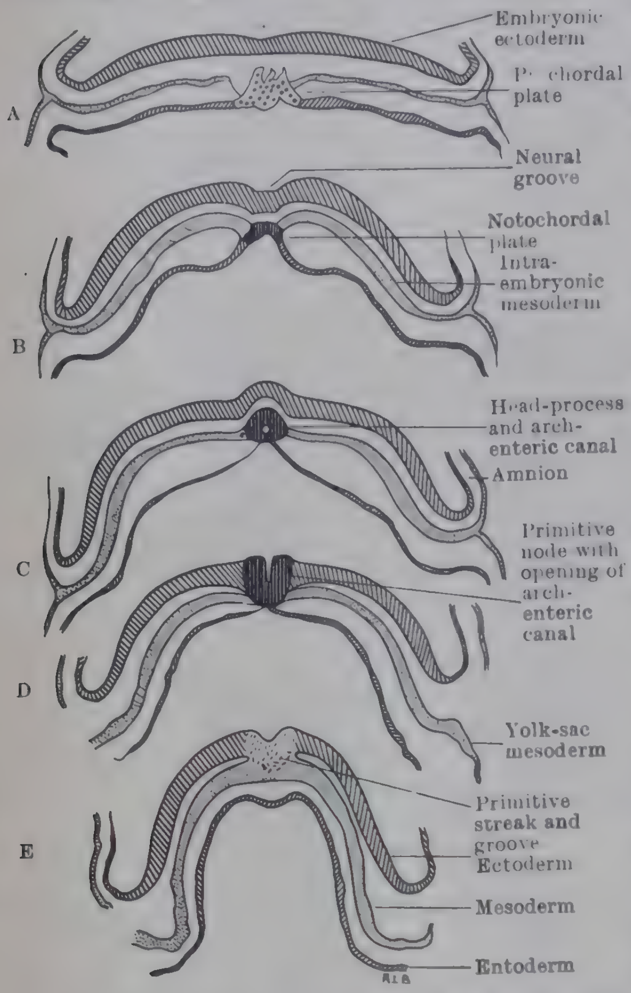

FIG. 55.—TRANSVERSE SECTIONS OF 18-DAY PRESOMITE EMBRYO, TO SHOW RELATION OF HEAD-PROCESS TO PRIMITIVE STREAK AND PROCHORDAL PLATE. × 70. (After Heuser, 1932 *a*.) For the position of the sections, see Fig. 112, p. 96.

Formation of Notochord and Embryonic Mesoderm. — The notochord and the embryonic mesoderm are formed from the primitive streak—the notochord from its cephalic end, and the embryonic mesoderm from its lateral margins and caudal end.

In the primitive vertebrate *Amphioxus*, in which a complete *gastrula* is formed, both the notochord and the mesoderm are derived from the inner layer of the wall of the gastrula, *i.e.*, from the entoderm (Fig. 52). Their connection with the primitive streak in higher vertebrates is explained by the morphological interpretation that the primitive streak represents the fused and elongated lips of the *blastopore*, or opening into the entodermal cavity of the gastrula. As an essential preliminary to the formation of the notochord, there appears a structure which corresponds, though remotely, to the part of the wall of a simple blastula that is invaginated to form the entodermal lining of the gastrula; this is the *head-process*, to which further reference is made below. Although the nature of this event in human development is greatly obscured by the precocious formation of other parts, and especially of a complete entodermal sac from the inner cell-mass, and can be clarified only by extensive comparative studies, nevertheless it is an excellent example of that recapitulation with a purpose to which reference has been made in the General Introduction (p. 13).

As soon as the primitive streak is established its cephalic end becomes a node or centre of growth—the *primitive node*—by means of which the length and, to a certain extent, the breadth of the body are increased. The portion of the body formed by the activity of the primitive node is the dorsal portion, from the back part of the roof of the nose to the caudal end of the trunk. The perineum and the ventral wall of the body, from the perineum to the umbilicus, are formed from the caudal part of the primitive streak. Nevertheless, the primitive streak undergoes little or no increase in length; indeed, as growth continues, it becomes relatively shorter compared with the total length of the embryonic region; for the new material, formed by its borders and its cephalic extremity, is transformed into the tissues of the embryo as rapidly as it is created.

Notochord.—The notochord, or primitive skeletal axis, is formed indirectly by the proliferation of cells from the cephalic end of the primitive streak. It appears first as a narrow rod of cells, called the **head-process**, which projects headwards from the primitive node between the ectoderm and the entoderm (Figs. 53, 54, 62).

The head process then wedges its way among the entodermal cells, and so comes to form part of the wall of the primary entodermal cavity. From that period onwards, as its more caudal parts are formed by continued proliferation from the primitive node, they also are at once intercalated in the dorsal wall of the entodermal sac (Fig. 62).

The head-process is at first solid, but presently a cavity appears in the rod of cells and tunnels it from the ectodermal surface of the primitive node headwards, though not quite to its cephalic end (Figs 55, 56). The floor of the tunnel, *i.e.*, the cells next the cavity of the entodermal vesicle, then breaks down, the roof flattens out, and the head-process is then represented by a plate of cells intercalated in the dorsal wall of the vesicle—the *notochordal plate* (Figs. 57, 64 A, 68). As the tunnel in the head-process breaks down, its caudal end is necessarily

Fig. 56.—Transverse Section through 'Tail-fold' of Young Embryo enclosed in Amnion. The archenteric canal in the head-process is seen beneath the neural plate on the upper surface, the primitive streak and groove on the lower (reversed) surface. Between them is the caudal cul-de-sac of the yolk-sac, separated from the ectoderm by the secondary mesoderm spreading from the primitive streak; below is the body-stalk with the allantois and umbilical vessels.

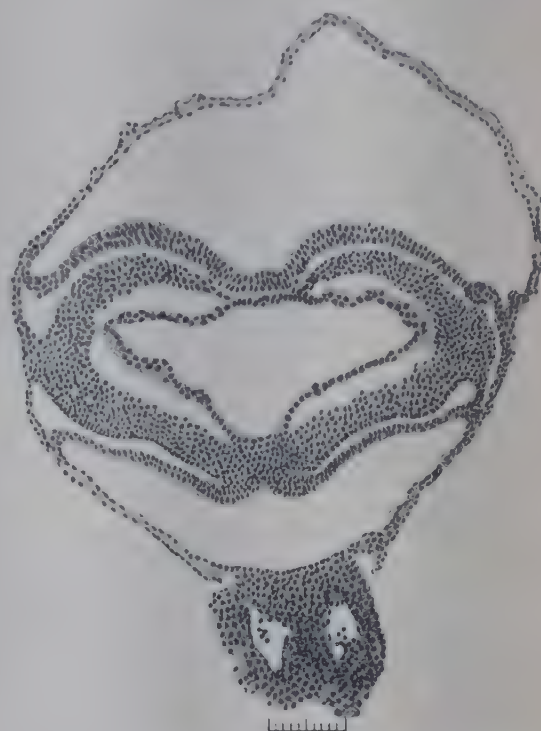

Fig. 57.—Transverse Section of Same Embryo six sections nearer the Head-End. The notochordal plate lies beneath the neural plate on the upper surface; the primitive groove is on the lower surface; the amnion cavity is divided into two parts as the primitive streak mesoderm is continuous with the mesoderm of the amnion. (Embryo M'Intyre. Bryce, 1924.)

left as a passage from the cavity of the amnio-embryonic vesicle through the primitive node to the cavity of the entodermal vesicle—the *neurenteric canal.*

The tunnel which is formed in the head-process is known as the *archenteric canal*, because it is thought to be homologous with the archenteron (entodermal cavity) of *Amphioxus*; from its relation to the formation of the notochord, it is called also the *notochordal canal*. The story of the head-process seems to indicate that the entodermal vesicle is a precocious and specialized formation which does not contain the inherited potentiality of notochord formation. This resides in the primitive node, and before a notochord can be formed it is necessary that it should express itself in the formation of a more 'primitive entoderm' which is carried forward into the roof of the 'entodermal vesicle' by a modified process of gastrulation. When that has been accomplished, then the notochord is formed exactly as in *Amphioxus*.

At a later period the notochordal cells are excalated from the entoderm, and they again form a cylindrical rod of cells in the median plane between the floor of the ectodermal neural groove and the re-formed entodermal roof of the primitive alimentary canal, which, in the meantime, has been more or less moulded off from the dorsal part of the entodermal sac (Fig. 65 B). The neurenteric canal disappears, but for a time the caudal end of the notochord

remains connected with the cephalic end of the primitive streak. The cephalic end of the notochord is continuous with the entoderm of a small portion of the embryonic area which lies immediately beyond the cephalic end of the neural groove. This part of the entoderm, indicated at an earlier date by enlargement of its cells, has been named the *prochordal plate* (Fig. 55); it may give rise directly to the anterior end of the notochord and to mesoderm of the head (Hill & Florian, 1931; Heuser, 1932a). But there is no mesoderm between it and the ectoderm, and this bilaminar region, because it afterwards forms the boundary membrane between the cephalic end of the primitive entodermal canal and the primitive buccal cavity or oral pit, is called the **bucco-pharyngeal membrane** (Fig. 71). It disappears in the fourth week of embryonic life, and immediately afterwards the cephalic part of the notochord separates from the entoderm, but the caudal end remains continuous with the primitive streak until the formation of the neural tube is completed.

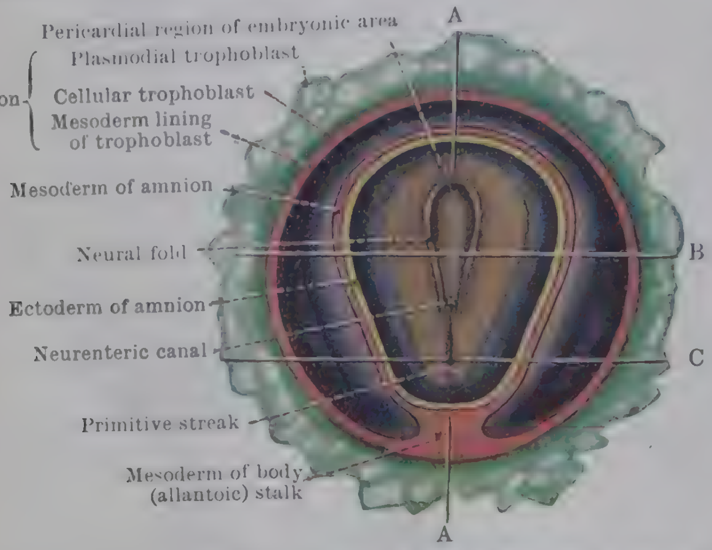

FIG. 58.—SCHEMA OF DORSAL SURFACE OF EMBRYONIC AREA OF ZYGOTE AFTER THE REMOVAL OF PART OF THE CHORION AND PART OF THE AMNION.

After a time the cylindrical notochordal rod is surrounded by secondary mesoderm which becomes converted into the vertebral column. As the vertebral column is formed the notochord is enlarged in the regions of the intervertebral discs and for a time assumes a nodulated appearance.

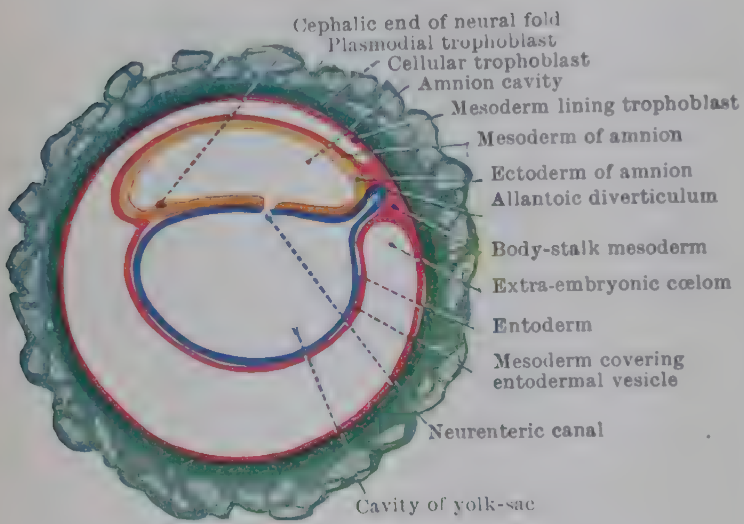

FIG. 59.—SAGITTAL SECTION OF ZYGOTE ALONG LINE A-A IN FIG. 58.

Ultimately the notochord disappears as a distinct structure, but remnants of it are believed to persist as the pulpy centres of the intervertebral discs. The extension of the notochord into the region of the head is of interest from a morphological, and possibly also from a practical, point of view. It extends through the base of the cranium from the anterior border of the foramen magnum into the posterior part of the body of the sphenoid bone. Its presence in the posterior part of the skull-base suggests that that region was, primitively, of vertebral nature. As the notochord passes through the occipital portion of the skull it pierces the basilar portion of the occipital region first from within outwards and then in the reverse direction (p. 212). It lies, therefore, for a short distance, on the ventral surface of the rudiment of the occipital bone, in the dorsal wall of the pharynx; proliferation of remnants of its pharyngeal portion may give rise to tumours known as *chordomata*.

Differentiation of the Embryonic Mesoderm.—It has already been noted that the *primary mesoderm*—derived either from the inner cell-mass or directly from the trophoblast—is formed outside the embryonic area, and is therefore *extra-embryonic mesoderm* (p. 41).

After the formation of the embryonic area, the ectodermal thickening which forms the primitive streak becomes the main source of the mesoderm; and as this mesoderm appears after the primary mesoderm, and is formed in the embryonic

area, it may be termed **secondary mesoderm** or **embryonic mesoderm**. It is the formation and fate of this embryonic mesoderm which arises from the primitive streak that is now to be considered.

The primitive streak (Figs. 58, 63) is formed by the proliferation of the ectodermal cells of the caudal part of the embryonic area. The deeper cells of the streak which displace any primary mesoderm that may lie in the median plane and thus come into contact with the entoderm, are the rudiments of the embryonic mesoderm, which buds off from the primitive streak into the interval between the ectoderm and the entoderm (Figs. 56, 57, 63). The superficial cells form part of the surface ectoderm of the embryo.

The embryonic mesoderm soon forms a continuous sheet of cells which spreads laterally and headwards in the embryonic area on each side of the median plane. Each of these lateral sheets is thickest where it abuts against the notochord and the wall of the neural groove, and thinnest at its peripheral margin, where it is continuous with the extra-embryonic mesoderm (Fig. 64 A).

At the cephalic end of the embryonic area the medial margins of the mesodermal sheets fuse together across the median plane, forming a transverse bar called the **pericardial mesoderm** (Fig. 69), because the pericardium is afterwards developed in it. The area in which this mesoderm lies is named the *pericardial region* of the embryonic area (Fig. 58).

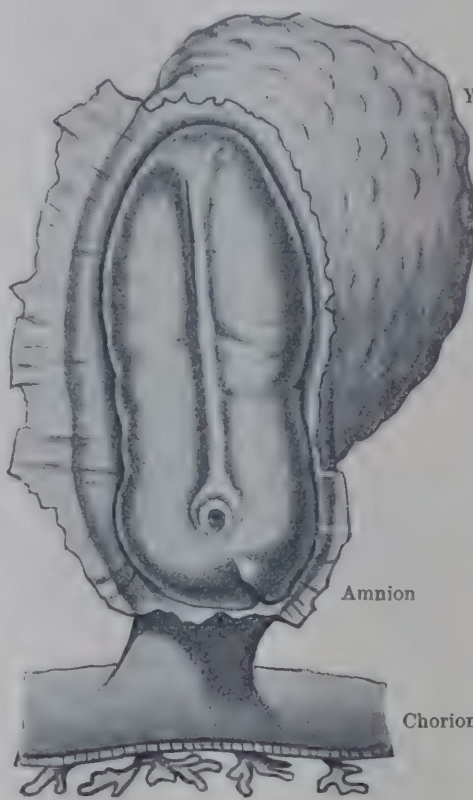

FIG. 60.—DORSAL VIEW OF HUMAN EMBRYO (v. SPEE) OF 20 DAYS. (Keibel & Elze, 1908.) Length of embryonic area 1·54 mm. The chorion is attached to the caudal end of the embryo by the body-stalk. A portion of the amnion is still attached to the margin of the embryonic area, the dorsal surface of which is exposed. In the median plane of the area is the neural groove, and at the caudal end of the groove is the neurenteric canal. The caudal part of the area is bent ventrally, and upon it is the remains of the primitive groove. The yolk-sac with blood-islands is seen at the upper and right part of the illustration. For median section of this embryo, see Fig. 61.

Between the bar of pericardial mesoderm and the cephalic end of the neural groove, and bounded laterally by the mesodermal sheets, there is a small part of the embryonic area in which the ectoderm and entoderm are in contact. This is the **bucco-pharyngeal area**. It afterwards becomes the **bucco-pharyngeal membrane** (Figs. 71, 75), which has been noted (p. 48) as the transitory membrane that separates the primitive mouth or oral pit from the cephalic end of the primitive entodermal alimentary canal. When the bucco-pharyngeal membrane disappears the oral pit and the primitive alimentary canal become continuous with each other.

Between the bucco-pharyngeal area and the cephalic end of the primitive streak the medial margins of the mesodermal plates are separated from each other by the notochord and the neural groove (Fig. 64 B), and still more caudally they are united with the sides of the streak (Fig. 63).

Intra-Embryonic Cœlom.—After the intra-embryonic mesodermal sheets are definitely established, a series of cleft-like cavities appear in their peripheral margins. These cavities, on each side, soon run together to form the rudiments of the **intra-embryonic cœlom** (Fig. 64 B).

The septum of cells at the lateral border of the embryonic area on each side, which, for a time, separates the intra-embryonic from the extra-embryonic cœlom, soon disappears, and the cœlom becomes then one continuous cavity (Fig. 65 B).

The intra-embryonic cœlom extends medially also, but the medial extension ceases at some distance from the median plane, except at the cephalic end of the embryonic area, where the two halves of the cœlom become continuous with each other through the interior of the pericardial mesodermal bar (Figs. 70, 71). The further development of the intra-embryonic cœlom into the several parts of the body-cavity of the embryo is described on p. 92.

As the intra-embryonic cœlom is forming and extending, a longitudinal constriction appears in each half of the mesoderm a short distance from its medial border. This constriction separates each plate into three parts: (1) a medial bar called the **paraxial mesoderm**, which lies at the side of the neural groove and the notochord; (2) the constricted portion, called the **intermediate cell-mass**; and (3) the part lateral to the constriction, called the **lateral plate** (Fig. 65 B).

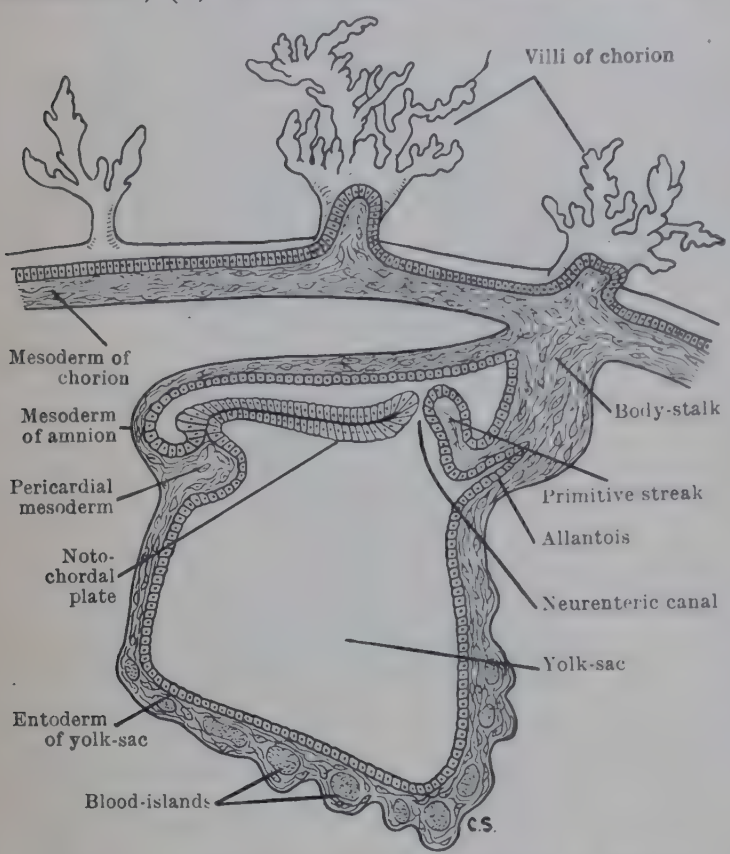

FIG. 61.—RECONSTRUCTED MEDIAN SECTION OF HUMAN EMBRYO OF 20 DAYS. (After v. Spee, 1889.) For dorsal view of this embryo, see Fig. 60.

The intra-embryonic cœlom is confined, in the human embryo, to the lateral plate, which it divides into a superficial layer next the ectoderm, called the **somatic mesoderm**, and a deeper layer next the entoderm, called the **splanchnic mesoderm**. Ectoderm and somatic mesoderm together constitute the *somatopleure*: entoderm and splanchnic mesoderm are together known as the *splanchnopleure*.

The medial borders of the somatic and splanchnic mesoderm are continuous with each other round the medial border of the cœlom. The lateral border of the somatic mesoderm is continuous, at the margin of the embryonic area, with the mesoderm which covers the outer surface of the amnion; the lateral border of the splanchnic layer is continuous with the mesoderm on the wall of the extra-embryonic portion of the entodermal vesicle or yolk-sac.

Paraxial Mesoderm.—Each paraxial mesodermal bar soon assumes the form of a triangular prism. The cephalic portion of each paraxial bar, as far as the middle of the hind-brain (see p. 60), remains unsegmented, but the remainder is cut into a number of segments, called the **mesodermal somites**, by a series of transverse clefts (Figs. 73, 75). The first cleft appears in the region of the hind-brain, and the others are formed successively, each caudal to its predecessor. Only three or four somites lie in the region of the head. The segmentation of the paraxial bars begins before they have reached their full length, and somites continue to be separated off as the paraxial bars are extended by proliferation from the nodal point at the cephalic end of the primitive streak. The total number of somites in the human embryo is thirty-eight or thirty-nine, not counting a few that develop in the tail and soon disappear.

When the somites are first defined they are solid masses of cells, but in a short time a cavity—the **myocœle**, because muscles are derived from the somites—appears in each mass.

In many animals the myocœle is continuous with the more lateral parts of the cœlom through a cavity in the corresponding portion of the intermediate cell-mass—the *nephrocœle*, because the excretory (nephric) organs are derived from the intermediate cell-mass.

The ventro-medial portion of the hollow mesodermal somite is known as the **sclerotome** (Goodsir, 1856), since it produces *scleratogenous cells* which are responsible for the formation of 'hard' skeletal structures. The cells of the scleratogenous section of the somite undergo rapid proliferation and assume the character of the variety of mesoderm to which the special name of **mesenchyme** has been given. Some of these cells invade the myocœle; others migrate towards the notochord; finally, the scleratogenous cells separate from the remainder of the somite, and, as they increase in number, they migrate along the sides of the notochord and neural tube (which has been formed in the meantime from the neural groove) and mingle with those of the opposite side and with those derived from adjoining cephalic and caudal somites (Fig. 67). In this way a continuous sheath of mesoderm is formed around the neural tube and the notochord; it is called the **membranous vertebral column**, and, in later stages, the following structures are differentiated from it — the vertebral column and its ligaments, and the dura mater of the brain and spinal cord (see p. 61).

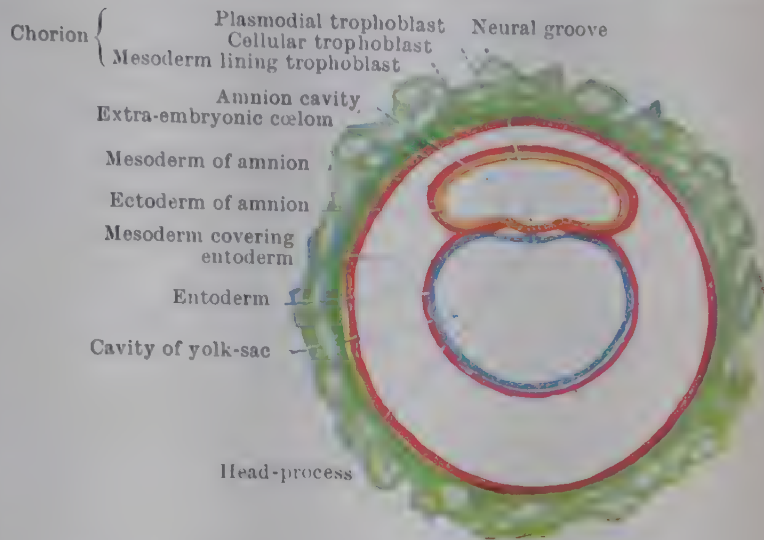

FIG. 62.—TRANSVERSE SECTION OF ZYGOTE ALONG LINE B IN FIG. 58.

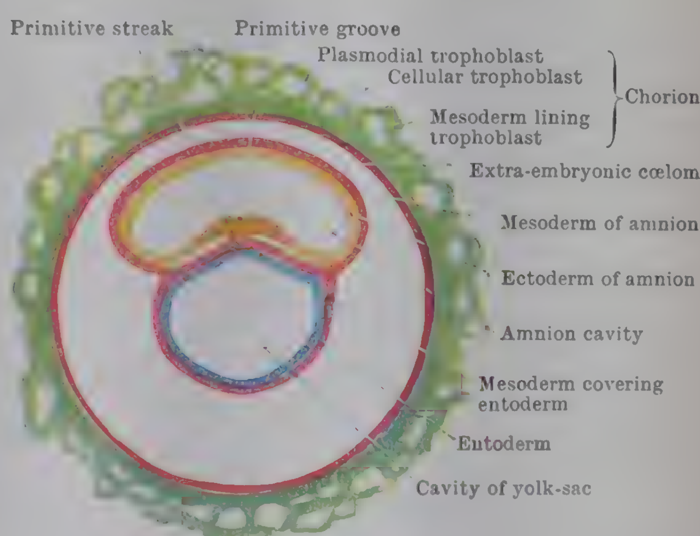

FIG. 63.—TRANSVERSE SECTION OF ZYGOTE ALONG LINE C IN FIG. 58.

The part of a mesodermal somite left after the separation of the sclerotome is called a **myotome**; each myotome gives rise to a flat plate with incurved dorsal and ventral margins, known as a **muscle-plate** because from these plates voluntary muscle-fibres are derived (Fig. 67). The outer portion of each of the myotomes is developed into the cells of subcutaneous connective tissue; consequently it is spoken of as a *cutis-plate*.

Intermediate Cell-Mass.—The continuous tract of cells, lateral to the paraxial mesoderm on each side, to which this name is given, remains unsegmented; but as it gives rise to a series of excretory structures it corresponds to the segmented portions of mesoderm known in lower forms as **nephrotomes**. The intermediate cell-mass gives rise to the greater part of the urogenital system (p. 74), with the exceptions of the genital glands, most of the urinary bladder, the urethra, and the prostate.

Lateral Plates.—The cells of the lateral plates give origin to:—(1) the lining mesothelial cells of the great serous cavities of the body—the pleuræ, the pericardium, and the peritoneum; (2) the majority of the connective tissues (with the exception of those of the vertebral column and the head); (3) the greater part or the whole of the mesoderm of the limbs; and, probably, (4) the plain muscle-fibres of the walls of the alimentary canal and the blood-vessels. Most of these tissues are derived from mesenchymatous cells budded off from the lateral plates.

Cephalic Mesoderm.—It has already been noted that the mesoderm of the

head becomes segmented only in the region of the caudal part of the hind-brain, where four cephalic mesodermal somites are formed on each side. From the scleratogenous portions of these somites the occipital part of the skull and the corresponding part of the dura mater of the brain are developed; and their muscle-plates give rise to the intrinsic muscles of the tongue.

The unsegmented part of the cephalic mesoderm gives rise to the remaining muscles and connective tissues of the head-region.

Mesenchyme.—Before the formation of the embryo many cells, of irregular

form and wandering habits, appear between the more definite layer of mesoderm and the adjacent ectoderm or entoderm. They are called **mesenchyme-cells.** The scleratogenous cells that wander out from the somites are of this nature; the remainder of the mesenchyme is derived largely from the lateral plates of mesoderm, though it may have other sources, possibly even from ectoderm and entoderm.

The complete rôle of the mesenchyme in development has not yet been elucidated, but in addition to connective tissues in general, the tissues of the vascular and lymphatic systems, the reticulo-endothelial system in general and plain muscle-fibres in the walls of the alimentary canal and elsewhere, it appears to be concerned with the development of striated muscles in the limbs, which have not been proved to be directly derived from myotomes.

Germ-Layers and their Derivatives.—The formation and development of the embryonic area have now been traced to a point at which the general relation

of the three main cellular sheets or layers to each other can be understood (Figs. 62-67). The *ectoderm*, the *entoderm*, and the *mesoderm* are in the early stages of

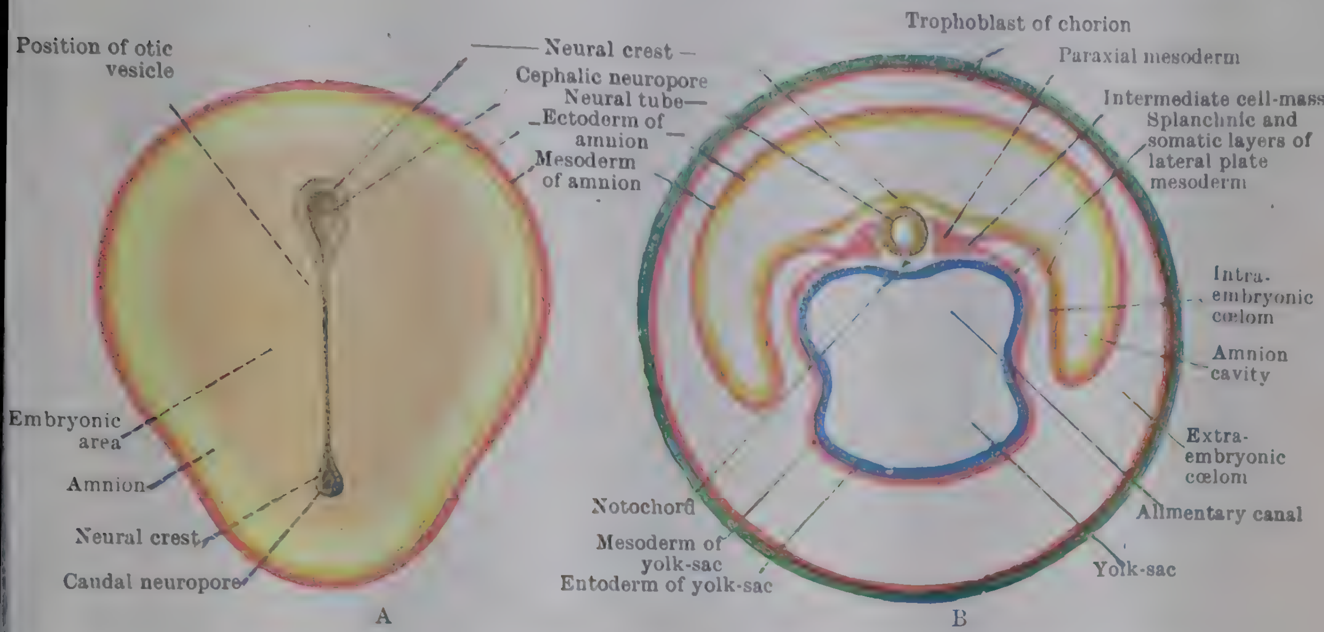

FIG. 65.—A. DIAGRAM OF EMBRYONIC AREA showing closure of neural groove with cephalic and caudal neuropores. Compare with surface view of embryo in Fig. 73 and with Figs. 115, 116.

B. CORRESPONDING TRANSVERSE SECTION; the neural tube has formed but has not separated from the surface ectoderm. The section also shows union of intra- and extra-embryonic parts of cœlom, paraxial bars, intermediate masses and lateral plates of mesoderm, with separation of lateral plates into somatic and splanchnic layers by the intra-embryonic part of the cœlom.

development distinct sheets of cells, each with its own part to play in the building-up of the embryo and its organs; they are therefore known as the primary **germ-**

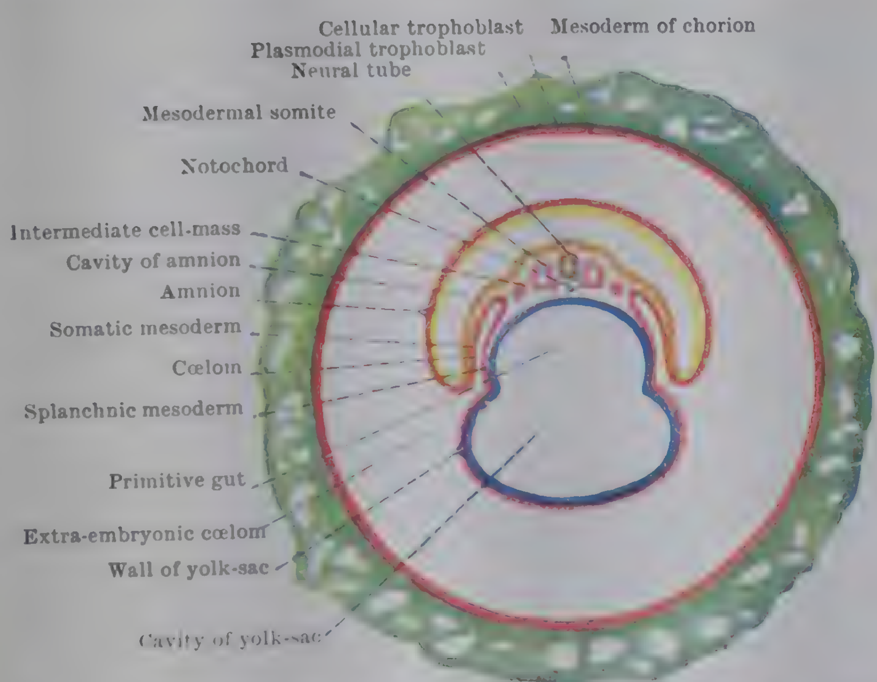

FIG. 66.—TRANSVERSE SECTION OF THE ZYGOTE SHOWN IN FIG. 73, showing the differentiation of the mesoderm.

layers. It must be emphasized, however, that the germ-layers are not independent elements in the structural organization of the embryo, or even completely specific: on the contrary, their interaction and co-operation are essential for normal development; and, since the destiny of their cells is partly due to their positions, they may even, under abnormal or experimental conditions, deputize for one another.

Before the description of the formation of the embryo and of the initial stages in the development of the principal organs, it is useful to summarize the

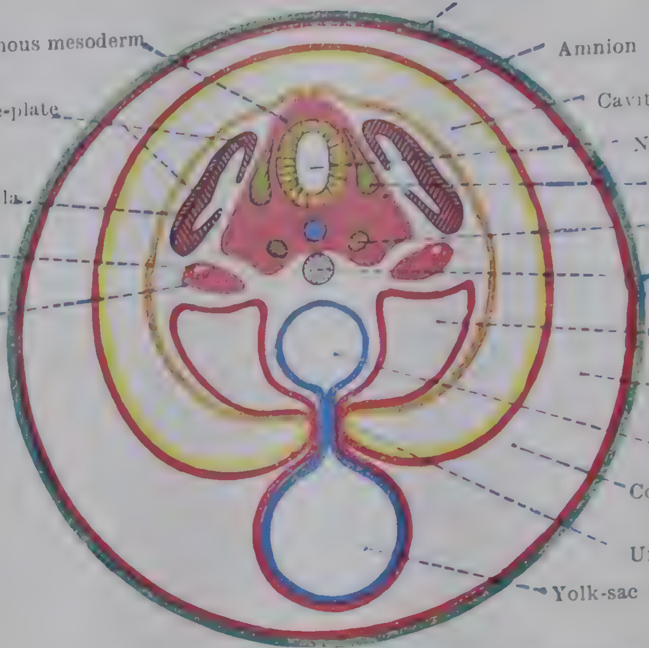

FIG. 67.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE, showing differentiation of mesoderm, formation of umbilicus, and ventral extension of amnion. The notochord is in the scleratogenous mesoderm between the neural tube and the aorta.

parts played by the three germ-layers. In general, it may be said that there is a functional distinction between them: thus, the *ectoderm*, the original external covering of the body, has a protective function, and, since it is in contact with the external environment, it is also the source of the essential elements of the sense-organs and of the whole of the nervous system; the *entoderm*, the original lining of the internal tube that becomes the alimentary and respiratory tracts, has digestive and absorbing functions; and the *mesoderm*, between the other two, gives origin to connective and muscular tissues, is the basis of the circulatory system, and provides for excretion and reproduction by means of the urogenital organs.

FIG. 68.—TRANSVERSE SECTION OF THE SAME YOUNG HUMAN EMBRYO AS IN FIGS. 56 AND 57. The neural plate in a shallow neural groove is seen on the surface of the embryonic area; beneath it is the notochordal plate in the roof of the yolk-sac. Note the commencing cœlomic spaces in the sheets of lateral mesoderm which are continuous with the thickened paraxial mesoderm and the mesoderm of the amnion and yolk-sac. (Embryo M'Intyre. Bryce, 1924.)

The following table, arranged in parallel columns for convenience of reference, gives some details of the derivatives of the germ-layers.

FORMATION OF THE EMBRYO

The transformation of the relatively flat embryonic area into the form of the embryo is due, in the first instance, to the rapid extension of the area compared with the slow growth of the immediately adjacent parts; and the later modelling of the various parts of the embryo is due to different rates of growth in different regions.

By the rapid proliferation of cells from the nodal growing-point at the cephalic end of the primitive streak, the surface length of the area is increased, whilst its cephalic and caudal ends remain relatively fixed; consequently the area becomes convex longitudinally. At the same time, the cephalic end of the neural groove is pushed away from the nodal point, so that it appears to rise out of the embryonic area and projects beyond its cephalic border. As a result of this movement the bucco-pharyngeal and the pericardial areas become reversed in position, and a **head-fold** is formed. This fold is bounded dorsally by what is now the head-portion of the embryo, and ventrally by the reversed pericardial region (Fig. 70).

The rapid growth at the nodal point not only produces a head-fold, but at the same time it forces the rest of the primitive streak over the caudal end of the embryonic area, thus forming a **tail-fold**.

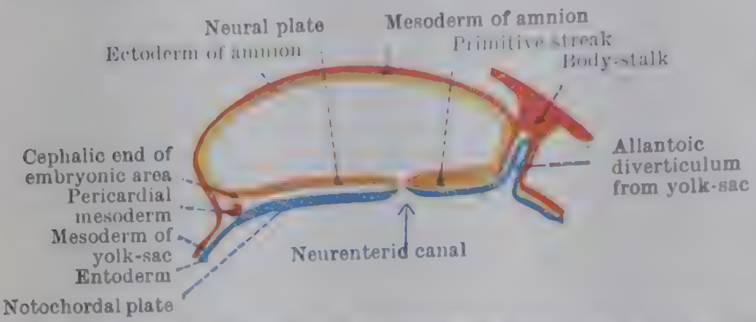

FIG. 69.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA AND AMNION BEFORE THE FOLDING OF THE AREA.

As the head-fold and the tail-fold are being produced by the longitudinal increase of the embryonic area, transverse growth of the area results in the formation of right and left **lateral folds** (Figs. 65, 66), and as the various folds are formed the embryo rises, like a mushroom, into the cavity of the amnion.

The portion of the entodermal sac which is enclosed within the embryo by the folding of the embryonic area is the **primitive entodermal alimentary canal.** The part which remains outside the embryo is the definitive **yolk-sac**; and the connecting passage between the two is the **vitello-intestinal duct** (Fig. 75).

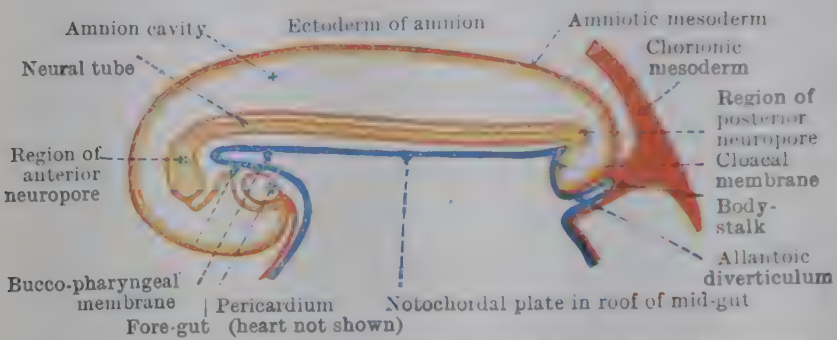

FIG. 70.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA SHORTLY AFTER THE FOLDING HAS BEGUN. The pericardial mesoderm is carried into the ventral wall of the fore-gut, and the cœlom has extended through it. The cephalic end of the neural tube and the caudal part of the primitive streak are bent ventrally, and the latter now forms the cloacal membrane.

That portion of the primitive alimentary canal which lies in the head-fold is termed the **fore-gut**, the part in the tail-fold is the **hind-gut**, and the middle portion, which at first is in open communication with the yolk-sac, is the **mid-gut**.

As the extension of the embryonic area and its folding proceed, the margin of the area, which remains relatively stationary, becomes the margin of an orifice through which the primitive alimentary canal of the embryo communicates with the yolk-sac, and the intra-embryonic part of the cœlom with the extra-embryonic part. That orifice is the **primitive umbilical orifice**. Around its margin the body-wall of the embryo, formed by the somatopleure, is continuous with the wall of the amnion.

The young embryo is connected also with the inner surface of the chorion by a band of tissue which is continuous with the caudal part of the wall of the amnion. The mesoderm in this region is thickened, and it contains in its interior the **allantoic diverticulum**, which is primarily derived from the entodermal sac (Fig. 70) but is afterwards connected with the hind-gut (Fig. 71): it contains also the blood-vessels that pass between the embryo and the chorion. This connecting band between embryo and chorion is generally called the **body-stalk**; but, since the entodermal diverticulum which it contains represents the mammalian **allantois**, it is also termed the allantoic stalk.

At first the umbilical orifice is relatively large, but as the embryo rapidly extends in all directions from its margins the orifice soon becomes relatively small. Ultimately the margins of the orifice fuse together, closing the opening and forming a cicatrix on the ventral wall of the abdomen known as the **umbilicus** or **navel**.

THE EMBRYO

While the embryonic area is being folded into the form of the embryo, the neural groove on the surface of the area is being converted into the neural tube. After the neural tube is completely closed and separated from the surface, during the fourth week, the embryo is an elongated organism, with a larger cephalic end and a smaller caudal end, attached by the body-stalk to the chorion. Its dorsal surface is continuous and unbroken, but its ventral surface is separated into cephalic and caudal portions by the umbilical orifice. It contains three cavities:—(1) The cavity of the neural tube; (2) the primitive alimentary canal, which is a portion of the entodermal vesicle constricted off during the folding of the embryonic area (Figs. 66, 67); (3) the embryonic cœlom.

The embryonic cœlom consists of a pericardial portion, which lies in a projection ventral to the fore-gut between the growing head and the umbilicus, and

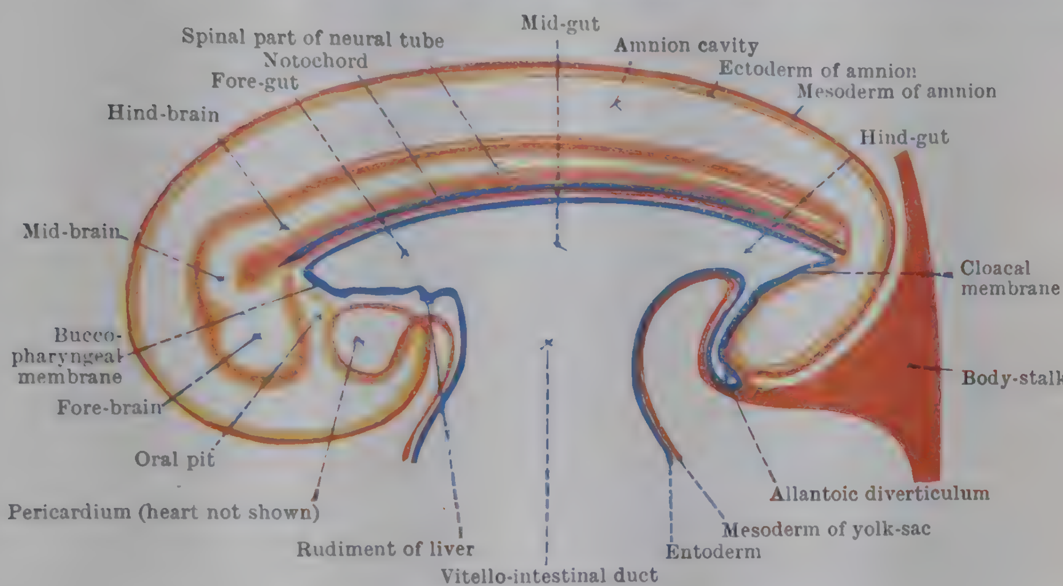

FIG. 71.—SCHEMA OF SAGITTAL SECTION OF EMBRYO AFTER THE FOLDING HAS DEFINED BOTH FORE-GUT AND HIND-GUT.

right and left lateral portions, which lie at the sides of the fore-gut, the mid-gut, and the hind-gut.

The right and left portions communicate with each other, ventral to the fore-gut, through the pericardial portion; at the sides of the mid-gut and ventral to the hind-gut, they communicate also with the extra-embryonic cœlom at the lateral and caudal margins of the umbilical orifice.

By this time the embryo has become easily distinguishable from the remainder of the zygote, and it is so far developed that indications of its general plan of organisation are discernible.

It has, as yet, no limbs, but the general contour of the head and body are defined. It possesses a primitive skeletal axis—the notochord—afterwards replaced by the permanent vertebral column. On the dorsal aspect of the notochord lies the neural tube, which is the rudiment of the brain and the spinal cord.

At the sides of the neural tube and the notochord are the mesodermal somites and the ganglia of the spinal nerves (Figs. 66, 67).

Ventral to the notochord is the primitive alimentary canal closed at its cephalic end by the **bucco-pharyngeal membrane**, and at its caudal end by the **cloacal membrane**; this was originally the caudal portion of the primitive streak, and it now separates the amniotic cavity from the caudal end of the hind-gut (Figs. 71, 75), which becomes the **entodermal cloaca** when the primary excretory (mesonephric) ducts open into it (p. 74).

At the sides of the primitive alimentary canal are the right and left parts of the cœlom, and between the dorsal angle of each half of the cœlom and

the mesodermal somites of the same side lies the intermediate cell-mass, which is the rudiment of the greater part of the urogenital system (Figs. 66, 67).

Ventral to the fore-gut is the pericardial mesoderm, thickening behind to form the *septum transversum* (pp. 71, 93) and traversed by the pericardial portion of the cœlom, which is connected dorsally, on each side, with the corresponding lateral portion of the cœlom; and ventral to the hind-gut is the cloacal membrane. Between the pericardial region at the one end and the cloacal membrane at the other is the umbilical orifice, through which the mid-gut communicates with the yolk-sac, the intra-embryonic part of the cœlom with the extra-embryonic cœlom, and the allantoic diverticulum with the cloaca (Figs. 66, 71).

The Limbs

For some time after its general form is well-defined the embryo is entirely devoid of limbs (Figs. 115-117). During the fifth week a slight ridge appears on each side, opposite the intermediate cell-mass in the interior. On this ridge the rudiments of the limbs—the **limb-buds**—are formed as secondary elevations (Fig. 72); the upper limb precedes the lower limb in time of appearance and in the development of its segments (Figs. 118-120). (See also p. 325.)

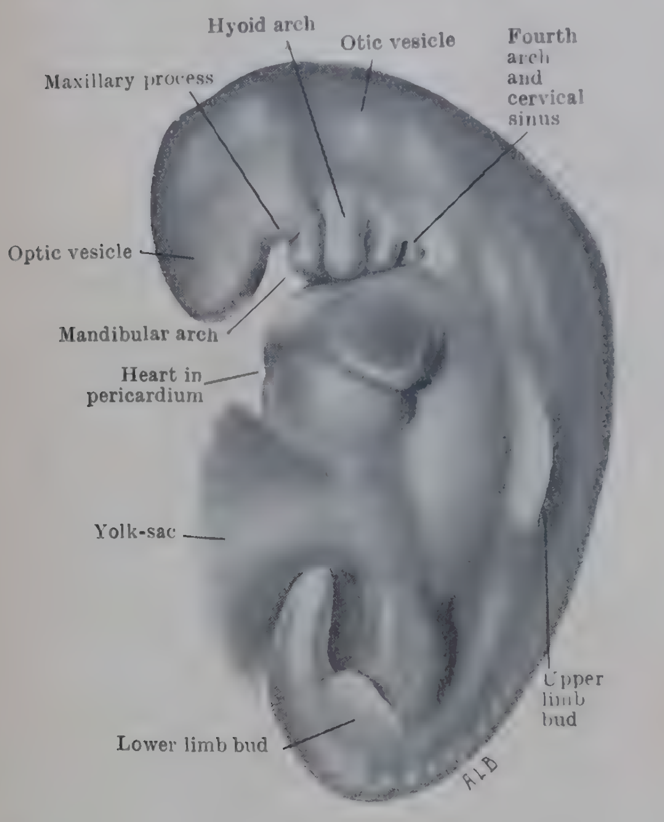

Fig. 72.—Human Embryo, 5·3 mm. long, to show the Development of the Limb-Buds. (After G. L. Streeter, *Carnegie Contrib. Embryol.*, Embryo No. 8066, 1945.) The rudiment of the Upper Limb, more advanced than that of the Lower Limb, appears as a longitudinal ridge on the side of the embryo.

Shortly after each limb-bud has appeared, it assumes a semilunar outline; it projects at right angles from the surface of the body, and it possesses dorsal and ventral surfaces, and cephalic or preaxial, and caudal or post-axial borders. The bud is the rudiment of the distal segment—hand or foot—of the future limb.

As the limb-rudiment increases in length the more proximal segments of the limb are differentiated. At the same time the limbs are folded ventrally, so that their original ventral surfaces become medial and their original dorsal surfaces lateral, and the convexities of the elbow and knee are directed laterally. At a later period, on account of a rotation which takes place in opposite directions in the two limbs, the convexity of the elbow is turned towards the caudal end of the body and that of the knee towards the head (Fig. 121).

The distal segment of each limb is, at first, a flat plate with a rounded margin, but it soon differentiates into a proximal or basal part and a more flattened marginal portion (Fig. 119). It is along the line where these two parts are continuous that the rudiments of the **digits** appear. They become evident as small elevations on the dorsal surface of the limb-bud about the sixth week; the ridges extend peripherally, and by the seventh week the fingers project beyond the margins of the hand-segment (Fig. 120), but the toes do not attain a corresponding stage of development until the early part of the eighth week (Fig. 121).

The **nails** are later developments, with finger-nails always in advance of toe-nails. They are apparent by the end of the third month but do not reach the ends

of the digits until the last month of fœtal life, a point which may be noted as a sign of maturity.

Each limb-bud is essentially an extension from a definite number of segments of the body. It consists, at first, of a core of mesenchyme covered with ectoderm. As it grows, the anterior primary rami of the spinal nerves of the corresponding segments are prolonged into it, together with a number of blood-vessels. The nerves remain as the nerves of the fully-developed limb, but the blood-vessels are reduced in number and are modified to form the permanent main trunks.

The mesenchymatous core of the primitive limb-rudiment is derived mainly from somatic mesoderm of the lateral plate. As the development proceeds it is differentiated into the cartilaginous and other connective tissue elements which are the rudiments of the skeletal framework and the fasciæ of the fully-formed limb.

The rudiments of the muscles of the limbs appear in the mesenchyme as **pre-muscle masses** which have no direct connection with the myotomes of the segments to which the limb-buds are related. There is evidence, however, that cells do migrate from the myotomes to mingle with the mesenchyme of the limbs; and in this way the myotomes may take part in the development of the limb-muscles which are innervated by the nerves of the segments to which they belong.

OUTLINE OF DEVELOPMENT OF NERVOUS SYSTEM

Early Stages of Development of Nervous System.—No definite trace of the nervous system is present until the primitive streak has appeared and the embryonic area has passed from a circular to a pear-shaped form. An area of thickened ectoderm, called the **neural plate**, then appears in the longitudinal axis of the cephalic half of the embryonic area. It begins to differentiate near the cephalic end of the area, and its caudal extremity embraces the nodal end of the primitive streak. Its margins fade into the surrounding ectoderm; but, while the plate lengthens with the elongation of the embryonic area, its margins are elevated by the thickening mesoderm beneath them, and so they become distinct.

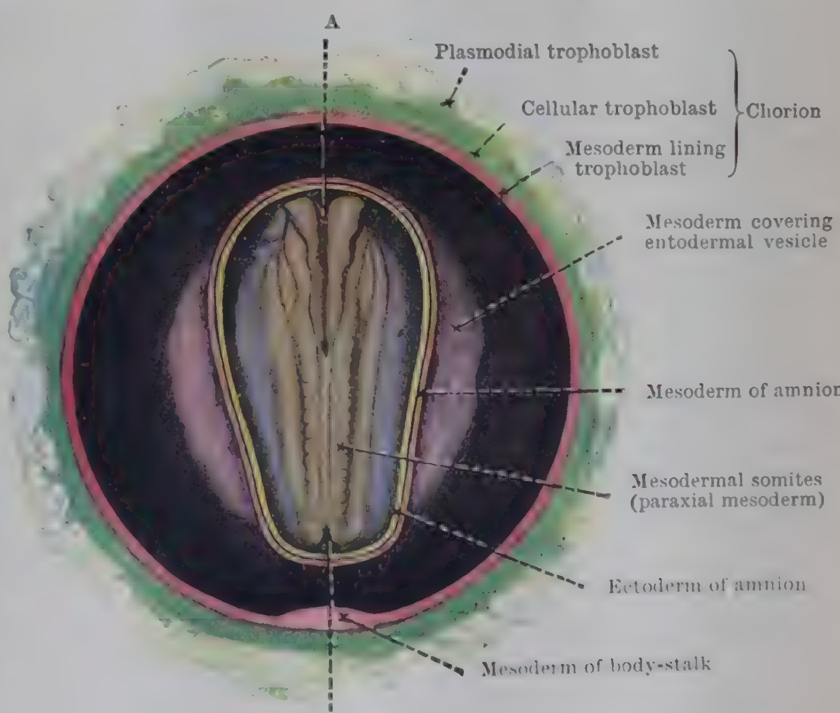

Fig. 73.—Schema of Dorsal Aspect of Embryo, showing partial closure of neural groove. For section along line A-A see Fig. 80. Portions of the chorion and amnion have been removed. The neural folds have fused, except in the cephalic and caudal regions; both the cephalic and the caudal ends of the embryo have been bent ventrally and thirteen mesodermal somites have been formed.

As the margins of the neural plate are raised the plate is necessarily folded longitudinally, and the sulcus so formed is called the **neural groove** (Figs. 60, 64, 114). Each half of the neural plate, as it is raised to form a lateral wall for the groove, is then named a **neural fold**. At a very early period the neural folds unite to form a cephalic boundary of the neural groove, and, a little later, they unite caudal to the neurenteric canal and across the primitive streak. After the neural groove is thus defined, the neural folds approach each other until they meet and fuse in the median plane, and the neural groove is converted into the **neural tube**. The ventral wall of the tube,

formed by the central part of the original neural plate, is called the *floor-plate*; the dorsal wall, formed by the union of the neural folds, is called the *roof-plate*, and it is soon separated from the surface-ectoderm.

The fusion of the margins of the neural folds to form the roof-plate begins in the cervical region, and from there it extends headwards and tailwards. The last parts of the roof-plate to be formed are, therefore, its cephalic and its caudal extremities; consequently, for a time, the **neural canal**, which is the cavity of the tube, opens on the surface at the two ends; the openings are called the **cephalic** and the **caudal neuropores** (Fig. 65 A). Eventually, however, about the third week of embryonic life, both apertures are closed and, for a time, the neural canal becomes a completely closed cavity.

Failure of union of the neural folds to form a closed neural canal may occur at any point but is commonest at the two ends, and it is the basis of gross malformations such as *anencephaly* and complete *spina bifida*. The union of the neural folds is an example of the process of 'embryonic healing' by which growing edges come together and unite to form a continuous structure—as in the case of the face and palate (pp. 63, 65), or to enclose a cavity—as in the case of the neural canal, or the lens of the eye (p. 60), or the otic vesicle (p. 67). Keith (1921) has emphasized the importance of this process, which he speaks of as the "healing of evolutionary wounds".

As the neural folds rise and approach each other their dorsal margins give rise on each side to a column of cells which comes to lie in the angle between the neural tube and the surface-ectoderm. This column is called the **neural crest** (Fig. 64).

The neural crest is the rudiment of the cranial and spinal nerve-ganglia, the sympathetic ganglia, the chromaffin cells of the chromaffin organs (medulla of suprarenal glands, etc.), and the primitive sheaths of the peripheral nerves; details will be found in the Section on the Peripheral Nervous System and also, in the case of the chromaffin organs, in the Section on the Ductless Glands (p. 809).

The neural tube becomes transformed into the brain and spinal cord, and the brain-portion gives origin also on each side to the essential part of the eye—the retina—and the optic nerve.

Differentiation of Neural Tube.—Before the neural groove is converted into a closed tube, an expansion of its cephalic part indicates the distinction between brain and spinal cord.

While the cerebral portion is still unclosed, three secondary dilatations of its walls indicate its separation into three sections—the primitive **fore-brain**, the **mid-brain**, and the **hind-brain** (Figs. 73-75, 85).

Shortly after the three segments of the brain are defined, and before it becomes a closed tube, a vesicular evagination forms at the cephalic end of each side-wall of the primitive fore-brain. These evaginations are the **primary optic vesicles**, and they are the rudiments of the **optic nerves**, the **retinæ**, and the **posterior epithelium of the ciliary body** and of the **iris**. As the optic vesicle approaches the surface of the head, the lens of the eye develops from the overlying ectoderm (p. 18), which thickens and forms a depression which is finally cut off from the surface by the union of its edges. The **lens-vesicle**, thus produced, is received into a depression in the optic vesicle which deepens until the vesicle is transformed into the **optic cup**. (For the development of the Eye, see the Section on the Organs of the Senses.)

When the cephalic portions of the neural folds meet and fuse dorsally the secondary dilatations become the primitive brain-vesicles, each vesicle possessing its own cavity and walls; but the cavities of the three vesicles are continuous with one another, and the cavity of the hind-brain is continuous with the central canal of the spinal part of the neural tube.

After the three brain-vesicles are formed, a diverticulum grows out from the cephalic end of the primitive fore-brain. This is the rudiment of the **secondary fore-brain**. It soon divides into right and left halves, which are the rudiments of the **cerebral hemispheres** of the adult brain.

After their formation the cerebral hemispheres expand rapidly in all directions. They soon overlap the primitive fore-brain and the mid-brain, and eventu-

lly the hind-brain also, and each gives off from the cephalic end of its ventral wall a tertiary vesicle—the **olfactory diverticulum**—which becomes converted, later, into the olfactory bulb and olfactory tract.

Flexures of Brain and Head (Figs. 72, 74, 85). In conformity with the general curvature of the embryo, but due mainly to the rapid, unequal growth of the three brain-vesicles, the head-region of the embryo bends ventrally as the brain develops. At first the curvature is continuous, but very soon it is accentuated opposite the mid-brain to form the **cephalic flexure**; the mid-brain, which remains relatively small, becomes the most prominent part of the head, and, as the flexure increases until its angle becomes quite acute, the fore-brain and the hind-brain approach each other until their ventral walls lie almost parallel.

At the same time a **cervical flexure** develops at the junction of the hind-brain with the spinal portion of the neural tube; it affects the whole head and keeps the facial region in close relation with the pericardium.

At a later stage the exuberant growth of the hind-brain causes that vesicle to bend in an opposite direction to the other flexures, so that its ventral wall forms a prominent convexity. This bend affects the brain only, and it is called the **pontine flexure** as it occurs in the region where the pons is formed.

The cervical flexure eventually disappears as the heart and pericardium descend into the thorax and the neck is formed; but the cephalic and pontine flexures have a permanent influence on the form of the brain.

(For details of the development of Brain and Spinal Cord, see the Section on the Central Nervous System.)

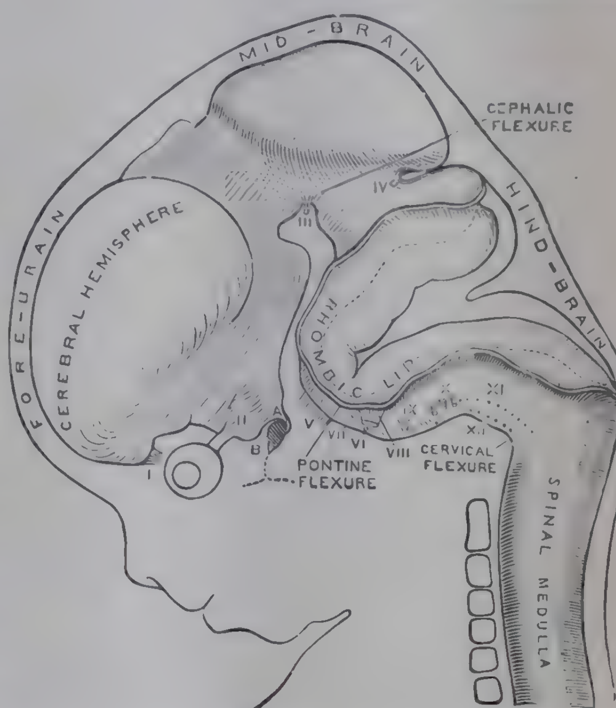

FIG. 74.—HEAD OF HUMAN EMBRYO OF 8 WEEKS TO SHOW THE PRIMARY PARTS OF THE BRAIN AND THE CEPHALIC, CERVICAL, AND PONTINE FLEXURES (His).

A, B, Cerebral and buccal rudiments of hypophysis cerebri. The cranial nerves are indicated by numerals.

Cavities and Meninges of Neural Tube.—The cavity of the spinal portion of the neural tube becomes the central canal of the spinal cord. The cavities of the primitive brain-vesicles are transformed into the ventricles, the interventricular foramina, and the aqueduct of the mid-brain. All these cavities are filled with *cerebrospinal fluid*, secreted by the *choroid plexuses* of blood-vessels which invaginate the thin wall of the ventricles at certain places.

The cavities of the developing cerebral hemispheres become the **right** and **left lateral ventricles** of the brain. The cavity of the central portion of the fore-brain becomes the **third ventricle**, and the Y-shaped aperture of communication between the third ventricle and the lateral ventricles is the **interventricular foramen**.

The cavity of the hind-brain vesicle becomes the **fourth ventricle**, and the cavity of the primitive mid-brain is converted into the **aqueduct of the mid-brain**, which connects the third ventricle with the fourth.

After the neuropores (p. 60) are closed, the cavity of the neural tube is, for a time, a completely enclosed space. Subsequently three membranous sheaths or *meninges* are developed around the tube; they are the **pia mater**, the **arachnoid mater**, and the **dura mater**. The dura mater, which is the outermost, is derived from the scleratogenous parts of the mesodermal somites; but the pia mater, which is the innermost, and the intervening arachnoid mater are possibly formed in part by ectodermal cells derived from the neural crest (Harvey *et al.* 1933).

As the meninges are differentiated narrow **subdural** and more extensive **subarachnoid spaces** are formed between them. After a time, the **median aperture of the fourth**

ventricle and a pair of **lateral apertures** appear in the dorsal wall of the fourth ventricle and in the pia mater which covers it, and thus the fourth ventricle becomes connected with the subarachnoid space. By these apertures, cerebro-spinal fluid passes into the subarachnoid spaces and a circulation is set up (p. 1003).

Early Development of Alimentary Canal and Formation of Oral and Anal Pits

The greater part of the permanent alimentary canal is derived from the entodermal vesicle and is therefore lined with entodermal cells. This part is enclosed in the embryo as it is folded off from the remainder of the zygote (Figs. 71, 80), but the two ends of the alimentary canal are formed by depressions of the surface of the embryo and are therefore lined with ectoderm.

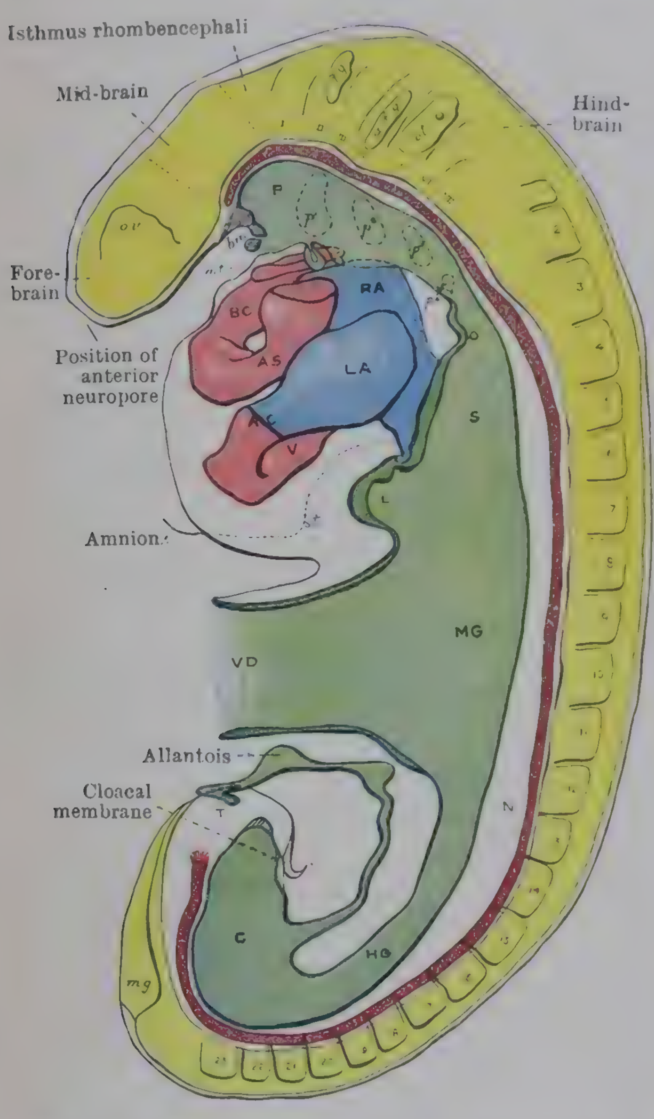

Fig. 75.—Reconstruction of Human Embryo, 2·5 mm. long, with Twenty-three Pairs of Somites. (Cf. Fig. 117, p. 98. (Thompson, 1907.)

The cephalic end of the alimentary canal is formed from a portion of a space called the **stomodæum** or **oral pit**, which lies, at first, between the ventrally-bent extremity of the head and the bulging pericardial region (Figs. 71, 75). When the oral pit first appears it is separated from the entodermal alimentary canal by the **bucco-pharyngeal membrane**, but when that septum disappears, during the fourth week, the oral pit communicates with the fore-gut. Later, it is separated into nasal and oral portions by the formation of the palate, and the oral portion forms that part of the mouth in which the gums and the teeth are developed.

The terminal portion of the permanent canal is formed by the elevation of a surface fold around a pit-like hollow called the **proctodæum** or **anal pit** (Fig. 88), which is separated from the blind end of the entodermal alimentary canal until about the eighth week by the **anal membrane**, which is a portion of the more extensive cloacal membrane mentioned on p. 57.

Derivatives of the Oral Pit.—When the oral pit is definitely established, it is bounded cranially by the bent, terminal part of the head, caudally by the conjoined ends of the **mandibular arches** (p. 66), and laterally by the **maxillary processes**, which grow ventrally from the dorsal parts of the mandibular arches. The space is open ventrally, and it is closed dorsally by the bucco-pharyngeal membrane until that membrane disappears (Fig. 75).

In the roof of the oral pit in front of the attachment of the bucco-pharyngeal

membrane there is a depression which is deepened by the growth of mesoderm around it so that it appears as a diverticulum of the roof. It is lined with ectoderm and is known as **Rathke's pouch**. The blind end of the pouch comes into relation with the hypophysial diverticulum from the floor of the third ventricle of the brain and dilates. The dilated part becomes the anterior lobe of the **hypophysis cerebri**

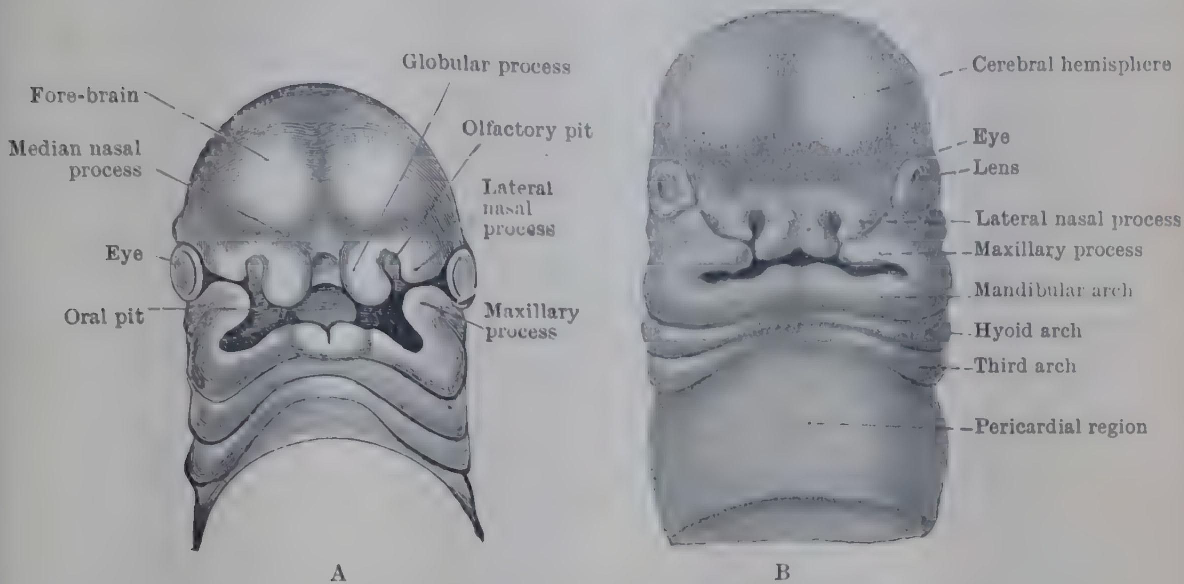

FIG. 76.—TWO STAGES IN DEVELOPMENT OF FACE. Cf. Fig. 1028, p. 1202.

B. COMPLETION OF UPPER LIP. Note the union of maxillary process with lateral and medial nasal processes to form cheek and upper lip.

or *pituitary body*; the rest disappears (Figs. 86-88). (For the development of the hypophysis, see the Section on the Ductless Glands.)

Development of Face and Separation of Nose and Mouth.—The frontal end of the head lies in the cephalic boundary of the oral pit and is called the **fronto-nasal process**. The upper part of the fronto-nasal process remains undivided and represents the region of the future forehead; but a pair of shallow depressions—the **olfactory pits**—divide the lower part into a *median nasal process* and a pair of *lateral nasal processes*; and a median groove divides the median process into right and left *globular processes* (Figs. 76 A, 1028, p. 1202). As the margins of these processes increase in height the olfactory pits deepen.

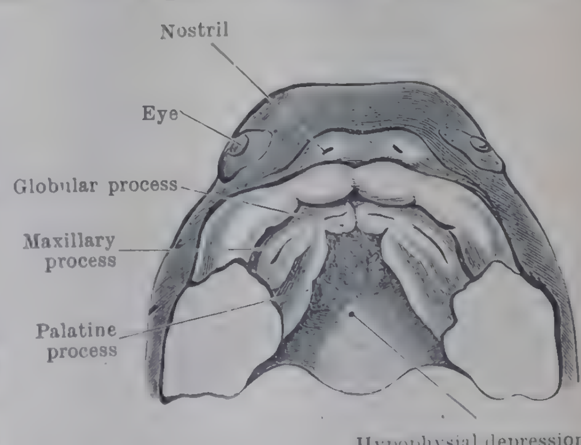

FIG. 77.—PORTION OF THE HEAD OF A HUMAN EMBRYO ABOUT 8 WEEKS OLD (His). The lips are separated from the gums, and the line of the dental lamina is visible in the gums. The palatine processes are growing inwards from the maxillary processes.

The lateral boundary of the oral pit is at first formed by the maxillary process springing from the dorsal part of the mandibular arch. As the maxillary process grows forwards it approaches the lateral nasal process, and the projecting eye is enclosed in the angle between them; and the groove between the two processes—the **naso-lacrimal sulcus**—leads downwards and forwards from the eye to the olfactory pit (Figs. 76 B, 1028).

As growth proceeds and each maxillary process grows ventrally, it fuses with the lateral nasal process along the line of the naso-lacrimal sulcus, and then, carrying the lateral nasal process with it, it fuses also with the globular process of the same side and overgrows it. The olfactory pits are thus completely separated, for a time, from the oral pit and they lie in the newly constituted ledge which now forms its boundary. This ledge consists of the two globular processes, fused into a

single mass, and the two maxillary processes—the lateral nasal processes being shut off from the margin of the ledge by the maxillary processes (Fig. 76 B).

Thus, the upper parts of the *cheeks* are formed by the maxillary processes and the *upper lip* by their fusion with the lower part of the median nasal process. At a later stage, the *maxillæ*—the bones of the upper jaw—are formed in the mesodermal core of these united processes; the *premaxillæ,* which ossify separately but in the human jaw unite with the maxillæ and are not seen on the surface (p. 234), are developed in the median nasal process. The lower parts of the cheeks and the *lower lip* are derived from the mandibular arch; the *aperture of the mouth,* which is at first wide, is gradually reduced by the progressive fusion of the maxillary processes with the mandibular arch.

FIG. 78.—CORONAL SECTION THROUGH THE NOSE AND MOUTH OF A 20 MM. HUMAN EMBRYO ABOUT 7½ WEEKS OLD (×28).

The *external nose* is developed from the nasal processes: the lateral nasal process forms the lateral part of the external nose, including the ala, and the prominence of the nose rises gradually from the root of the median nasal process where it blends with the forehead. The external openings of the olfactory pits become the *nostrils.*

Along the line of fusion of the maxillary and lateral nasal processes there remains a buried tract of ectodermal cells; it leads from the developing eye to the olfactory pit, and is the rudiment of the **naso-lacrimal duct** by which the tears are drained to the nasal cavity.

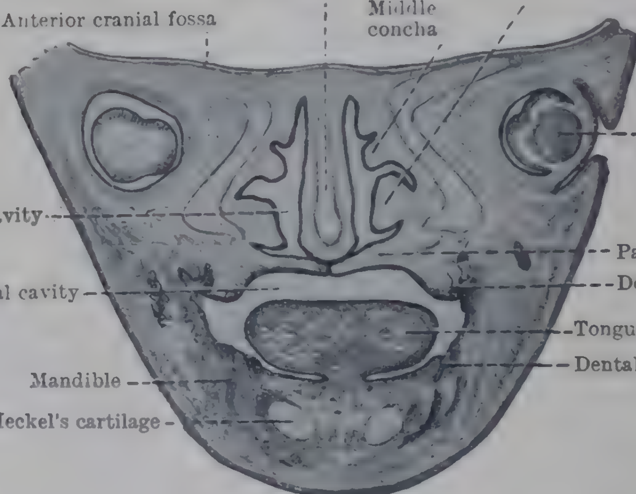

FIG. 79.—CORONAL SECTION THROUGH FACE OF HUMAN EMBRYO ABOUT 9 WEEKS OLD.

The olfactory pits at first are blind and are separated from the cavity of the oral pit by thin **bucco-nasal membranes**: but these soon disappear, and the olfactory pits then communicate directly with the cavity of the oral pit through openings which are called the **primitive posterior apertures of the nose.** The olfactory pits now form the **primitive nasal cavities**; they extend upwards and backwards excavating the roof of the main cavity of the oral pit on each side so that a median **nasal septum** appears between them.

After the formation of the primitive apertures of the nose a ledge grows from

the medial surface of each maxillary process towards the median plane. These ledges—the **palatine processes**—are separated for a while by the developing tongue, which rises from the floor of the primitive pharynx (Fig. 78), but they meet and fuse during the third month of intra-uterine life, the fusion beginning ventrally and being completed dorsally in the region of the uvula. In this way the palate is formed, and bone develops in the ventral portion of it and becomes the *hard palate*; the dorsal portion becomes the *soft palate*. The original oral cavity is thus separated into a cranial and a caudal portion. The cranial portion is the **nasal cavity**; it is divided into lateral halves as the palatine processes fuse also with the free edge of the nasal septum (Fig. 79). The caudal portion of the original cavity blends with the ventral part of the primitive pharynx. It forms the cavity of the vestibule of the mouth and from its walls the gums and teeth are developed.

The separation of the lips and cheeks from the gums and the development of the teeth and of the salivary glands are described in the Section on the Digestive System.

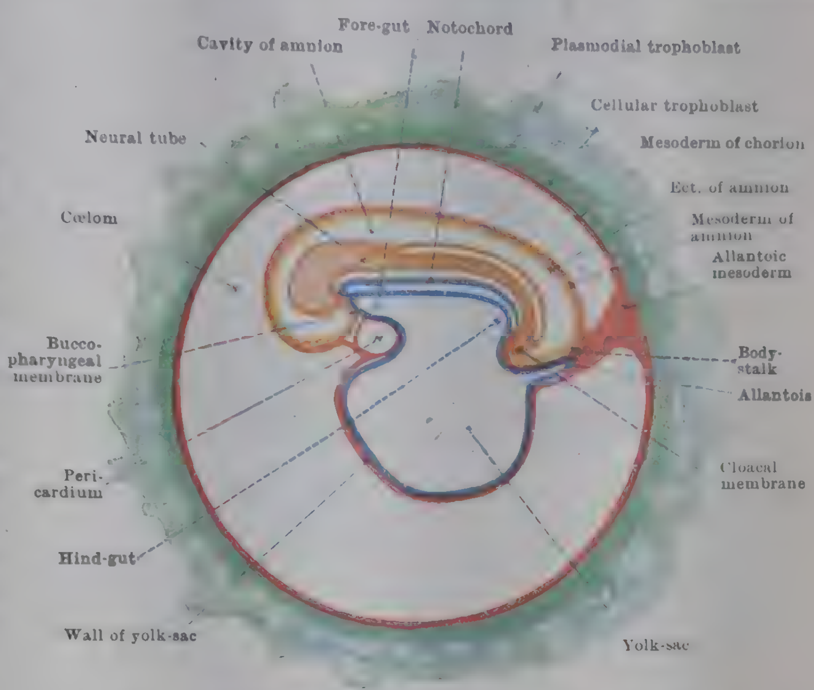

FIG. 80.—MEDIAN SECTION OF ZYGOTE SHOWN IN FIG. 73.

As in the case of the neural folds (p. 59), the union of the various elements from which the face and palate are formed takes place by a process of 'embryonic healing'; and failure of union causes a variety of malformations. The commonest are *hare-lip* and *cleft palate*, which often occur together. Hare-lip is due to failure of union of the maxillary and median nasal processes; it may occur on one or both sides; and, when it is double, the premaxillary part of the upper jaw is isolated and often develops into a projecting mass (Fig. 1201, p. 1467).

DIFFERENTIATION OF FORE-GUT

Derivatives of the Side-Wall.—While still separated from the oral pit by the bucco-pharyngeal membrane the cephalic part of the fore-gut, situated dorsal to the pericardium (Fig. 75), dilates to form the primitive pharynx, and thirteen depressions are formed in its walls. There are five in each side-wall called the **pharyngeal pouches**. There are two in its ventral wall: the first is the rudiment of the thyroid gland; and the other, situated more caudally, is the origin of the respiratory system and provides the epithelial lining of larynx, trachea, bronchi, and lungs. The thirteenth depression is called **Seessel's pouch**. It is formed in the dorsal wall, immediately caudal to the dorsal end of the bucco-pharyngeal membrane, and it extends into the floor of the primitive cranium (Fig. 86).

Simultaneously with the formation of the pharyngeal pouches internally a series of grooves appear externally. They correspond in position with the first four pharyngeal pouches, and they are called the **external pharyngeal grooves** (Figs. 72, 117). There is no external groove corresponding to the fifth pouch, which has a common opening into the pharynx with the fourth (Figs. 81, 83).

The pharyngeal pouches and the external grooves divide each side-wall of the primitive pharynx into a series of bars called the **pharyngeal arches**. The bars are five in number, but the fifth is distinctly visible only in the inner aspect of the pharynx.

Because of the obvious resemblance to the homologous parts in gill-breathing vertebrates, the formations described are often called **branchial** pouches, clefts, and arches.

The first pharyngeal bar is the rudiment of the maxillary and mandibular regions; it is called the **mandibular arch**. The second is the **hyoid arch**. The others are numbered as the third, fourth, and fifth arches. Each pharyngeal arch consists at first of simple mesoderm—covered externally by ectoderm, internally by entoderm—but a series of similar structures soon develop in them. Each arch then contains a cartilaginous skeleton, a muscle-rudiment, two nerves (main and subsidiary), and an artery. The cartilage of the first arch (Meckel's cartilage) is the forerunner of the *mandible* (p. 204); those of the second and third give rise to the *hyoid bone* (p. 207); those of the fourth and fifth arches belong to the *larynx* (p. 723). The arteries are the *aortic arches* which connect the ventral and dorsal aortæ (Fig. 106); the history of these vessels is mentioned on p. 91 and described with the Vascular System. The muscles and nerves of the arches are dealt with on p. 555 and with the Peripheral Nervous System.

When the arches first appear, they extend from the level of the dorsal wall

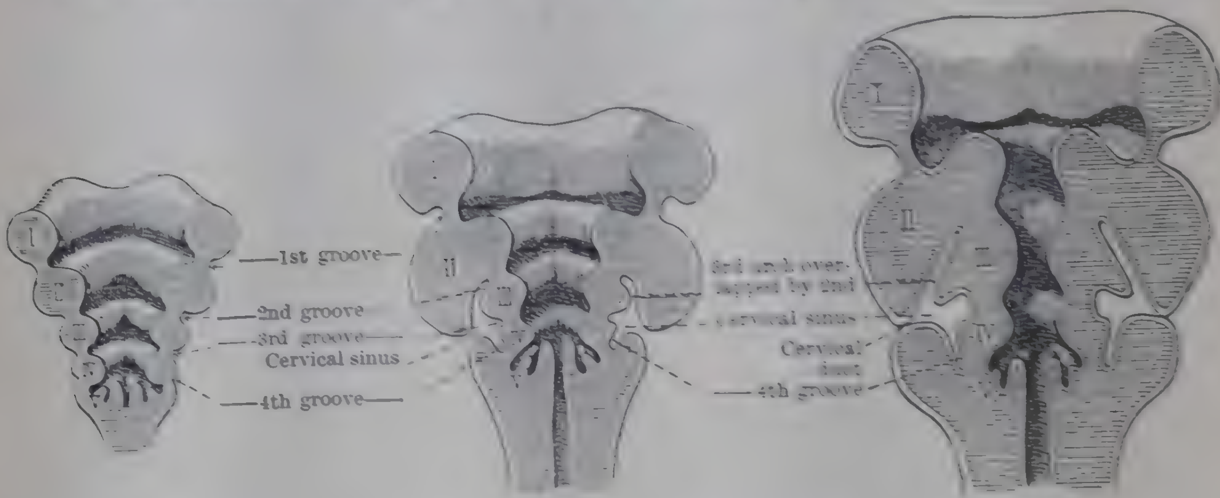

FIG. 81.—SCHEMA SHOWING FORMATION AND CLOSURE OF CERVICAL SINUS.

of the fore-gut to the pericardium; but as growth proceeds, and the neck is developed between the head and the pericardium, the ventral ends of the arches come to lie in the ventral wall of the primitive pharynx, though the mandibular arch is the only one that meets its fellow of the opposite side externally. The growth of the mandibular and the hyoid arches soon greatly exceeds that of the other arches, which gradually recede from the surface until, on each side, they lie at the bottom of a depression—the **cervical sinus**—overlapped by the caudal border of the hyoid arch (Figs. 81, 118). The increasing growth of the hyoid arch reduces the opening of the cervical sinus to a narrow channel called the *cervical duct*, but this is soon obliterated, and then the sinus becomes the *cervical vesicle*. The cervical vesicle lies at the side of the third pharyngeal groove, and it is associated with the second and fourth grooves by narrow canals called the 'branchial' ducts, which are the remains of the external pharyngeal grooves or 'branchial clefts'. Ultimately these submerged spaces (lined with ectoderm) are obliterated; but they may on occasion give rise to a *branchial cyst* or—if the communication with the exterior remains and a separating membrane (see below) breaks down—a *branchial fistula* (p. 811). There is some evidence that the ectoderm of the cervical vesicle comes into contact with the entoderm of the third pharyngeal pouch and takes part in the formation of the thymus (p. 811).

Frazer (1926) gives a different interpretation of the changes in this region. His observations show that the area of the cervical sinus is reduced to a triangular field by a ridge which limits it behind, and a ventral (epipericardial) ridge which separates the ventral ends of the arches from the pericardial swelling. These ridges contain pre-muscle cells passing forwards from the occipital myotomes to the developing tongue. The fourth arch is covered in by the growth of the posterior ridge, and the flattened third arch remains on the surface, so that the closure of the cervical sinus is only partial.

The portion of the wall of the primitive pharynx which lies between any two adjacent arches and separates the external groove from the internal pouch is called the **separating membrane**. In the earliest stages it consists of ectoderm and entoderm separated by mesenchyme; then the mesenchyme disappears, so that, for a time, the membranes consist of ectoderm and entoderm only. At a later period the ectoderm and entoderm are again separated by ingrowing mesoderm.

In gill-breathing animals the membranes break down so that *gill-clefts* are formed; but, except as a malformation, the separating membranes are never perforated in mammalian development, so that no complete 'cleft' ever exists.

The first external pharyngeal groove is the only one that is not submerged in the cervical sinus (Fig. 1028, p. 1202); it is the site of the formation of the **external auditory meatus**, and a series of tubercles which appear at its margins develop into the **auricle** of the external ear. In Man, as in other mammals, the organ of hearing consists of:—the **internal ear** or labyrinth; the **middle ear** or tympanum, which is connected to the pharynx by the **pharyngo-tympanic tube**; and the **external ear**, which includes the external auditory meatus and the auricle. The **tympanic cavity** and the **pharyngo-tympanic tube** are developed from a lateral extension of the upper part of the cavity of the primitive pharynx, between the first and third arches, which contains in its floor the second arch and parts of the first and second pouches; it is called the **tubo-tympanic recess** (Frazer, 1914). [A part of the cavity of the second pharyngeal pouch may be represented in the adult by the *intratonsillar cleft*, which passes into the upper part of the tonsil in the side-wall of the pharynx (Fig. 83).] The **tympanic membrane**, which separates the tympanic cavity from the external auditory meatus, is formed in the position of a 'separating membrane' between the tubo-tympanic recess and the first external groove. But it is a secondary formation, since the deeper part of the meatus is first formed by a solid plug of ectodermal cells which later breaks down in its centre to form the meatus.

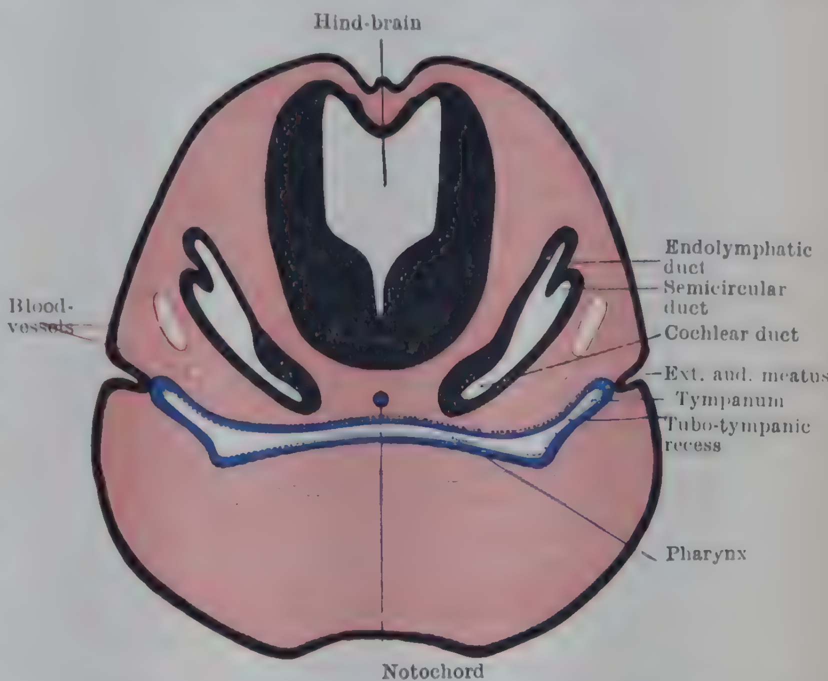

FIG. 82.—DIAGRAM OF TRANSVERSE SECTION THROUGH THE HEAD OF AN EMBRYO. Showing the rudiments of the three parts of the ear and their relation to the tubo-tympanic recess and the first pharyngeal groove.

The development of the conducting parts of the organ of hearing is thus intimately associated with the development of the primitive pharynx. Meanwhile, the essential part of the organ—which is concerned with the function of balancing the body as well as with the sense of hearing—has developed from the ectoderm of the side of the head in close relation to the hind brain and the 'auditory' (eighth cranial) nerve (Figs. 75, 85). The **otic vesicle**, formed by thickening and invagination of the ectoderm, becomes converted into the **membranous labyrinth** which includes the *utricle*, the *saccule*, and the three *semicircular ducts*, all concerned with equilibration, and the *duct of the cochlea* which contains the essential organ of hearing. But for the details of the development of the Ear the student must refer to the Section on the Organs of the Senses.

The third pharyngeal pouch opens, like the first and second, directly into the cavity of the fore-gut, but the communication is soon drawn out into a duct-like

passage; the fourth and fifth pouches lie in the side-wall of a common recess which opens by a single aperture or 'duct' into the cavity of the primitive pharynx (Fig. 83).

The cavities of the third, fourth, and fifth pouches ultimately disappear.

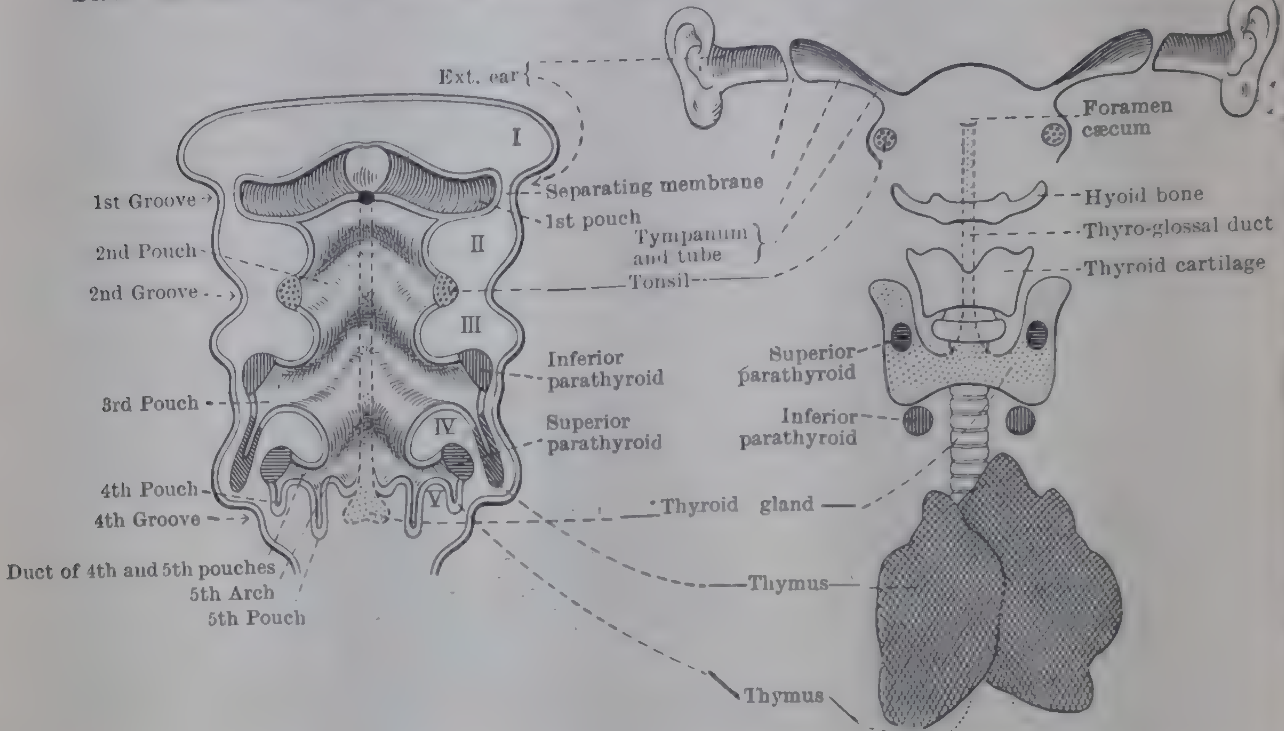

Fig. 83.—Schema showing the Pharyngeal Pouches, the External Pharyngeal Grooves, the Pharyngeal Arches and the Thyro-Glossal Duct and some of their Derivatives. I, II, III, IV, and V, the five arches. The cervical sinus is not represented.

Before they disappear a diverticulum, at first hollow but afterwards solid, grow from the ventro-lateral wall of each, and a solid **epithelial body** buds from the dorso-lateral wall of each of the third and fourth pouches (Fig. 83).

Organs derived from Pharyngeal Pouches.—The diverticula and the epithelial bodies of the third, fourth, and fifth pouches give rise to a series of important organs which belong to the 'ductless glands' of the body (Fig. 83). The

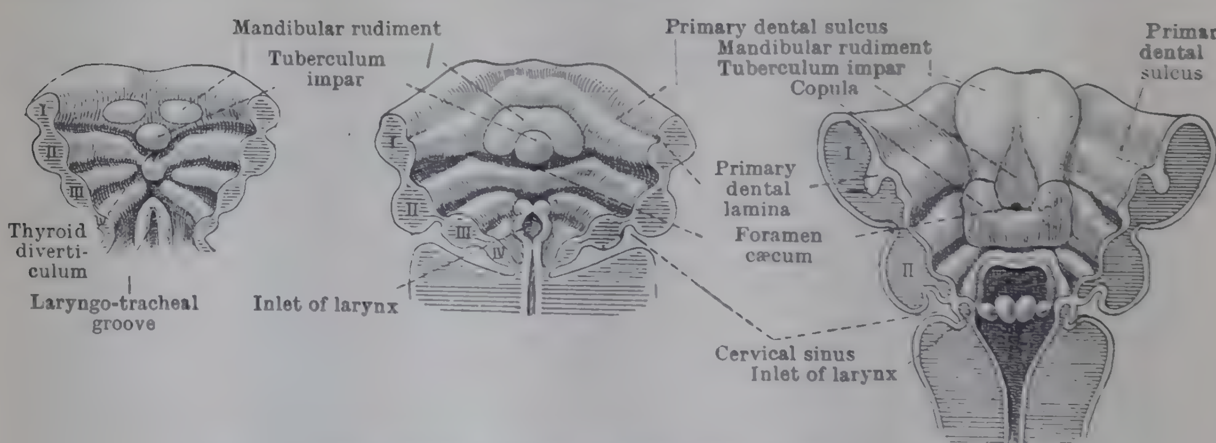

Fig. 84.—Schema showing Stages in the Development of the Tongue.

diverticula from the third and fourth pouches are concerned in the development of the **thymus**; and the epithelial bodies of the same pouches become the **parathyroid glands**. Changes in the situation of these organs occur as the heart in its pericardium moves caudally and the neck is formed; thus, the thymus extends into the thorax, and the parathyroids alter their relative position, the one derived from the third pouch being drawn down so that it comes to lie inferior to the other.

The diverticulum from the fifth pharyngeal pouch is transformed into the

ultimo-branchial body, which receives its name because it is the last of the series of organs derived from the branchial region of the pharynx. It is associated with the corresponding lobe of the thyroid gland and may contribute to its formation (Weller, 1933). The development of all these organs (including the thyroid gland) is dealt with in detail in the Section on the Ductless Glands.

Derivatives of Ventral Wall.—The main rudiment of the **thyroid gland** appears first as a diverticulum from the ventral wall of the primitive fore-gut. It begins in the median plane between the ventral ends of the mandibular and hyoid arches. It first grows ventrally into the substance of the neck, and then caudally, passing ventral to the cartilage bars which appear in the second, third,

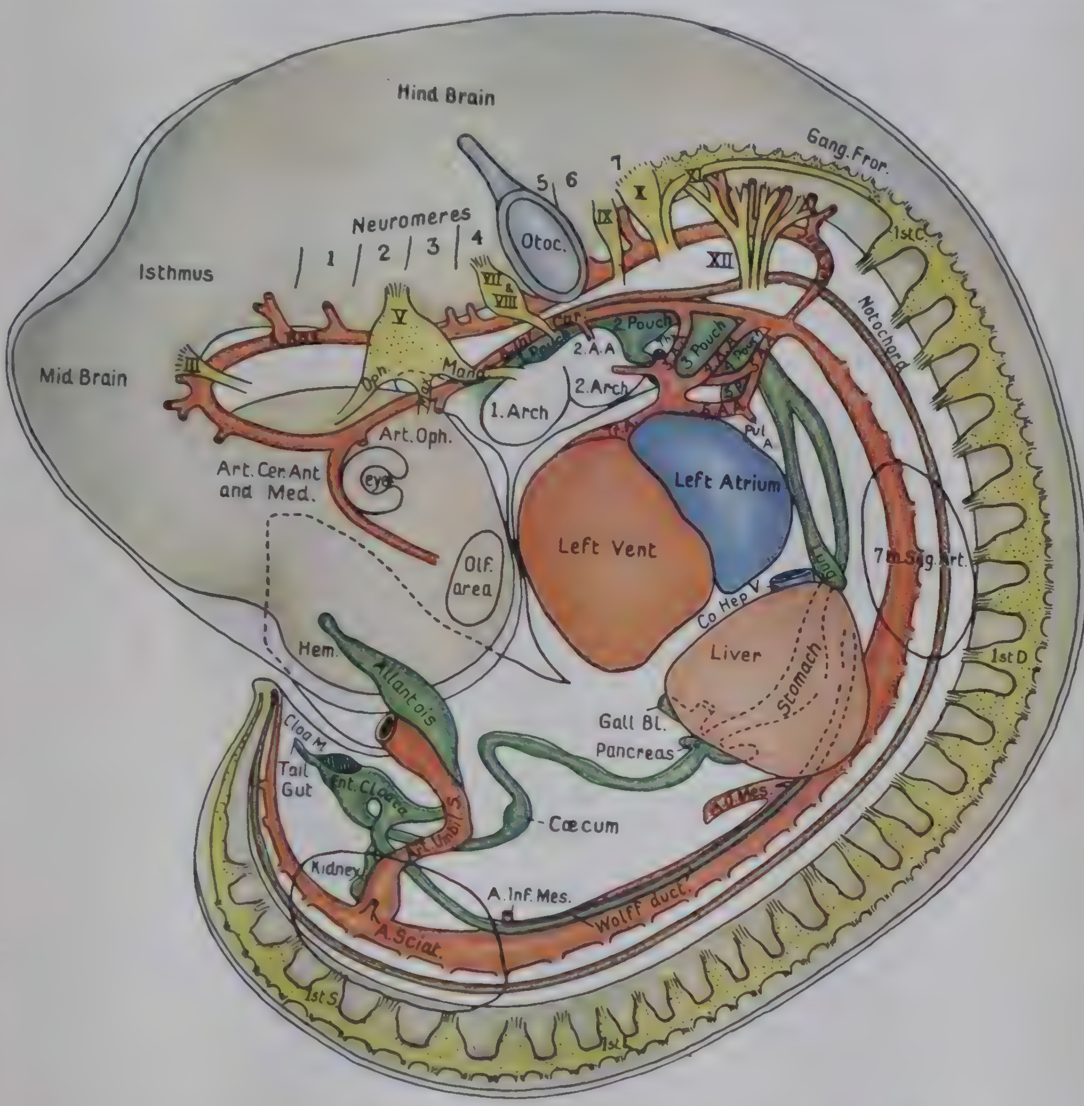

FIG. 85.—RECONSTRUCTION OF HUMAN EMBRYO, 7 mm. long. (Peter Thompson, *Studies in Anatomy*, University of Birmingham, 1915.) Cf. Fig. 75 and subsequent figs. showing differentiation of the alimentary canal. *1st D*, 1st thoracic ganglion; *Co. Hep. V.*, Common hepatic vein; *Gang. Fror.*, Froriep's ganglion (XII); *Hem.*, cerebral hemisphere; *Otoc.*, otic vesicle; *Wolff. duct*, mesonephric duct.

and fourth arches and are developed into the hyoid bone and the cartilages of the larynx. When the caudal end of the diverticulum reaches the level of the origin of the trachea it becomes bilobed, and is thus differentiated into the isthmus and the adjacent parts of the two lobes of the permanent gland (Fig. 83). The stalk of the diverticulum is the **thyro-glossal duct**; the position of its original upper end is indicated by the **foramen cæcum** of the tongue. The caudal end of the stalk sometimes persists and is transformed into the *pyramidal lobe of the thyroid* gland, and persistence of other parts of the duct may give rise, at any point between the gland and the tongue, to swellings known as *thyro-glossal cysts*.

Respiratory System.—A more caudally situated diverticulum from the ventral wall of the fore-gut is the rudiment of **the respiratory system** (Figs. 84, 86). It first appears behind the developing tongue as a longitudinal groove bounded at

its cranial end and on each side by a ∩-shaped ridge (Fig. 84). The caudal end of this **laryngo-tracheal groove** soon dilates into a pouch. Then the pouch and groove are separated from the more dorsal part of the fore-gut, which becomes the *œsophagus*, by a constriction which passes from the caudal towards the cranial end. The constricting process ceases before the separation reaches the cranial end of the respiratory rudiment, which therefore remains in communication with the pharynx and forms the permanent *inlet of the larynx*. As the groove is separated from the primitive fore-gut it is converted into a tube which is gradually differentiated into the *larynx* and the *trachea*. The pouch at the caudal end of the tube soon divides into right and left lobes, each of which is the rudiment of the epithelium lining the bronchi and lung of the corresponding side.

The Tongue.—The mucous membrane of the tongue is formed by *four separate rudiments* which appear in the ventral wall of the primitive pharynx. Two of these are elevations formed on the ventral ends of the mandibular arches. The third is a median elevation, called the **tuberculum impar**, which is situated immediately caudal to the conjoined ventral ends of the mandibular arches. The

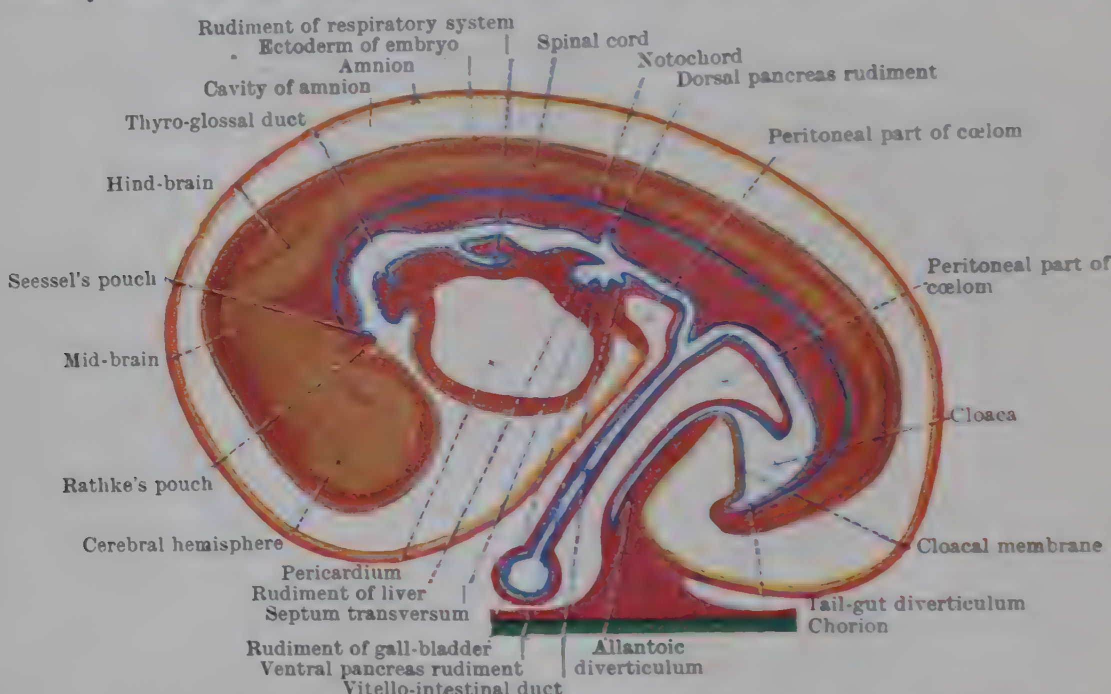

FIG. 86.—SCHEMA OF SAGITTAL SECTION OF 5 MM. EMBRYO (about 5 weeks old), showing dorsal and ventral diverticula of alimentary canal. The heart is not shown. (After Mall, modified.)

fourth rudiment, the **copula** of His, so called because it is formed by the conjoined ventral ends of the second and third pairs of arches, is separated from the tuberculum impar by the orifice of the thyroid rudiment (Fig. 84).

The elevations on the mandibular arches submerge the tuberculum impar and unite to form the greater part of the anterior two-thirds of the tongue—the part on which all the papillæ are developed. The posterior third of the tongue, which lies in the ventral or anterior wall of the permanent pharynx, is formed by a V-shaped swelling which rises from the copula and blends with the anterior two-thirds along the line of the *sulcus terminalis*. The foramen cæcum is a depression left in the median plane at the junction of the two parts of the tongue, and it therefore indicates the site of origin of the thyroid gland.

Derivative of Dorsal Wall.—The only dorsal diverticulum from the cranial part of the fore-gut is **Seessel's pouch**, which is formed immediately behind the dorsal attachment of the bucco-pharyngeal membrane (Fig. 86). The ultimate fate of the pouch in human development is uncertain, but it may be represented by a depression, known as the *pharyngeal bursa*, in the naso-pharyngeal tonsil, which is situated in the nasal part of the pharynx (p. 589 and Fig. 502).

Abdominal Portion of Fore-Gut.—The portion of the fore-gut that has now been considered gives rise to the lower part of the mouth (with the exception of

the lips, teeth, and gums) the pharynx, the thyroid gland, the thymus, the parathyroid glands, the respiratory organs, and the œsophagus. The œsophagus extends through the part of the embryo that will become the thoracic region of the body, and the remainder of the fore-gut is situated in the upper part of the abdominal region. The abdominal portion of the fore-gut is differentiated into the **stomach** and the first and second parts of the **duodenum**, and from it the liver and pancreas take origin as outgrowths.

In that region it is attached to the posterior wall by that part of the general dorsal mesentery of the gut (splanchnopleure) known as the *dorsal mesogastrium* because its main attachment is to the stomach. It lies dorsal to the *septum transversum*—the mesodermal partition continuous with the caudal wall of the pericardium (Fig. 86)—from which a *ventral mesogastrium* will be separated as the liver grows into it (p. 95).

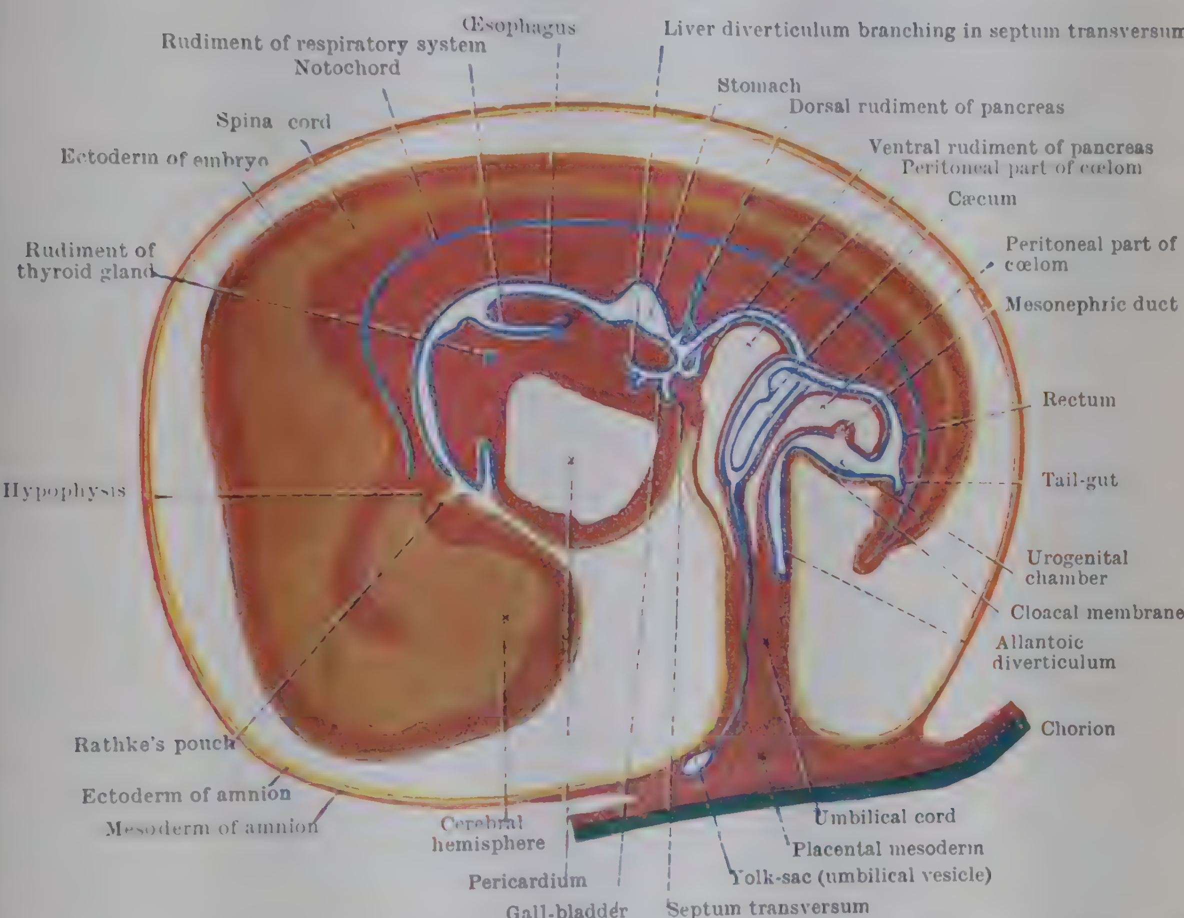

Fig. 87.—Schema of Sagittal Section of 10 mm. Embryo (about 6 weeks old), showing further stages in the development of the diverticula from the primitive gut and rotation of the mid-gut loop in which the rudiment of the cæcum has appeared. Note the passage of the gut into the umbilical cœlom. The heart is not shown. (After Mall, modified.)

Liver and Pancreas.—When the embryo is about four weeks old and has attained a length of 2·5 mm. a diverticulum appears in the angle between the widely open vitello-intestinal duct and the ventral wall of the fore-gut (Fig. 75) and grows into the septum transversum (Fig. 79); and when the length of the embryo has increased to about 4 mm. another diverticulum is formed in the dorsal wall of the duodenal part of the fore-gut a little nearer the stomach. The ventral pouch is the rudiment of the *liver*, the *gall-bladder*, the *bile-ducts*, and a portion of the *pancreas*. The remainder of the pancreas is formed from the dorsal diverticulum (Figs. 86, 87).

The further development of these organs and of the parts derived from the mid-gut and hind-gut, mentioned in the following outline, is considered in the Section on the Digestive System.

Differentiation of Mid-Gut and Hind-Gut

Derivatives of Mid-Gut.—The mid-gut is that part of the primitive alimentary tract which is in free communication with the yolk-sac by the vitello-intestinal duct. It is transformed into the greater part of the **small intestine** (from the entrance of the bile-duct into the duodenum to the end of the ileum) and part of the large intestine (cæcum and appendix, ascending colon and most of the transverse colon).

Derivatives of Hind-Gut.—The parts formed from the hind-gut are: (1) The remainder of the large intestine, except a small portion of the anal canal; (2) the urachus and part of the urinary bladder; (3) the urethra in the female, and part of the urethra in the male.

As development proceeds, the mid-gut forms a U-shaped tube with cephalic and caudal limbs, and a ventral knuckle which points towards the umbilical orifice, through which it remains connected with the yolk-sac by the narrowed and elongated **vitello-intestinal duct** (Fig. 86).

In embryos about 8 or 9 mm. long (between five and six weeks old) there appears about the middle of the caudal limb of the loop an enlargement which is the rudiment of the **cæcum** and **vermiform appendix**, thus demarcating the large intestine from the small.

But before this rudiment appears rotation of the loop has begun, and the growth of other structures in the abdomen, especially of the liver, is relatively so great that there is not sufficient room for the developing intestines. When the embryo is between 5 and 8 mm. long, the loop begins to pass out through the umbilical orifice into an **umbilical sac** which has been formed in the umbilical cord by the enclosure of part of the extra-embryonic cœlom (cf. Figs. 86, 87, 88).

As the loop enters this sac its limbs lie already side by side—the cephalic limb on the right, the caudal on the left—and there it remains for a considerable time while a further stage of its rotation and further development take place.

The chief change that now occurs is the rapid elongation of the part of the loop (mainly the cephalic limb) that becomes small intestine, which is thrown into the numerous coils of the **jejunum** and **ileum**. The vitello-intestinal duct has meanwhile separated from the loop and disappeared, leaving the coiling gut free in the umbilical sac. With the duct there goes also the part of the vitelline artery which ran along it to the yolk-sac—the embryonic part of that artery remaining in the mesentery of the loop as the *superior mesenteric artery*, which thus supplies both small and large intestine.

As the intestines return into the abdomen the last stage of the rotation of the loop occurs. The rotation as a whole is usually described as taking place round the superior mesenteric artery as an axis; and it is now completed by the passage of the caudal limb of the loop to the right in front of the trunk of tha artery and in front of the coils of small intestine derived from the cephalic limbt so that the cæcum—the last part to leave the umbilical sac—comes to lie immed,iately below the right lobe of the liver.

Subsequently, certain parts of the large intestine are fixed in their permanent positions by peritoneal adhesions. The **ascending colon** and the **transverse colon** are derived from the distal part of the caudal limb of the loop, whilst the proximal part of the hind-gut is transformed within the abdomen into the **descending colon** and the **pelvic colon**. The developing intestines remain in the umbilical sac until the embryo is about 40 mm. long and about ten weeks old, when they return rather suddenly to the abdomen, in which room is obtained by reduction in the rate of growth and therefore in the relative size of the liver (Frazer & Robbins, 1915); after the return of the intestines to the abdomen the cœlomic space in the umbilical cord is obliterated.

Occasionally the site of attachment of the vitello-intestinal duct is indicated by the persistence of a portion of it as a *diverticulum of the ileum* (Meckel's diverticulum) not far from the cæcum. This diverticulum may rarely be attached to the back of the umbilicus by a fibrous thread; such a thread, from the distal small intestine to the umbilicus and continuous with the end of the superior mesenteric artery, is normally present in many new-born animals (*e.g.*, cats).

The umbilical sac and its communication with the peritoneal cavity may fail to close; and the child may then be born with the malformation of the abdominal wall known as *congenital umbilical hernia*. The developmental extrusion of the intestines from the abdomen of the embryo is so striking a phenomenon that it is often called the 'normal umbilical hernia'.

Development of Caudal Part of Hind-Gut.—When the hind-gut is first enclosed, its blind end and its ventral wall are bounded by the caudal portion

FIG. 88.—SCHEMA OF 25 MM. EMBRYO (about 8 weeks old), showing complete separation of cloaca into dorsal and ventral parts and the temporary ventral hernia of a portion of the gut through the umbilical orifice. The heart is not shown. (After Mall, modified.)

of the primitive streak—the **cloacal membrane**—which is bent ventrally during the folding-off of the embryo (Fig. 86).

The terminal part of this portion of the gut becomes expanded to form a chamber called the **entodermal cloaca**, because the entrance of the **mesonephric ducts** from the primitive kidneys which open into it, one on each side, recalls the permanent *cloaca* of the lower vertebrates.

The ventral part of the cephalic end of the cloaca is continuous with the allantoic diverticulum, and the dorsal part with that portion of the hind-gut which forms the descending colon and the pelvic colon.

As the temporary tail is formed and turned ventrally by the growth energy of the nodal point situated at the caudal end of the neural tube, a diverticulum of the caudal end of the dorsal part of the cloaca is prolonged into it, forming the **tail-gut.** This soon becomes shut off from the cloaca. It entirely disappears before the temporary tail is absorbed into the caudal end of the body (Figs. 86-88).

At a later period the cloaca itself is divided by a septum into a dorsal part which become the **rectum**, and a ventral part called the **urogenital chamber** (Figs. 88 and 672, p. 791). The septum begins in the angle between the allantoic diverticulum and the ventral wall of the hind-gut, and grows towards the surface till it reaches and fuses with the cloacal membrane; the membrane is thus separated into urogenital and anal portions, both of which disappear about the eighth week.

In both sexes the urogenital chamber is separable into three portions: (1) a cephalic portion called the **urachus**, which is continuous with the remnant of the allantois and becomes the *median umbilical ligament*; (2) a middle portion, which becomes the greater part of the *urinary bladder*; and (3) a caudal portion, known as the **urogenital sinus**, which becomes the *urethra* and the *vestibule of the vagina* in the female and part of the *urethra* in the male.

Urogenital System.—It has been noted (p. 51) that the greater part of the urogenital system is derived from the intermediate cell-mass of the mesoderm; that includes the series of excretory organs known as the **pronephros**, the **mesonephros**, and the **metanephros**—the last forming the permanent *kidney*—and the two primary ducts, the **mesonephric** and **para-mesonephric ducts**, which have a different fate in the two sexes. The history of these ducts and their relation to the urogenital part of the cloaca, with details of the development of the urogenital chamber itself, of the sex-glands from the genital ridge and of the external genital organs will be found in the full account of the development of the Urogenital System in the appropriate Section.

Derivative of Anal Pit.—The anal pit is a surface depression which owes its origin to the elevation of the surface around the margin of the anal portion of the cloacal membrane (Fig. 88). It forms the lowest portion of the **anal canal** of the adult.

FŒTAL MEMBRANES AND PLACENTA

Nutrition and Protection of Embryo.—While the zygote is passing along the uterine tube, and for a brief period after it enters the uterus—until the oolemma disintegrates and the blastula stage is reached—it depends for its nutrition upon the metaplasmic granules originally stored in the ovum.

As the human ovum is small, and as it contains but little metaplasm, there is urgent necessity for an external source of nutritive supply, and of oxygen for tissue respiration, and for provision for the removal of waste-products of its metabolism. It is probable that the naked morula obtains some food-material from the uterine secretions as well as the fluid essential for transformation into a blastula; but development cannot proceed beyond that stage until an intimate connexion between the zygote and the uterus is established by the critical operation of *implantation* or *embedding* in the endometrium.

That process, by which the trophoblastic covering of the sac within which the embryo develops and grows comes into direct contact with the maternal blood, is associated with the early development of a primitive heart and blood-vessels by means of which materials are carried to and from the embryo; but the details of the establishment of the embryonic circulation, which is related primarily to the yolk-sac and the placental area of the chorion, cannot be understood until the formation and arrangement of the *fœtal membranes* have been considered.

These important structures—the chorion, the amnion, the yolk-sac, and the allantois—have necessarily been named in describing the early stages of development, and it is convenient now to consider them together, noting their significance and functions, before the process of implantation and the development and structure of the placenta are described. The fœtal membranes are indeed intimately related to each other, and they are all, including the placenta, ultimately attached to the embryo by the umbilical cord, and are separated from it when the cord is severed.

Evolution of Fœtal Membranes.—The fœtal membranes are specialized portions of the somatopleure and splanchnopleure (p. 50) of the vertebrate embryo. In other words, parts of the original body-wall (amnion and chorion) and parts of the original gut (yolk-sac and allantois) are set aside to provide organs that adapt the embryo and fœtus to its temporary environment. These organs are extra-embryonic structures concerned with protection, nutrition, respiration, and excretion; and the manner in which they perform these functions, as well as the details of their arrangement, differs in different groups of animals. The four membranes are found only in the higher classes of vertebrates—the reptiles, the birds, and the mammals—whose embryos develop either within an egg-shell or within the body of the mother. Since they all possess the characteristic protective membrane called the amnion, the reptiles, birds, and mammals are grouped together as the *Amniota*.

The **amnion** provides a cavity full of fluid in which the embryo may develop under conditions which resemble the watery environment of the embryos of lower vertebrates—the amnion has been called a 'private pond'. Its mode of formation (Fig. 89, B, C, D) implies another external covering—the **chorion**—which is the remaining part of the extra-embryonic somatopleure.

The embryos of fishes and amphibia do not require an amnion, since for the most part they hatch from the egg and develop in water; and the only 'fœtal membrane' they possess is a yolk-sac which contains enough food-material for the initial stages of development. All the

Amniota also possess a **yolk-sac**, and in the embryos of all those that are oviparous—including the lowest group of mammals (the monotremes)—it is filled with food-material. Although the yolk-sac ceases to have any importance as a food-store in the viviparous mammals, including Man, it is retained in them because of its intimate relation to the development of the gut and also because the earliest blood-vessels are formed in its wall (Fig. 101).

The fourth membrane—the **allantois**—is as characteristic of the *Amniota* as the amnion itself; and it has a very remarkable history. It grows out as a diverticulum from the ventral wall of the hind-gut (Fig. 90), and in reptiles and birds it serves primarily as a urinary bladder for the embryo; its relation to the gut is exactly the same as that of the permanent urinary bladder of the amphibia, with which it is probably homologous. But the allantois in these animals, as it increases in size, comes into contact with the chorion and fuses with it to form a combined membrane which lines the inside of the egg-shell. This membrane, in virtue of the blood-vessels it contains, provides for the respiration of the embryo by gaseous exchange through the porous shell between the air and the blood. Thus, the allantois of oviparous animals comes secondarily, through fusion of its wall with the chorion, to act functionally as an embryonic

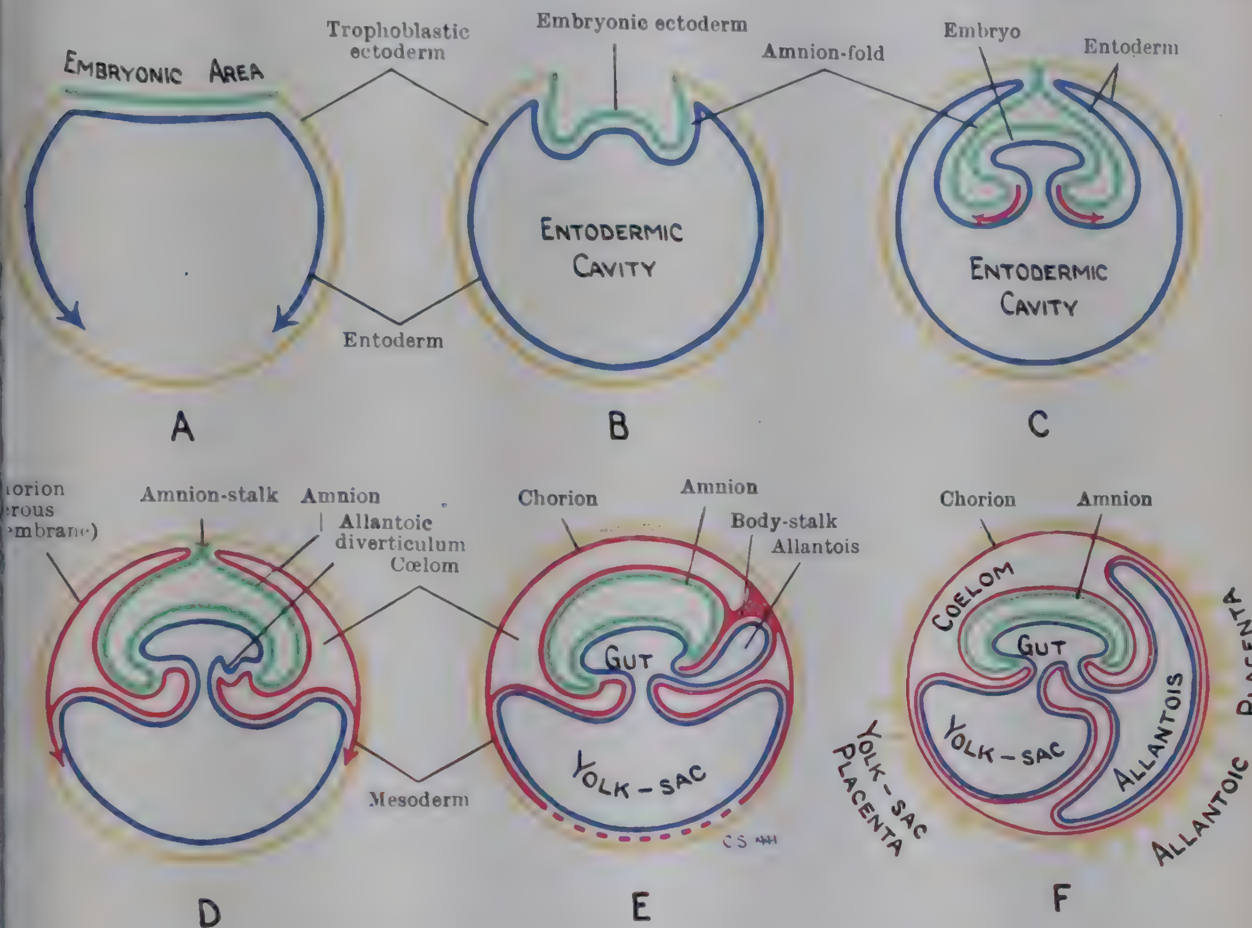

FIG. 89.—DIAGRAMS OF STAGES IN THE EVOLUTION OF THE FŒTAL MEMBRANES. (Adapted from Graham Kerr's *Text-Book of Embryology: Vertebrata*. Macmillan & Co.)

For detailed explanation, see text. Yellow = trophoblastic ectoderm; green = amniotic and embryonic ectoderm; blue = entoderm; red = mesoderm.

"lung". In most viviparous mammals the chorion is vascularized in the same manner by blood-vessels carried to it by the allantois and is thus enabled likewise to act as a respiratory membrane; but in this case the exchange of oxygen and carbon dioxide is not with the air but with the blood of the mother; and, in addition, food-materials also can be obtained by the embryo from the same source by the formation of a *placenta*.

The 'type' of placenta depends upon the extent to which the maternal tissues are destroyed by the action of the trophoblast (p. 81); when the uterine blood-vessels are opened into, so that the trophoblast comes into direct contact with the maternal blood, the placenta is said to be of the *haemochorial* type (Mossman, 1937).

The series of diagrams in Fig. 89 illustrate the evolution, development, and mutual relations of the fœtal membranes in the *Amniota*, with the proviso that the amount of yolk influences the disposition of the various layers. The form of the blastula in particular depends on the amount of yolk present in the egg (p. 23), but in general it becomes a two-layered vesicle by the growth of the entoderm round the inner surface of the ectodermal wall. Only a portion of the wall of the blastula—the 'embryonic area'—is destined to form the embryo; and as the entoderm grows centrifugally from that region, it encloses the mass of yolk if present. The embryonic area is originally exposed on the surface (Fig. 89 A).

As the embryo grows, it begins to sink into the interior of the vesicle, and folds of the two-

layered wall grow up around it. These are the 'amnion-folds' and at first they include the entoderm as well as the ectoderm (B). The amnion-folds meet above the embryonic area and the entoderm is carried with them so that the embryonic area is separated from the surface by a double layer, each composed of ectoderm and entoderm; the ectoderm and entoderm are necessarily reversed in position in the inner layer, an arrangement, called "inversion of the germinal layers", which is found even in the development of some mammals (C). Meanwhile, the embryo rises out of the embryonic area and is 'folded-off' so that the gut is formed and its connexion with the rest of the entodermal vesicle, which becomes the **yolk-sac**, is reduced to a narrow passage.

The next stage is the growth of the mesoderm outwards from the embryo (C), progressively separating the extra-embryonic ectoderm and entoderm and excluding the entoderm from the amnion-folds (D). As it grows, the mesoderm covers the inner layer of ectoderm to form the definitive **amnion**, and it lines the outer layer of ectoderm (the *trophoblast* of viviparous mammals) which thus becomes the **chorion**, often called the *serous membrane* in oviparous animals. The two layers of mesoderm enclose the extra-embryonic cœlom between them. The relation between amnion and chorion, which depends on their common origin from the ectoderm, is indicated by the *amnion-stalk* (D) which may persist for some time; traces of it are found even in the human embryo (see below), though the cavity of the amnion appears without the formation of amnion-folds (p. 35). In the same diagram (D), the growth of the mesoderm over the entoderm to form the definitive **yolk-sac** is shown, and this continues until the mesoderm completely separates the yolk-sac from the chorion (E, F). The origin of the **allantois** as an outgrowth from the gut, carrying mesoderm with it, into the extra-embryonic cœlom is also indicated.

As the allantois enlarges, the amnion-stalk disappears and the connexion between embryo and chorion is reduced to mesoderm only—the *body-stalk* of mammals (E). There is a certain antagonism or reciprocal relation between the allantois and the yolk-sac; the yolk-sac is progressively reduced as the yolk is used up and as the allantois grows, so that in oviparous forms and in many viviparous mammals too, the yolk-sac is entirely or almost entirely excluded from contact with the chorion. Finally, in reptiles and birds, the membrane formed by the union of the wall of the allantois with the chorion acts as a respiratory membrane under the shell, and in most mammals it is the basis of the 'allantoic placenta'; but in some marsupial mammals the allantois remains small and a temporary 'yolk-sac placenta' is formed where the wall of the yolk-sac is in contact with the chorion (F).

In human development, both yolk-sac and allantois remain very small; but the placenta is of the allantoic variety because it is formed from the chorion in the region of the attachment of the body-stalk, into which the allantois grows.

Amnion.—The human **amnion** is formed from that portion of the wall of the ectodermal or amnio-embryonic vesicle which does not take part in the formation of the embryo (p. 35). It consists of ectoderm cells covered externally by a layer of extra-embryonic mesoderm, and it is continuous with the margin of the embryonic area (Figs. 90, 91). Whether the amnion is formed by splitting in the inner cell-mass or by separation of a layer of cells from the trophoblast (p. 35), the ectodermal cells of the amnion are at first continuous with the trophoblast (Fig. 51); a remnant of this connexion, in the form of a strand of cells passing from the amnion to the chorion in the body-stalk, persists in some early human embryos, and is a reminder of the evolutionary origin of the amnion by folds which meet to form an amnion-stalk (Fig. 89 D).

The cavity of the ectodermal vesicle, enclosed between the amnion and the embryonic area, is the **amnion cavity**; it is filled with fluid which raises the amnion in the form of a cupola over the embryonic region (Fig. 90). The amnion progressively enlarges as the amount of fluid increases until it fuses with the chorion and obliterates the extra-embryonic cœlom; by that time its attachment to the embryo is around the umbilical orifice and it forms a sheath for the umbilical cord (Fig. 98).

Yolk-Sac.—When the embryonic area is folded into the form of the embryo, the entodermal vesicle (secondary yolk-sac) is differentiated into three parts:—(1) a part enclosed in the embryo, where it forms the **primitive entodermal alimentary canal**; (2) a part which lies external to the embryo in the extra-embryonic cœlom—this is the yolk-sac proper or **definitive yolk-sac**; (3) the third portion is the **vitello-intestinal duct**, which connects the yolk-sac with the primitive alimentary canal (Figs. 75, 86, 87, 97).

The cavity of the yolk-sac is therefore in free communication with that of the alimentary canal, and their walls are continuous with each other and identical in structure, each consisting of an internal layer of entodermal cells and an external layer of mesoderm.

Free communication between the yolk-sac and the primitive alimentary canal appears to exist in the human embryo until it is four weeks old and about 2·5 mm. long (Fig. 75). During the fifth week the vitello-intestinal duct is elongated into a relatively long, narrow tube, lodged in the umbilical cord, and the yolk-sac, which has become a relatively small vesicle, is placed between the outer surface of the amnion and the inner surface of the chorion, in the region of the placenta. The reduced yolk-sac, on account of its relation to the umbilical cord, is sometimes called the *umbilical vesicle* (Figs. 86, 87). By the end of the fifth week, when the embryo has attained a length of about 5 mm., the vitello-intestinal duct begins to undergo atrophy, and it separates from the intestine when the embryo is about 11 mm. long; but remnants of it may be found in the umbilical cord up to the third month.

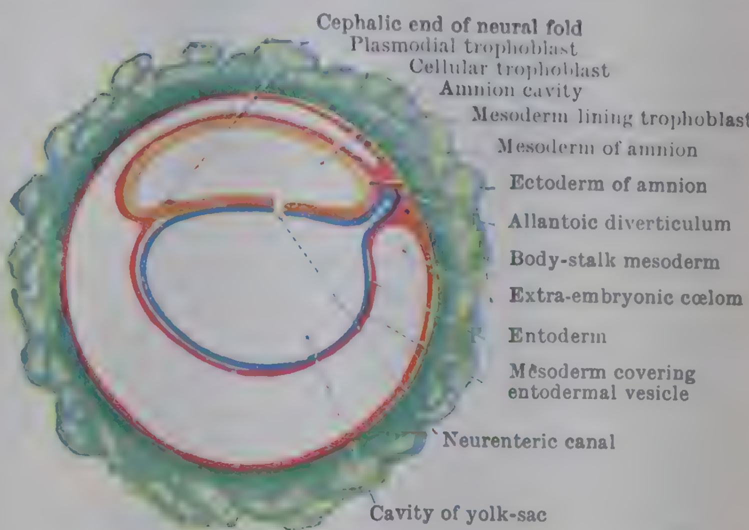

FIG. 90.—SAGITTAL SECTION OF ZYGOTE ALONG LINE A-A IN FIG. 58.

The yolk-sac itself persists until birth, when it may be found as a minute object lying between the amnion and the placenta near the end of the umbilical cord.

The human yolk-sac, since it contains no yolk, is in a sense a 'vestige' from the evolutionary point of view; yet, in the early stages of human development it is relatively quite large (Fig. 117), and it retains its special importance in the development of the blood and blood-vessels (p. 87). The vessels which develop in the wall of the yolk-sac are soon connected with others in the body of the embryo to form a *vitelline circulation.* This circulation is mainly responsible for the transfer of nutriment from the yolk to the embryos of birds and reptiles; and in mammals the vessels are formed in the same way since they are the basis of the vascular arrangements of the gut. At a very early period, before the paraxial mesoderm has commenced to divide into mesodermal somites, a number of **primitive vitelline arteries** are distributed to the yolk-sac from the primitive aortæ, and the blood is returned from the yolk-sac to the embryo by a pair of **vitelline veins** (Fig. 102).

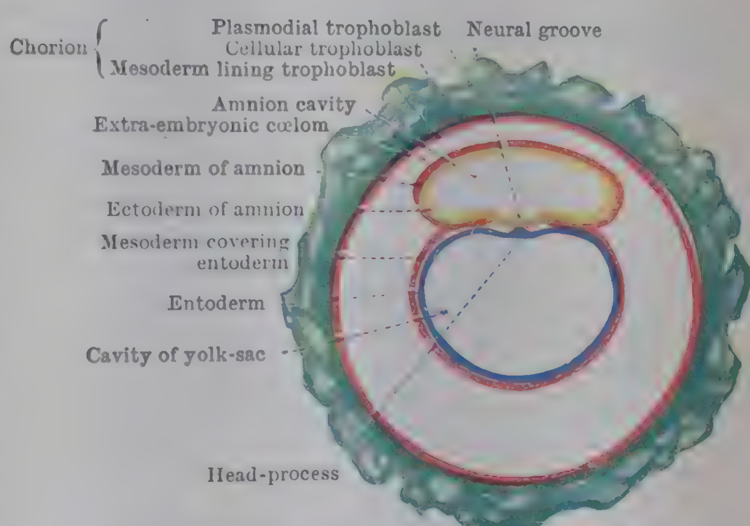

FIG. 91.—TRANSVERSE SECTION OF ZYGOTE ALONG LINE B IN FIG. 58.

After a time the arteries are reduced to a single pair, and the pair become converted into a single trunk, which passes through the umbilical orifice along the vitello-intestinal duct to the yolk-sac (Fig. 104). After the umbilical cord is formed, the extra-embryonic parts of the vitelline veins disappear and can no longer be traced in the cord. The same fate overtakes the vitelline artery—all except the portion of its intra-embryonic part which persists as the *superior mesenteric artery.*

Allantois.—The human **allantois**, like the yolk-sac, is a greatly reduced structure. In its relation to the chorion and the formation of the placenta, it too

may be considered an evolutionary vestige; but it cannot disappear entirely, for it is the basis of the development of the urinary bladder (pp. 73, 790). The allantoic diverticulum grows into the body-stalk but stops short of the chorion (Fig. 90); it arises from the primary entodermal vesicle and so appears at first to come from the yolk-sac; but its site of origin is included in the tail-fold of the embryo and so is transferred to the ventral wall of the cloacal part of the hind-gut (Figs. 69-

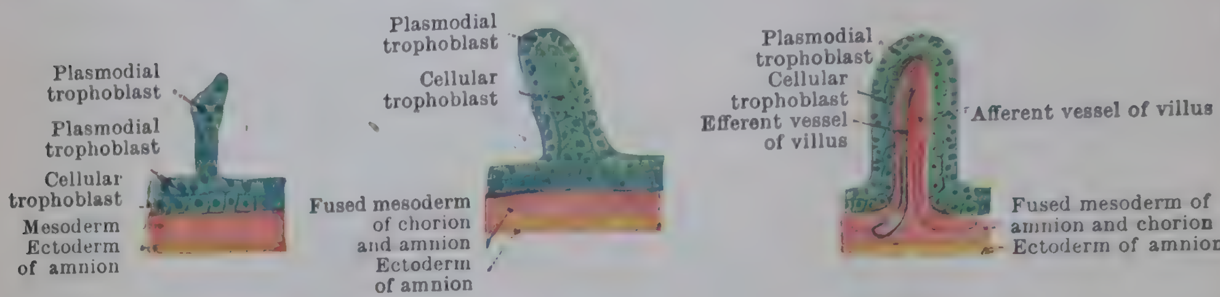

FIG. 92.—THREE STAGES IN THE FORMATION OF A CHORIONIC VILLUS.

71). The allantois is included in the umbilical cord, where it shrivels and disappears. It does not contribute directly to the formation of the urinary bladder, but it determines the site of the separation of the urogenital chamber from the cloaca (p. 73); and it is at first continuous with the *urachus*, which becomes the median umbilical ligament.

Chorion.—When the human blastocyst is first implanted in the endometrium, its wall consists solely of trophoblast (Figs. 39, 40); but the primary mesoderm soon appears and, after the formation of the secondary yolk-sac (p. 42), the **extra-embryonic cœlom** splits the primary mesoderm into two layers—one lining the inner surface of the trophoblast and the other covering the outer surfaces of the two inner vesicles (Figs. 90, 91).

The trophoblast and its lining of mesoderm together constitute the **chorion**, and the essential function of that membrane, in addition to providing an outer protective sac within which the embryo may develop in its amnion, is the formation of the **placenta**. The development and vascularization of the **chorionic villi**, and the separation of the chorion into placental and non-placental regions, are described with the account of the formation of the placenta itself (p. 81).

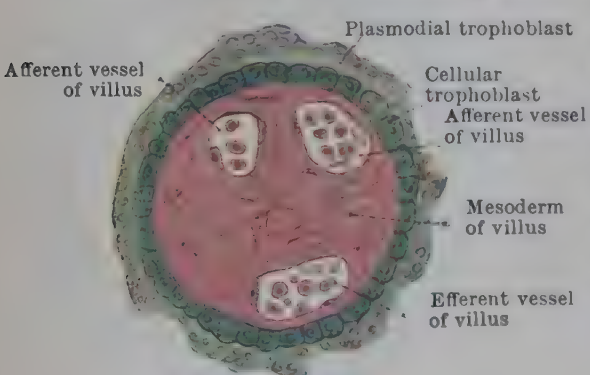

FIG. 93.—TRANSVERSE SECTION OF A SECONDARY CHORIONIC VILLUS. A loop of the afferent vessel has been cut at two points.

Body-Stalk and Umbilical Cord.—It has been explained (p. 42) that the mesoderm of the median part of the caudal portion of the amnion retains its connexion with the chorion and becomes thickened to form the **body-stalk**. In the thickened strand lies the allantoic diverticulum of the entodermal vesicle (Fig. 83), whilst through it, on each side of the allantois, pass the umbilical arteries and veins, by means of which blood is conveyed between the embryo and the chorion. It is important to note that the blood-vessels which thus pass through the body-stalk enter or leave the body of the embryo through the umbilical orifice, which is, at first, a relatively large aperture (Figs. 71, 104).

As the embryonic area is folded into the form of the embryo the amnion increases in extent, filling more and more of the extra-embryonic cœlom, and the embryo rises into its cavity. In other words, the walls of the amnion bulge ventrally round the ends and the lateral borders of the embryo (Figs. 70, 71, 96). As the distension of the amnion still continues, the ventral bulging round the margin of the umbilical orifice becomes more pronounced, the yolk-sac is forced farther and farther away from the embryo, the vitello-intestinal duct is elongated and it is surrounded by

a tube of mesoderm. The cavity that is present in this tube for a time—the proximal part of it becomes the umbilical sac—is an elongated part of the extra-embryonic cœlom, and its walls are covered by the amnion (Figs. 86-88). The caudal wall of the tube necessarily consists of the elongated body-stalk.

Umbilical Cord.—As the distension of the amnion still continues, the walls of the tube are forced against the vitello-intestinal duct, and the amniotic mesoderm fuses with the mesoderm surrounding that duct. When the fusion is completed, a solid cord—the **umbilical cord**—is formed (Figs. 97, 98, 100). It consists of an external covering of amniotic ectoderm, and a core of mesoderm in which lie the two umbilical arteries, a single umbilical vein formed by the fusion of the two primitive umbilical veins, and the remains of the vitello-intestinal duct and the vitelline vessels. One end of the umbilical cord is connected with the embryo; the other end is attached to the chorion. Near this attachment, in the mesoderm of the chorion, lies the yolk-sac, now a relatively small vesicle; and the allantois, continuous with the urachus of the urogenital chamber, projects into the cord from the embryo (Figs. 87, 97). For some time, too, the part of the cord where it springs from the belly of the embryo is distended by the *umbilical sac*, a portion of the cœlom in which the intestines develop (p. 72).

As the amnion grows still larger, all that part of its outer surface which does not take part in the formation of the umbilical cord is ultimately pressed into contact with the inner surface of the chorion, with which it fuses, and the cavity of the extra-embryonic part of the cœlom is thus obliterated (Fig. 98).

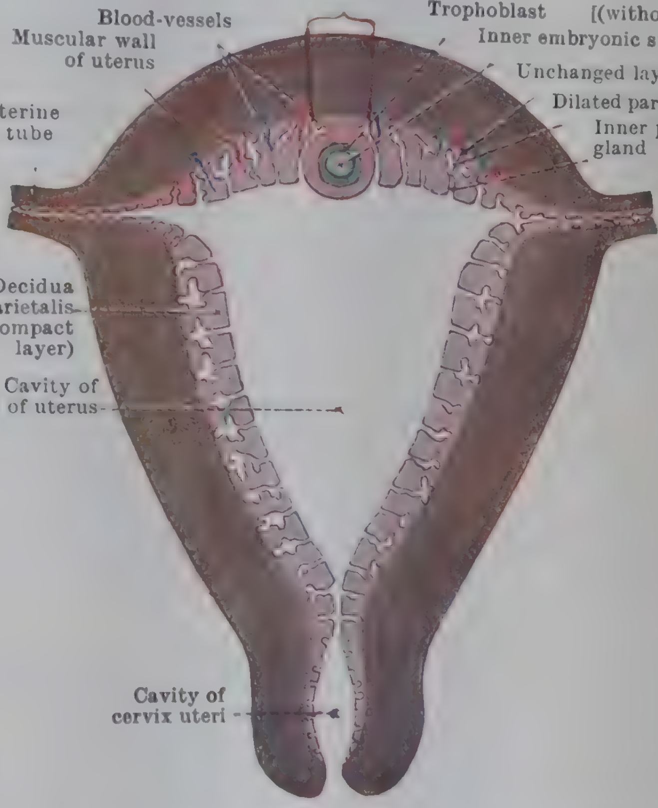

FIG. 94.—DIAGRAMMATIC CORONAL SECTION OF UTERUS, showing the various parts of the decidua and a zygote embedded in it.

The outer wall of the complete vesicle now consists of the fused chorion and amnion, and contains in its interior the amniotic cavity and the embryo, which is attached to the chorion by the umbilical cord.

When the umbilical cord is first formed it is comparatively short, but as the amniotic cavity increases the cord elongates, until it attains a length of from 18 to 20 inches (45 to 50 cm.); it then allows the embryo to float freely in the fluid in the amniotic cavity, whilst its nutrition is provided for by the flow and return of blood, through the umbilical cord, to and from the placenta, where interchanges take place between the maternal and the fœtal blood.

The Placenta.—The placenta is an organ developed for the purpose of providing the fœtus with food and oxygen, and removing the effete products produced by the metabolic processes which take place in the growing organism. It is formed partly from the chorion and partly from the mucous coat of the uterus, altered as explained below to form the uterine 'decidua'.

In the development of the placenta the blood-vessels of the fœtus and the blood of the mother are brought into intimate relation, so that free interchanges may readily take place between the two blood-streams; but the blood of the fœtus and

the blood of the mother are always separated from each other by two or more layers of fœtal cells.

The details of the early development of the human ovum are now almost completely known. It is highly probable that fertilization takes place in the lateral part of the uterine tube, that the zygote takes four to five days to pass along the tube, that it enters the uterus as a morula and begins to implant in six to seven days after ovulation (p. 34).

Endometrial Preparation.—The uterine mucous coat undergoes changes in preparation for the reception and retention of the zygote, and if implantation occurs the modified coat is known as the **uterine decidua.**[1]

The changes which take place, are, for the most part, hypertrophic in character. The vascularity of the mucous coat is increased, mainly by the dilatation of its capillaries. The tubular glands are elongated; they become tortuous, and dilatations form in their walls a short distance from their outer, closed extremities. At the same time the interglandular tissue increases in amount. As a result of the various changes the decidua is thicker, softer, more spongy, and more vascular than the endometrium during its resting phase.

Partly on account of the dilatation of the deep parts of the glands and partly on account of differences in texture of the internal and the external part of the decidua, the membrane is usually described as consisting of three layers:—(1) An internal layer, next the cavity, called the **stratum compactum.** (2) A middle layer—the **stratum spongiosum**—formed largely by the dilated parts of the glands. (3) An external **unchanged layer,** in which the comparatively unaltered outer ends of the glands lie.

These changes are an intensification of the periodic hypertrophy of the uterine mucous membrane which precedes menstruation. During menstruation the superficial part of the mucous coat disintegrates, and the whole of the stratum compactum with much of the stratum spongiosum is cast off. Repair ensues; and then the endometrium is built up again to the premenstrual state under the influence of the internal secretions, or hormones (p. 799)—*œstrin* and *progestin*—produced by the growing ovarian follicle and by the corpus luteum, the structure formed from the ruptured follicle after ovulation (p. 772). The evidence that ovulation occurs about 14 days before the expected onset of the next menstruation (Rock & Hertig, 1944, 1948) is reviewed by Davies (1948). This relation is of great importance in estimating the age of young embryos. If the ovum is not fertilized, the corpus luteum begins to degenerate, menstruation occurs, and thereafter the corpus luteum atrophies; but, if fertilization takes place, the corpus luteum grows and its increased secretion of progestin induces the final changes in the mucous coat, constituting the *decidual reaction,* which prepare it for the reception of the zygote. For further information the student should consult Marshall (1950), the chapters on reproductive physiology in standard text-books of Physiology or Obstetrics, or the account of the preparation of the uterus for the reception of the fertilized ovum in the special works on Human Embryology.

Implantation and Formation of Placenta.—When the zygote, in the morula stage, reaches the uterus, it acts as a parasite: it eats its way through the epithelium on the surface of the decidua, and implants itself in the stratum compactum (Figs. 39, 40). It may penetrate the decidua at any point of the wall of the uterine cavity; but it usually enters at some point of the dorsal or the ventral wall, and, pushing the glands aside, it is soon surrounded by the interglandular tissue of the stratum compactum of the decidua (Fig. 42). The aperture through which it passes is closed by proliferation of a portion of the trophoblast which acts as a sealing plug—the *operculum* (Teacher, 1924) (Fig. 41); and there is sometimes a *closing coagulum,* which may be partly blood-clot, superficial to the operculum and projecting from the aperture (Figs. 41, 47).

The portion of the decidua in which the zygote is embedded soon becomes thicker than the other parts of the membrane, and it is separated by the zygote into an internal part, called the **decidua capsularis,** and an external part—the **decidua basalis.** The remainder of the decidua—by far the larger portion—is the **decidua parietalis** (Fig. 95).

[1] A term based on the former belief that it has a larger share in the formation of the placenta and is to a great extent 'cast-off' when the placenta is detached.

As soon as the zygote becomes embedded in the decidua its trophoblast undergoes rapid proliferation and becomes multicellular wherever it is in direct contact with maternal tissue; and presently it differentiates into two layers—an inner cellular layer or **cytotrophoblast**, and an outer syncytial layer or **plasmoditrophoblast**. In the plasmodial layer cell-territories are not defined—an indication of intense growth-activity—and it consists therefore of multinucleated protoplasm.

As development proceeds, the trophoblast increases in thickness and continues to invade and destroy the decidua, probably by enzyme action. At this stage the decidual reaction becomes apparent. Its characteristic feature is the multiplication of the connective-tissue cells of the endometrium which become swollen and 'epithelioid' in appearance. These *decidual cells* (Figs. 43, 48) contain glycogen and lipoids, and they congregate in close proximity to the advancing trophoblast. Many of the decidual cells are engulfed by the trophoblast and doubtless they provide it with food-material; but it is generally believed that they act also as a defensive barrier against excessive penetration of the uterus by the trophoblast. If the balance between trophoblast and decidua

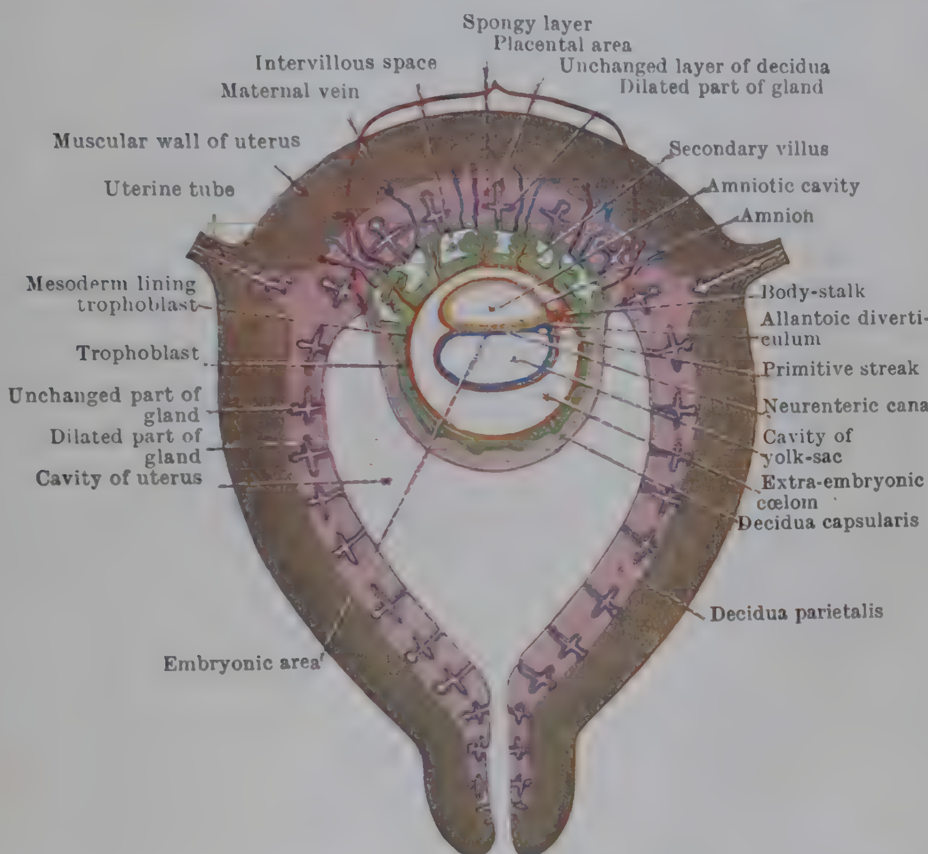

FIG. 95.—DIAGRAMMATIC CORONAL SECTION OF PREGNANT UTERUS AFTER THE FORMATION OF THE INTERVILLOUS SPACES.

is upset, then invasion may proceed without check—a rare occurrence that may result in a *chorionepithelioma*, one of the most malignant tumours known—or, on the other hand, the zygote may fail to implant properly and be cast off as an early *abortion*.

As the invasion of the decidua extends, the plasmoditrophoblast erodes the walls of maternal blood-vessels and itself becomes permeated with *lacunae* or spaces into which the maternal blood flows. The maternal blood thus begins to circulate slowly through the spaces in the trophoblast, the essential feature of the *haemochorial* type of placenta (p. 75).

The spaces in the plasmodium enlarge rapidly after the maternal blood begins to circulate within them, and the trophoblast becomes divided into three series of parts: (1) The **primary chorionic villi**, which lie between adjacent blood-spaces; (2) The parts which lie in contact with the mesoderm of the chorion and form, with the mesoderm, the **chorion-plate**; (3) The **basal layer**, composed of parts whch cover the maternal tissues and form the outer boundaries of the blood-spaces. The lacunar blood-spaces themselves are then called the **intervillous spaces** (Figs. 97, 99).

After a time each primary villus differentiates into a cellular core and plas-

modial periphery, and thereafter the villi are invaded by the mesoderm of the chorion and are thus converted into **secondary chorionic villi** (Figs. 95-97).

The first-formed villi are non-vascular, but by the time the secondary villi have developed the umbilical arteries have grown through the body-stalk into the mesoderm of the chorion, and branches from them enter the mesodermal cores of the villi, which thus become vascular. The secondary villi consist, therefore, of a mesodermal core, continuous with the mesoderm of the chorion and covered by a layer of cellular trophoblast (*Langhan's layer*) and a layer of plasmodium.

The proximal end of each villus is continuous with the chorion-plate of the intervillous spaces, formed by the chorion; the distal end is connected with the plasmodial basal layer of the trophoblast, which forms the outer boundary of the intervillous spaces and is fused with the maternal decidual tissue.

After a time the secondary villi send out numerous branches into the intervillous spaces, and thus increase greatly in complexity (Figs. 95-97). In this way two sets of secondary villi are differentiated :—(1) The **anchoring villi** which cross from the chorion to the basal layer of the trophoblast—they are attached to the basal layer of the trophoblast by cell-columns which are the outer parts of the primary villi not yet invaded by the embryonic mesoderm; (2) **Free or absorbing villi** which extend from the sides of the original secondary villi into the blood in the intervillous spaces (Figs. 97, 99).

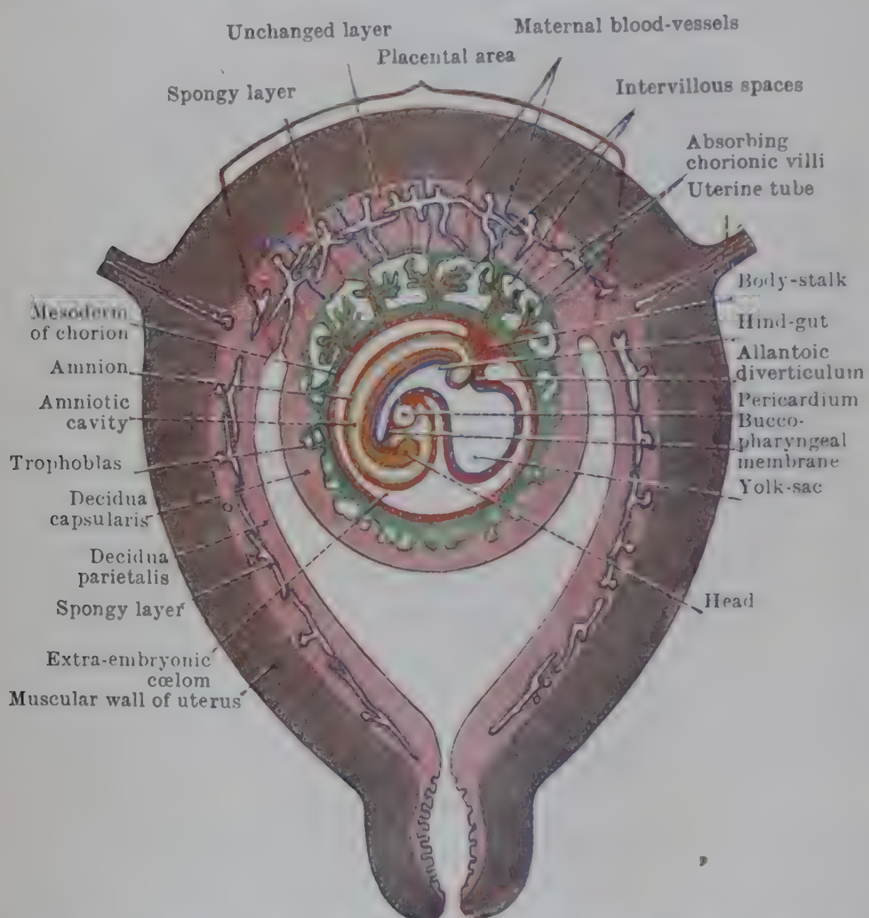

Fig. 96.—Diagrammatic Coronal Section of Pregnant Uterus at Period of Formation of Embryo. Note extension of amnion compared with stage shown in Fig. 95.

While the trophoblastic invasion of the compact layer of the decidua is proceeding, not only are the interglandular elements of the decidua destroyed, but the walls of the glands also; as a consequence, some of the glands in the decidua basalis open for a time into the intervillous spaces, and they become filled with blood which passes from the spaces into the cavities of the glands (Fig. 47). Frequently, however, before the glands are destroyed, their walls are converted into solid strands of cells, and thus the cavities of their more external undestroyed portions may become closed spaces.

The development of the chorionic villi does not proceed equally, however, in all parts of the membrane. As already noted, the trophoblast begins to thicken only where it is in direct contact with the uterine tissues. The embryonic pole of the blastula, which advances into the endometrium, is first affected and that region of the chorion, related to the body-stalk of the embryo—through which vascular connexions are established—maintains the lead thus acquired (Figs. 39-44). As implantation proceeds and the endometrium closes over the abembryonic surface of the zygote as it sinks deeper, the trophoblast reacts on that surface also and, for

a time, the whole surface of the chorion is covered with villi. But the supply of maternal blood is naturally less in the capsular portion of the decidua and is progressively diminished as the chorionic vesicle continues to expand, and the villi in that region undergo atrophy and disappear. When these degenerative changes have occurred, the portion of the chorion in association with the thinned decidua capsularis presents a relatively smooth surface and is known as the **chorion læve.** In the meantime the decidua basalis increases in thickness, and the villi associated with it increase in size and in the complexity of their branches. The portion of the chorion from which these large villi spring is termed the **chorion frondosum.**

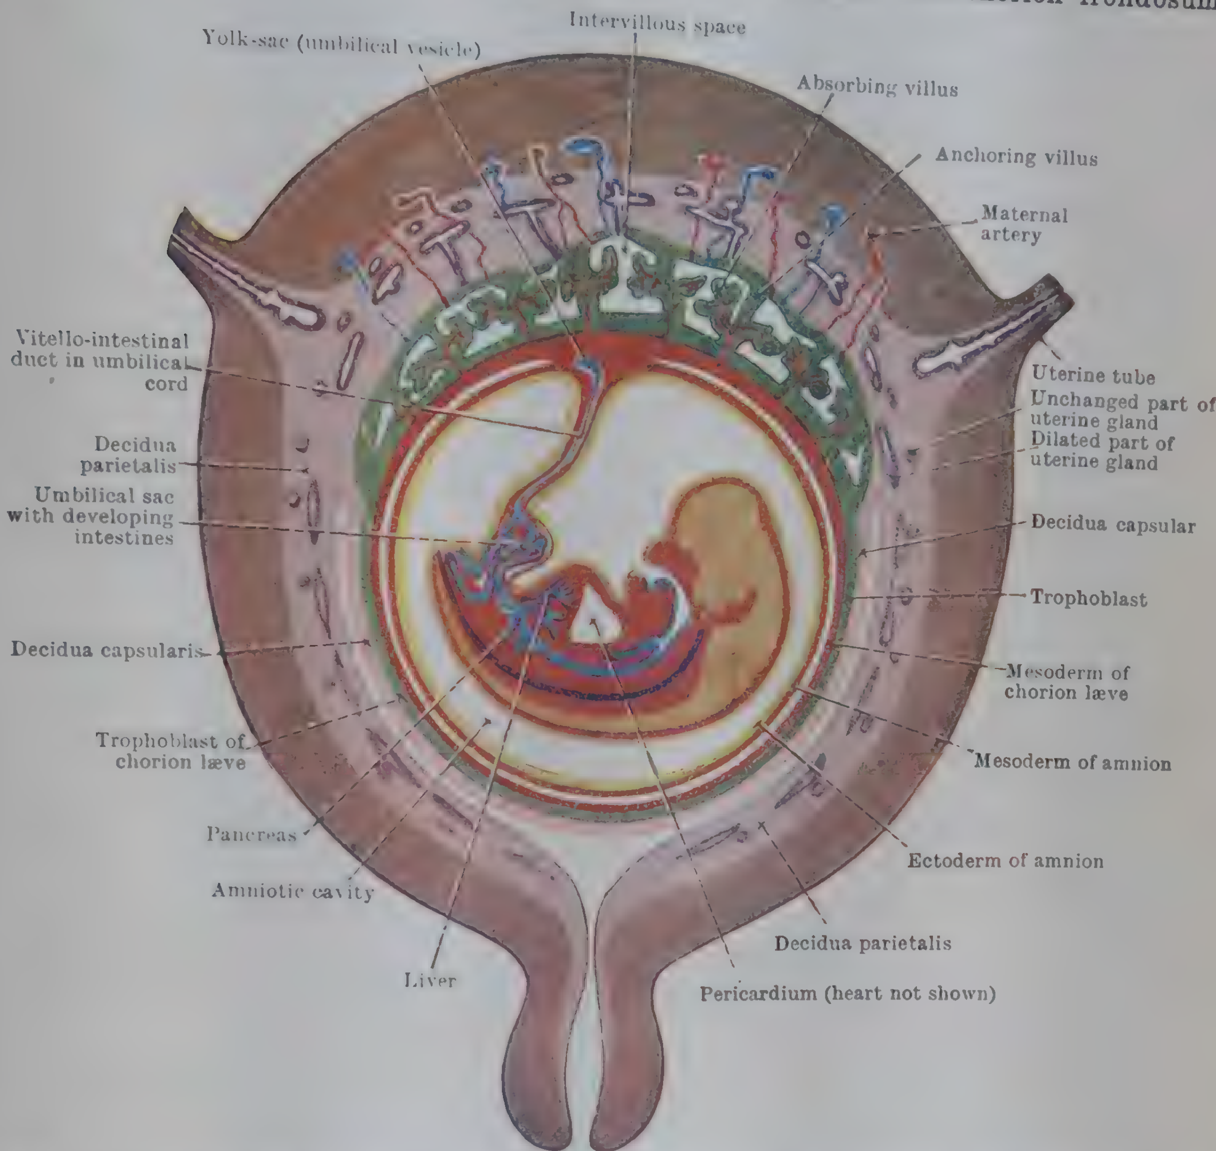

Fig. 97.—Diagrammatic Coronal Section of Pregnant Uterus after Formation of Umbilical Cord. Note that the expanding amnion has almost obliterated the part of the extra-embryonic cœlom which lies between it and the chorion. Cf. Fig. 121a, p. 101.

It is this portion of the chorion which takes part in the formation of the **fœtal portion** of the placenta, the **maternal (uterine) part** of that organ being formed by **the decidua basalis.**

The placenta, therefore, is formed mainly by the chorion frondosum and to a small extent only by maternal tissues; and the interchanges between the fœtal and the maternal blood take place in the substance of the fœtal part of the placenta through the trophoblast which covers the surfaces of the villi.

As the growth of the embryo and the distension of the amnion continue, the amnion is gradually forced against the chorion and fuses with it (Fig. 121 A, p. 101). When fusion is complete the extra-embryonic cœlom is obliterated and the zygote contains only one extra-embryonic cavity—the amniotic cavity—which contains the fœtus surrounded and supported by the amniotic fluid (Fig. 98).

At this period the cavity of the amnion is bounded by a wall composed of the

fused amnion, chorion, and decidua. As the distension of the amnion proceeds to a still greater extent, the part of the wall of the cavity formed by the fused amnion, chorion læve and decidua capsularis bulges more and more into the cavity of the uterus, until it is forced against the surrounding wall of the uterine cavity, where it fuses with the decidua parietalis, and thus the cavity of the uterus is obliterated. This fusion takes place towards the end of the second month, and as soon as it has occurred the discoid mass of placental tissue is continuous at its margin with the fused amnion, chorion, and decidua parietalis (Fig. 98).

After the second month the fœtus lies in the *amniotic cavity*, which is bounded by the fused chorion and uterine wall, except at the lower end of the uterus, over the internal os uteri, where the cavity of the body of the uterus communicates with the canal of the cervix; there the amniotic cavity is bounded by a membrane formed by the fused amnion, chorion læve, and the decidua capsularis only.

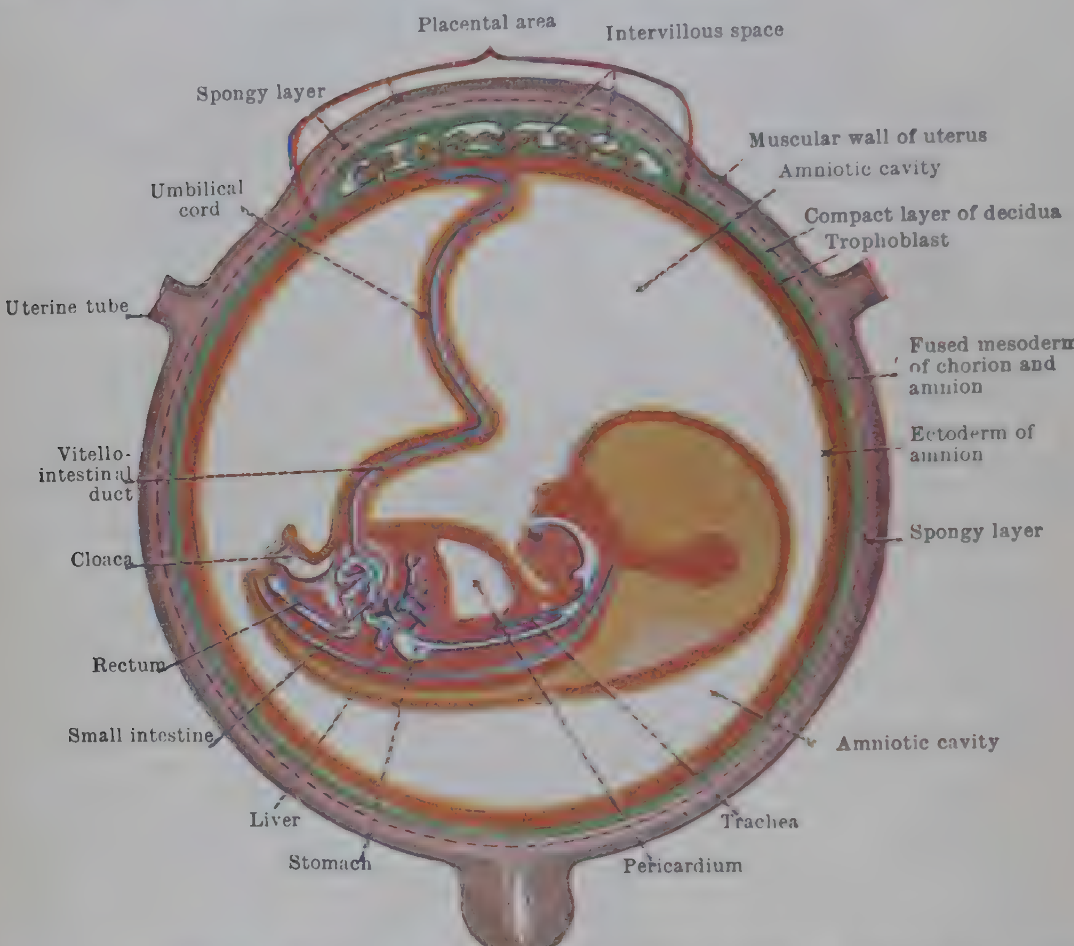

FIG. 98.—DIAGRAMMATIC SECTION OF PREGNANT UTERUS AFTER FUSION OF AMNION AND CHORION.

Completion of Placenta.—It has already been stated that each absorbing villus consists of a vascular, mesodermal core covered by a cellular and a plasmodial layer of trophoblast, the latter lying next the maternal blood in the intervillous spaces. As development proceeds and the intervillous spaces become larger, the villi become longer and more complicated, and at the same time the cellular layer of the trophoblast largely disappears, until in the majority of the villi the plasmodial layer alone covers the mesodermal core.

In still later stages, degeneration occurs not only in the villi, but also in the chorionic plate of the intervillous spaces and in the basal trophoblast which closes the spaces externally. One of the results of the degenerative processes is the deposit of fibrinoid material in the place originally occupied by the trophoblast: the fibrinous layers on the surfaces of adjacent villi adhere together, and the villi thus connected fuse into masses of intermingled fibrinous and vascular tissue.

When the fœtal (chorionic) part of the placenta is completed it consists of:—(1) the chorion plate closing the intervillous spaces internally; (2) the villi; (3) the intervillous spaces; and (4) the basal layer of the trophoblast, which closes the intervillous spaces externally and is perforated by the maternal vessels passing to and from the spaces.

The maternal (uterine) portion of the completed placenta consists from within out-

wards of :—(1) the basal layer of the decidua ; (2) the remains of the spongy layer of the decidua ; and (3) the unchanged layer (Fig. 99).

The basal layer of the decidua is the remains of the compact part of the decidua basalis of earlier stages. It is fused internally with the basal plate of the trophoblast, and is continuous externally with the spongy layer. The spongy layer contains a series of cleft-like spaces. These spaces are the cavities of the compressed remains of the earlier dilated portions of the glands of the stratum spongiosum from which the epithelial lining has to a great extent disappeared. The spongy layer is continuous externally with the unchanged layer, in which the unaltered outer parts of the glands and the intervening interglandular tissue lie.

The maternal blood-vessels pass from the muscular wall of the uterus directly into the placenta, where they traverse the maternal portion and the basal plate of the tropho-

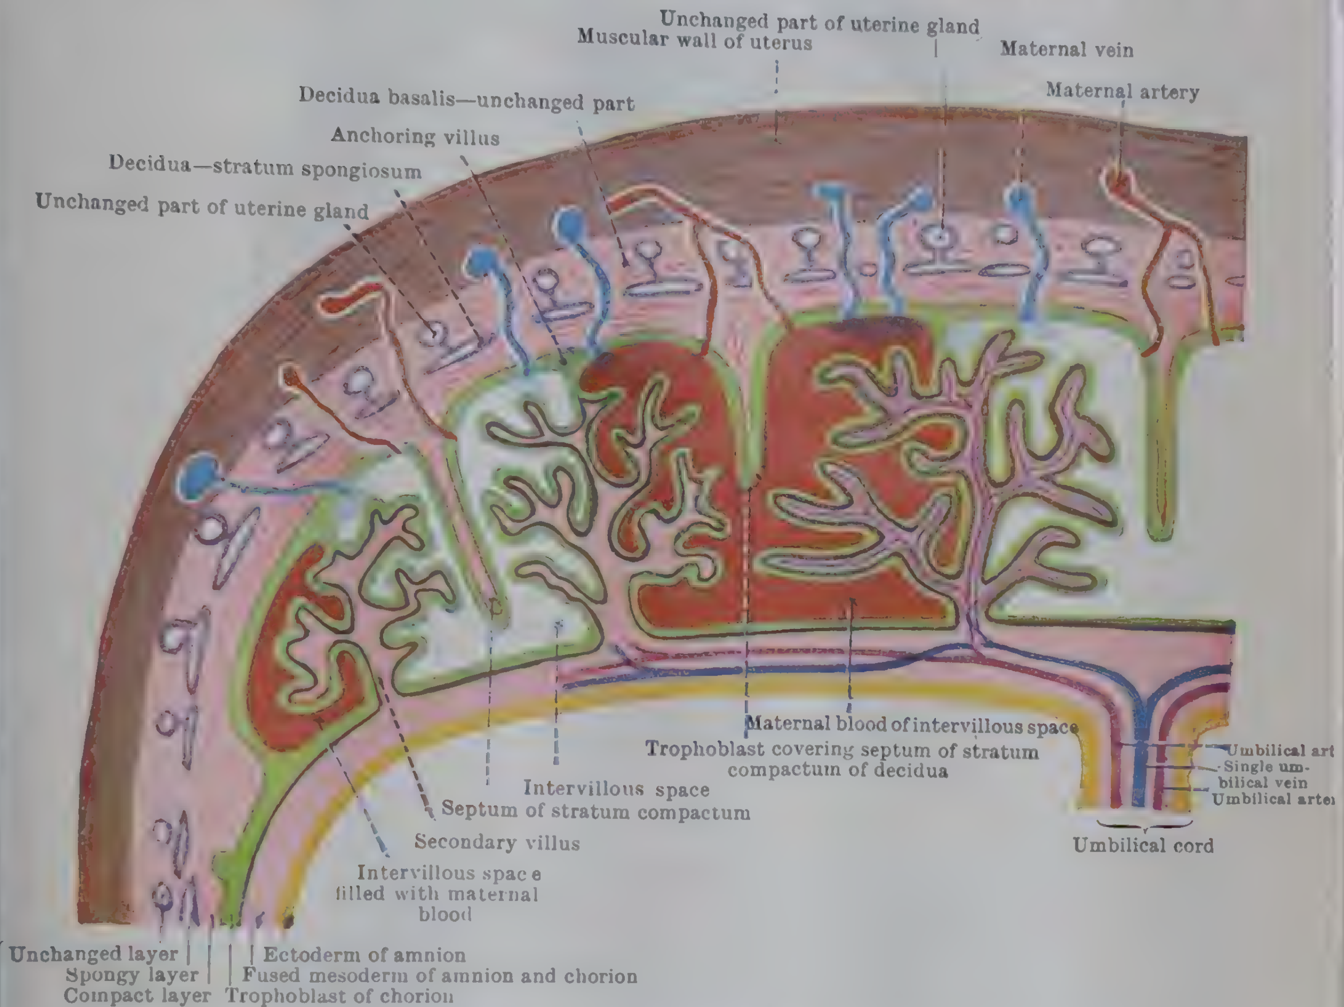

FIG. 99.—DIAGRAM OF STRUCTURE OF COMPLETED PLACENTA. The marginal sinus is not shown in the figure.

blast and open into the intervillous spaces. The arteries usually open on or near the septa and the veins begin in the areas between them. The veins of the pregnant uterus are greatly enlarged, and around the edge of the placenta there is a more or less complete venous space, called the *marginal sinus*, into which many of the maternal veins open ; it is believed by some observers that the greater part of the drainage of the intervillous spaces take place through the marginal sinus (Falkiner, 1939).

In addition, however, to the constituent parts already described, the fœtal part of the placenta contains some strands of maternal tissue, and in the maternal part there are portions of trophoblast.

The parts of the decidua found in the fœtal part of the placenta are a series of fibrous strands—the remains of parts of the stratum compactum which were not destroyed by the trophoblastic invasion. They form incomplete septa which serve to separate the placenta into lobes or *cotyledons*—from 15 to 20 in number. The cotyledons are spoken of as 'placental units' since each contains a main 'villous trunk' from which the free villi branch in the manner of a tree (Fig. 99). Recently it has been stated that most of the free villi take a recurved course back towards the chorion (Spanner, 1935) so that the whole system resembles a 'weeping willow' (Johnstone, 1945).

development proceeds, for the original plexuses are transformed into distinct stems and branches of varying size and importance. Therefore two groups of events in the development of the vascular system have to be considered—the evolution of the different kinds of blood-corpuscles and the development of the main embryonic blood-vessels.

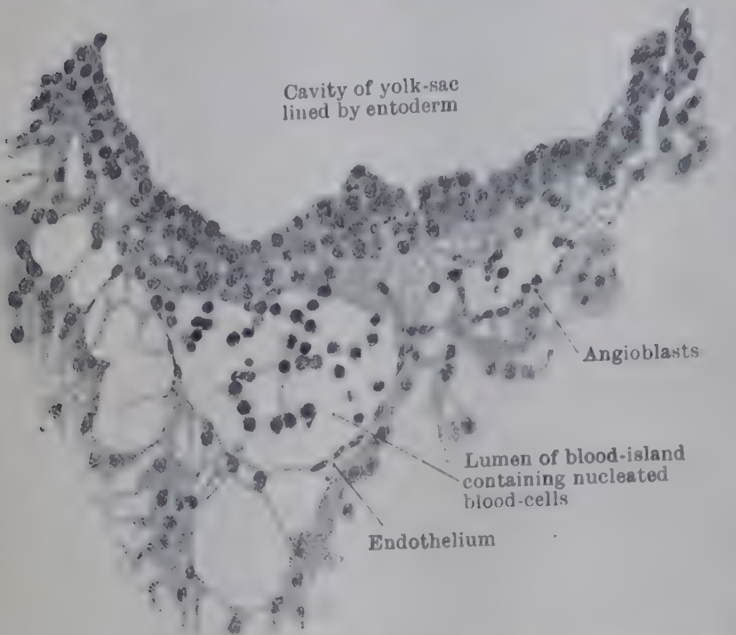

FIG. 101.—SECTION OF WALL OF YOLK-SAC OF YOUNG HUMAN EMBRYO (THIRD WEEK) SHOWING BLOOD-ISLANDS DEVELOPING IN THE MESENCHYME. × 250. (Thompson & Brash, 1923.)

Development of Blood-Corpuscles. — Numerous researches have been made with the object of discovering the mode of origin of the different kinds of blood-corpuscles, but there is as yet no general agreement either with regard to their exact genesis or to the terminology to be used in describing the stages through which they pass. This is indeed "one of the most controversial subjects in histology" (Maximow & Bloom, 1948).

The view that the angioblast is the parent-cell not only of the endothelium of blood-vessels but also of all the blood-corpuscles both red and white has been elaborated by Maximow (1924). It implies either that blood-formation in the growing embryo and fœtus takes place by the development of angioblastic cells from the mesenchyme in the same way as on the yolk-sac, or that the stem-cells that give rise to all the varieties of blood-corpuscles (*hæmocytoblasts*) are carried from the yolk-sac into the embryo to multiply there.

According to Sabin (1922), the angioblast produces the endothelium from which, by *intravascular* budding, only the red blood-corpuscles are derived. All the ordinary white corpuscles of the blood have an *extravascular* origin from a common progenitor —itself derived from the mesenchyme—called a *reticular cell*, by differentiation along special lines. A special kind of white corpuscle, few of which, however, are found in the blood-stream and most in the connective tissues, called a *clasmatocyte* or *histiocyte*, also is said to arise from the endothelium. The histiocytes, the reticular cells of reticular tissue and endothelium in certain situations all belong to the reticulo-endothelial system (pp. 12, 831).

The red blood-corpuscles pass through several stages to maturity; the original nucleated cells (*erythroblasts*) become laden with hæmoglobin, pass through a *normoblast* stage (in which the nuclei are contracted) and after the extrusion of their nuclei become *erythrocytes* or mature red blood-corpuscles.

This process goes on throughout life; it begins in the wall of the yolk-sac, is very active in the liver from the third month onwards, and occurs in the spleen in the later stages of intra-uterine life. When ossification begins, blood-formation is actively carried on in the developing bone-marrow; and after birth the continuous formation of red blood-corpuscles is entirely confined to that special hæmopoietic (blood-forming) tissue.

The three main kinds of white blood-corpuscles are *polymorphonuclear leucocytes, monocytes, and lymphocytes*. The bone-marrow is the great factory of the first two kinds (and their varieties) but the lymphocytes, which are relatively late in appearing, are formed in lymphoid (adenoid) tissue wherever it may be situated—in the spleen, in the mucous coat of the alimentary canal, and in the lymph-glands. All these cells reach the blood-stream by passing through the endothelial walls of blood-capillaries, but lymphocytes also reach it in great numbers *via* the lymph-vessels after the formation of lymph-glands.

In very young embryos both immature and mature blood-cells are present in the blood-stream, the mature cells being developed from the immature in the stream; but after bone-marrow and lymphoid tissue have been formed the proportion of immature cells decreases. After birth only mature erythrocytes pass into the blood-stream; but

under pathological conditions, in which there may be excessive formation of red corpuscles in the bone-marrow, immature reds (normoblasts) may again appear in the blood.

For discussions of the origin of the blood-corpuscles see Downey (1938) and Piney (1939).

Formation of Primitive Blood-Vessels.—It has been pointed out that in the yolk-sac area of the entodermal vesicle a plexiform system of tubes, filled with fluid and corpuscular elements, is formed from angioblastic cells (Fig. 101).

Similar but less easily demonstrated plexuses are formed in the mesenchyme of the body-stalk, and of the chorion, and also later in the embryonic area.

It is probable that the various plexuses become connected with one another very soon after they appear, so that a continuous capillary network is formed. By enlargement in some places and diminution in others the general vascular network becomes more open, and from this *retiform* arrangement by further enlargement of definite channels there are evolved what may be called the primitive stem-vessels of the embryo, through which the blood circulates from one area to another.

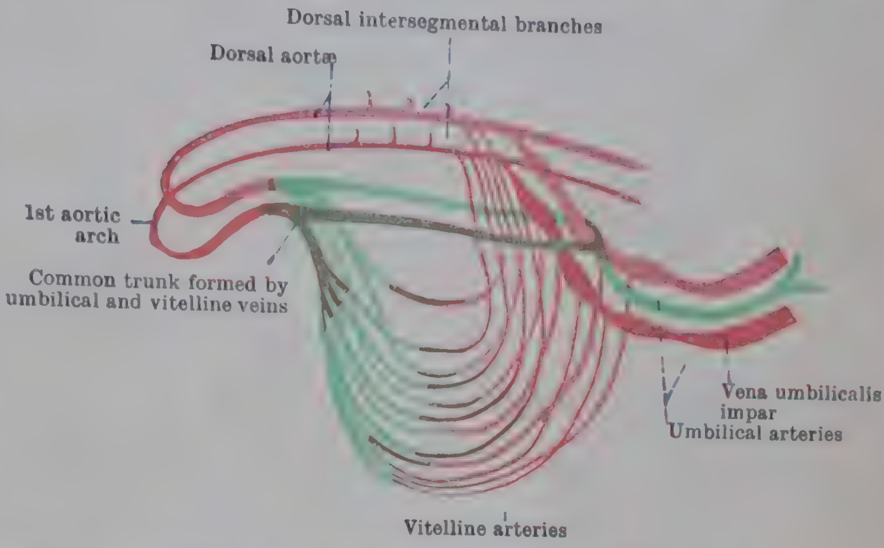

FIG. 102.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 1·35 MM. LONG, WITH SIX SOMITES. (After Felix, 1910, modified.)

In the embryonic area a pair of main stem-vessels are first differentiated; they are the **primitive aortæ**. These vessels appear in the splanchnic mesoderm of the pericardial region of the embryonic area, whence they extend to the caudal end of the area.

At their cephalic ends the primitive aortæ are continuous with another pair of stem-vessels called the **vitelline veins**, which emerge from the vascular plexus in the wall of the yolk-sac.

As the aortæ pass tailwards in the embryonic area, ventral to the paraxial bars of mesoderm (see p. 50), they give off a ventral series of paired branches, called **vitelline arteries**, which terminate in the vascular plexus in the yolk-sac wall (p. 77); and from the caudal and dorsal part of that plexus, represented in Fig. 102 by a series of dilatations, a pair of vessels—the **umbilical arteries**—pass along the body-stalk to the vascular plexus in the chorion. Another stem-vessel, called the **vena umbilicalis impar**, begins in the vascular plexus in the chorion and passes along the body-stalk to the caudal margin of the embryonic

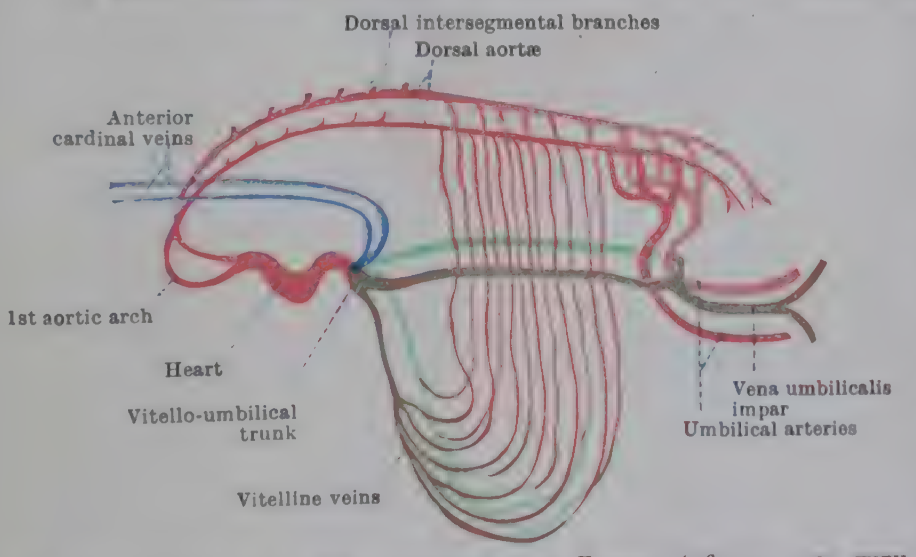

FIG. 103.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 2·6 MM. LONG, WITH FOURTEEN SOMITES (arteries after Felix, 1910, modified).

area, where it divides into *right* and *left umbilical veins.* These two umbilical veins run along the corresponding margins of the embryonic area and fuse with the corresponding vitelline veins at the points where the latter join the primitive aortæ, forming with them **vitello-umbilical trunks.** Therefore, when rhythmic contraction begins in the pericardial portions of the primitive aortæ, the blood is driven through the primitive aortæ and passes through their vitelline and umbilical branches to the yolk-sac and the chorion, whence it is returned to the aortæ by the vitelline and umbilical veins.

In the meantime lateral branches have been given off from the primitive aortæ, and in later stages, as the mesodermal somites are defined, they become the intersegmental arteries (Fig. 105); but for a time no purely intra-embryonic veins are distinguishable.

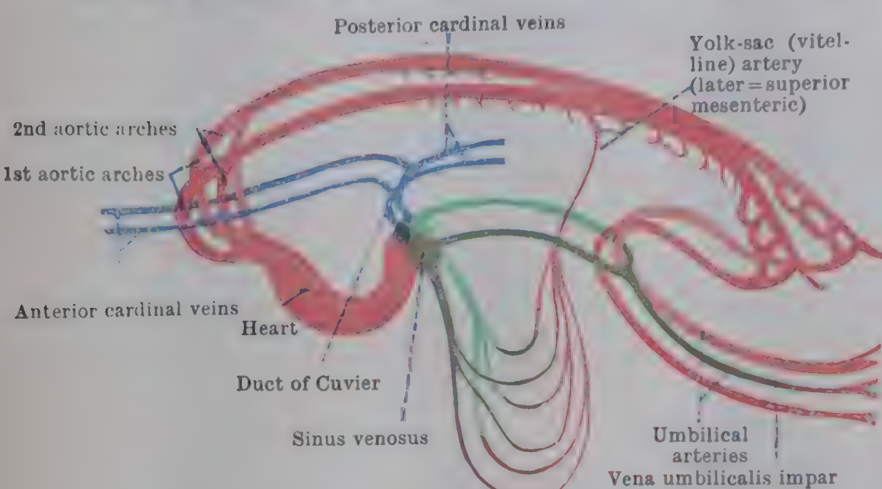

FIG. 104.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO WITH TWENTY-THREE SOMITES (arteries after Felix, 1910, modified).

As the head-fold is formed and the pericardial region is turned over into the ventral wall of the fore-gut (see p. 55), the cephalic parts of the primitive aortæ are carried ventrally in the fold, and so are bent into the shape of hooks. That condition is well seen in an embryo of 1·35 mm. length which had six mesodermal somites (Fig. 102).

Three parts of each primitive aorta are now defined: the short, ventral limb of the hook is the *primitive ventral aorta*; the long or dorsal limb is the *primitive dorsal aorta.* The bend, which connects the two limbs, is the *first aortic arch*; it runs along the side of the bucco-pharyngeal membrane in the substance of the mandibular arch. What were previously the cephalic ends of the primitive aortæ have now become the caudal ends of the primitive ventral aortæ; they lie in the substance of the septum transversum—the bar of mesoderm which separates the pericardial cavity from the extra-embryonic cœlom at the cephalic margin of the umbilical orifice—and in that situation the common vitello-intestinal venous trunks are continuous with the primitive aortæ.

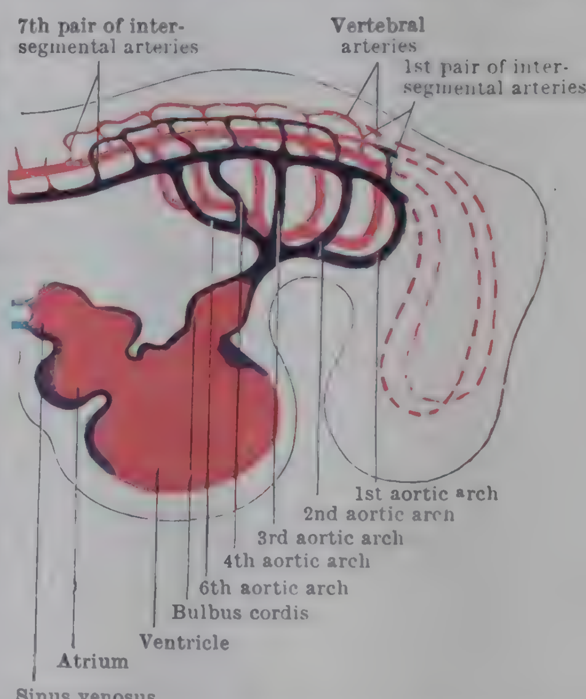

FIG. 105.—DIAGRAM SHOWING 5 MM. STAGE WITH FIVE AORTIC ARCHES. At this stage, as the 6th arch develops, the 1st and 2nd atrophy and disappear.

Three further important changes take place in the vascular system during the time in which the embryo grows a little more than another millimetre in length, and the tail-fold and lateral folds are formed and the number of its mesodermal somites increases to fourteen pairs.

(1) The caudal parts of the primitive ventral aortæ fuse together to form a single, median, tubular heart, which is divided by dilatations and constrictions into six parts, named, from the caudal, towards the cephalic end, the **sinus venosus** the **atrium**, the **atrio-ventricular canal**, the **ventricle**, the **bulbus cordis**, and the **truncus**

arteriosus. At the same time the heart increases in length more rapidly than the region in which it lies; it therefore becomes bent both in the longitudinal and the transverse direction, and its caudal and cephalic ends begin to come close together (Figs. 103, 104).

(2) The origins of the umbilical arteries are transferred from the vitelline plexus to the primitive dorsal aortæ from which they arise by three roots for each (Fig. 103).

(3) The **anterior cardinal veins** are defined (Fig. 103). They are the first pair of purely intra-embryonic veins. They begin in the head and end in the sinus venosus, which they enter, in the septum transversum, close to the common vitello-umbilical veins. They bring back to the heart the blood which has been distributed by the presegmental and intersegmental arteries to the head, neck, and headward part of the trunk of the embryo.

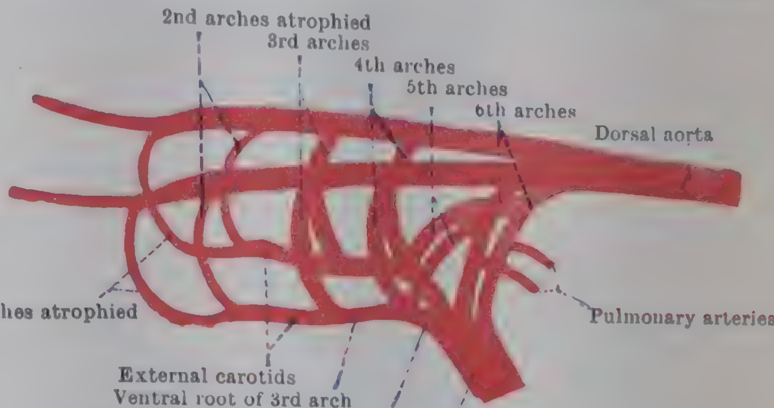

FIG. 106.—SCHEMA OF AORTIC ARCHES OF AN EMBRYO, 9 MM. LONG. (After Tandler, 1909, modified.) The first and second arches have atrophied and the transitory fifth has appeared.

Thereafter, numerous changes take place in the cardiac, the arterial, and the venous parts of the vascular system, and the rudiments of all the main blood-vessels of the adult are defined.

Heart.—The various chambers of the heart become more definitely demarcated (Fig. 105), the rudiments of the septa are formed by which the heart is divided into right and left sides, and valvular arrangements are developed.

Arteries.—The primitive dorsal aortæ fuse, from the region of the tenth (seventh cervical) somite tailwards, to form the permanent descending aorta (Fig. 104). The paired ventral or vitelline branches of the aortæ also fuse to form single trunks, and become reduced in number. In the abdominal region they are reduced to three main vessels—the cœliac artery, the superior mesenteric artery (which for a time passes to the yolk-sac as the vitelline artery) (Fig. 104), and the inferior mesenteric artery.

Branches are given off from the ventro-lateral aspects of the descending aorta to the rudiments of the nephric or urinary system, which are developed from the intermediate cell-mass, and to the rudiments of the genital glands.

Four additional pairs of aortic arches connecting the unfused portions of the primitive ventral and dorsal aortæ, appear in the following sequence, the second, the third, the fourth, and the sixth—the temporary fifth pair appearing later. These aortic arterial arches run in the *pharyngeal arches* of the embryo (p. 65), and they undergo a series of transformations as the arterial system of the thorax and neck develops. The first and second arches disappear, pulmonary arteries arise from the sixth arches (Fig. 106), and the truncus arteriosus divides so that a main pulmonary trunk communicates with the right side of the heart and the permanent aorta with the left side.

Veins.—Two additional pairs of intra-embryonic venous trunks are formed for the drainage of the hinder parts of the body.

The **posterior cardinal veins** (Fig. 104) appear in the thoracic and abdominal regions of the embryo dorso-lateral to the intermediate cell-mass.

They drain blood from the body-walls and from the nephric rudiments, and their cephalic ends join the anterior cardinal veins in the thoracic region at the point where the latter turn ventrally to enter the septum transversum (Fig. 104).

As soon as the union of the anterior and posterior cardinal veins is completed the parts of the anterior cardinals ventral to the points of union are called the **ducts of Cuvier**. The right duct later becomes the terminal part of the *superior vena cava*.

In the meantime the common vitello-umbilical venous trunks have been absorbed into the sinus venosus, and the vitelline and umbilical veins open independently into it; so that three pairs of veins now open into the sinus venosus of the heart.

The **subcardinal veins** appear in the abdominal region ventro-medial to the mesonephros—a large structure which contains nephric rudiments. They communicate both at their cephalic and caudal ends with the posterior cardinal veins.

In addition to the posterior cardinal and subcardinal veins still another pair of intra-embryonic veins is established at a later period in the abdominal and thoracic regions. They are called the **supracardinal veins** and they appear dorso-lateral to the descending aorta. All these veins are concerned in the complex manner of development of the *inferior vena cava.* (For the detailed development of the heart, the further history of the blood-vessels and the fœtal circulation see the Section on the Vascular System.)

CŒLOM AND DIAPHRAGM

Now that an outline of the formation of the body of the embryo and of the principal organs of the trunk—alimentary canal, respiratory system, excretory organs, heart and great vessels—has been given, the division of the cœlomic cavity into peritoneal, pleural and pericardial cavities and the manner in which these are separated from each other with the formation of the diaphragm may be considered.

The two parts of the cœlom—the extra-embryonic and the intra-embryonic—are derived independently as clefts in the mesoderm and are at first separate from each other (Figs. 64, B; 68); they become continuous, for a time, in the region of the umbilical orifice (Fig. 65, B), but are separated from each other again when the umbilical orifice closes. Later the extra-embryonic cœlom disappears, but the intra-embryonic remains as the cavities of the pericardium, pleura, and peritoneum.

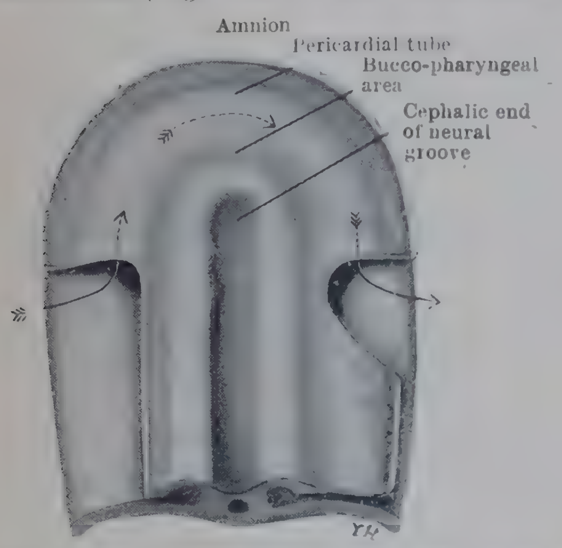

Fig. 107.—Schema of Intra-embryonic Cœlom seen from Dorsal Surface before folding of Embryonic Area. Portions of the somatopleure are cut away to show the continuity of the intra-embryonic cœlom of the two sides through the pericardial canal.

Extra-Embryonic Cœlom.—The formation of the extra-embryonic cœlom in the primary mesoderm has already been considered (p. 42). It is entirely obliterated when the outer surface of the expanding amnion fuses with the inner surface of the chorion (compare Figs. 96 and 97).

Intra-Embryonic Cœlom.—The intra-embryonic cœlom appears as a series of cleft-like spaces in the margin of the embryonic mesoderm (Fig. 68). The spaces fuse together to form a ∩-shaped cavity which divides the peripheral part of the embryonic mesoderm into a parietal or somatopleuric layer and a visceral or splanchnopleuric layer (p. 50). The bend of the ∩-shaped cavity is in the margin of the cephalic part of the embryonic region, and it has no direct communication with the extra-embryonic cœlom, but the greater part of each limb of the cavity, on account of the disappearance of its lateral wall, soon opens, laterally, into the extra-embryonic cœlom (Figs. 65, 107).

The transverse portion of the ∩ is the **pericardial cavity**. The adjacent parts of the limbs are best named at this stage **pericardio-peritoneal canals** (Frazer, 1940); they are invaded later by the growing lungs and are transformed into the *pleural cavities*. The remaining portions of the two limbs unite ventrally, as the umbilical orifice closes, to form the single **peritoneal cavity**.

As the head-fold forms, the pericardial part of the cavity is carried ventrally and caudally into the ventral wall of the fore-gut (Figs. 70, 71, 108). The mesoderm which originally formed its peripheral boundary then lies in the cephalic boundary

of the umbilical orifice; it becomes thickened to form an important mass called **the septum transversum** (Figs. 75, 86).

At the cephalic end of its dorsal wall, on each side, the pericardial cavity is still continuous with the pericardio-peritoneal canals which lie dorsal to the pericardium, between the fore-gut medially and the body-wall laterally.

Separation of Pericardial, Pleural, and Peritoneal Parts of Cœlom.—In the lateral wall of each pericardio-peritoneal canal, near its cephalic end, lies the duct of Cuvier, passing towards the heart; and between the canals the lung-buds arise from the end of the trachea (Fig. 108). On each side the lung-bud indents the medial wall and bulges into the cavity of the canal which now becomes a **pleural cavity** (Fig. 109). At the same time the ducts of Cuvier, as they pass to the heart, raise ridges in the body-wall—*pleuro-pericardial folds*—which constrict the openings between pleural and pericardial cavities (Figs. 108 C, 109 A). As the lung-buds grow the pleural cavities increase in size, and each passes ventrally round the side of the pericardium towards the ventral wall of the body, until it is separated from its fellow of the opposite side by a median interval only (filled with mesoderm), which becomes the anterior mediastinum and the anterior part of the superior mediastinum (Figs. 109, 110). At the same time the pleural cavity and the growing lung-bud grow towards the head of the embryo (Fig. 110, A). As the growing lung passes upwards it lies to the lateral side of the duct of Cuvier, which is thus pressed against the pleuro-pericardial opening, compressing it towards the median plane until it is obliterated. When this occurs the pericardial cavity is entirely shut off from the remainder of the cœlom and it becomes a completely closed space. Very

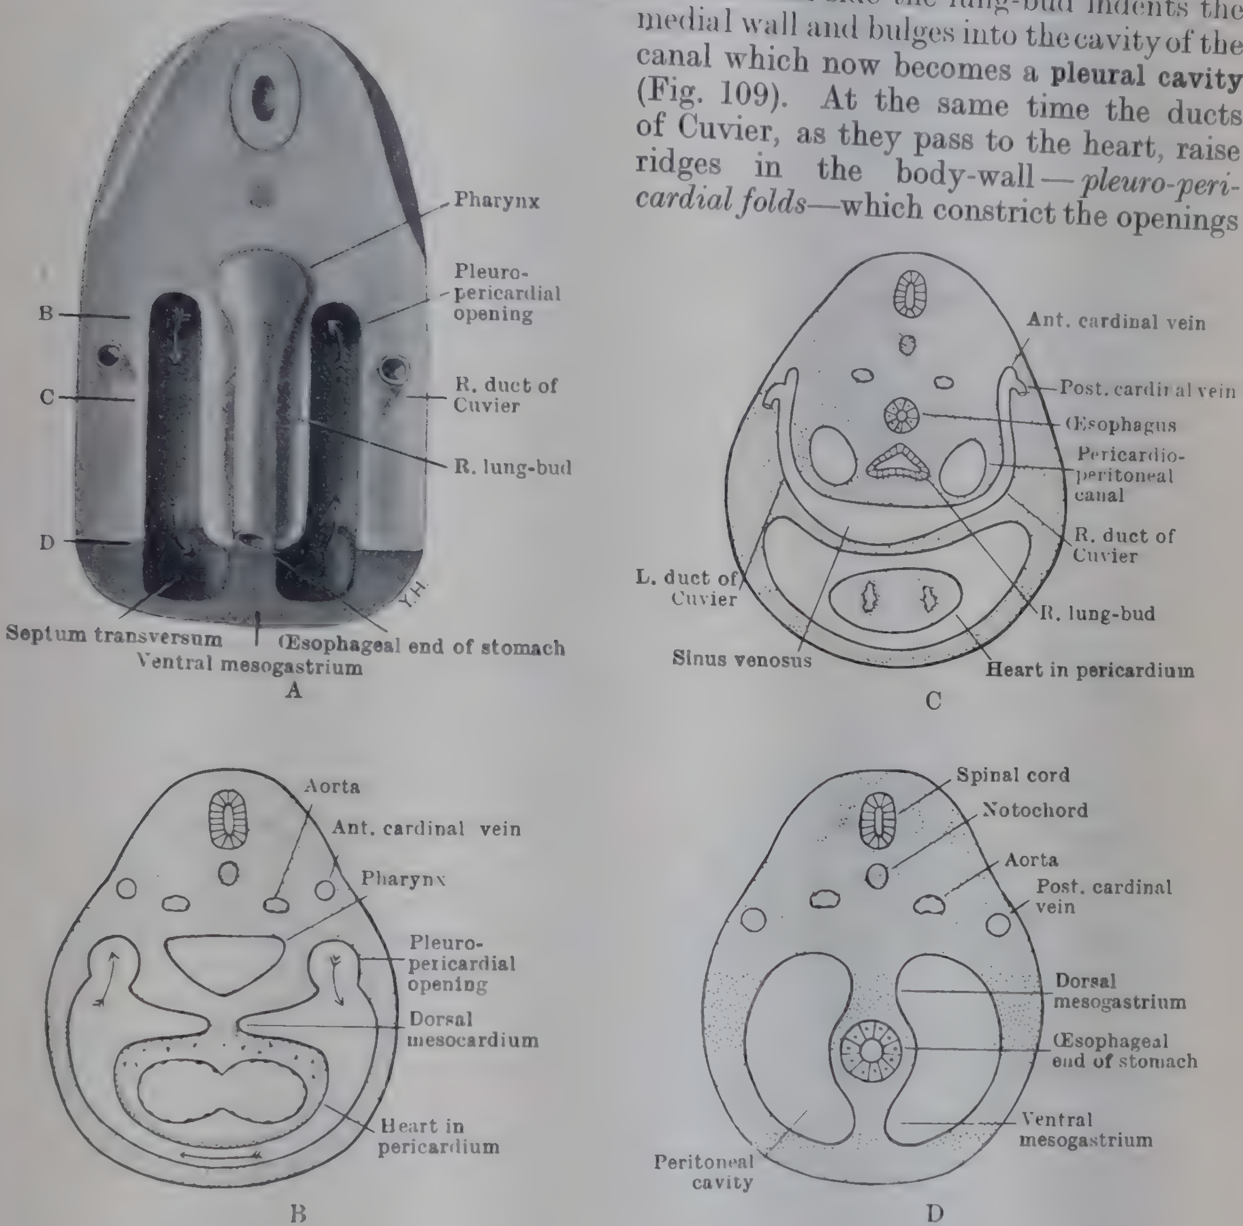

FIG. 108.—SCHEMATA OF EMBRYONIC CŒLOM AFTER FOLDING OF EMBRYONIC AREA BUT BEFORE THE SEPARATION OF THE VARIOUS PARTS. A: from dorsal surface; B, C and D (after Patten, 1946): at levels indicated in Fig. A.

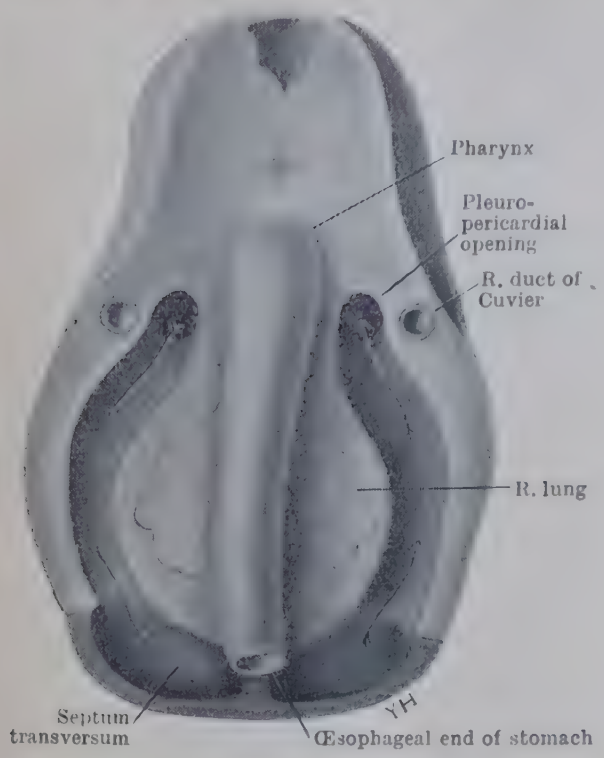
rarely, as an abnormal condition, the pericardial cavity remains in communication on one or other side with a pleural cavity.

As the closure of the pericardial cavity is taking place a pair of wing-like folds of the mesoderm of the body-walls appear caudal to the lungs. These *pleuro-peritoneal folds* are the



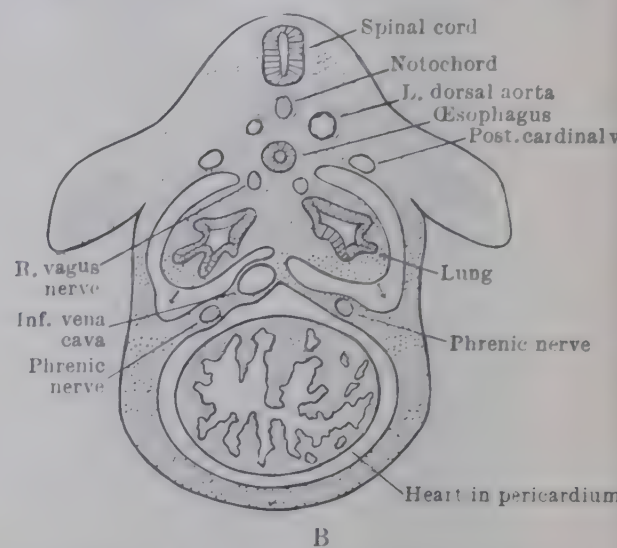


Fig. 109.—Schema of Later Stage of Differentiation of Cœlom. A: from dorsal surface. B (after Patten, 1946): transverse section cut at the level of lung-bud in A, showing commencing ventral extension of pleural cavities.

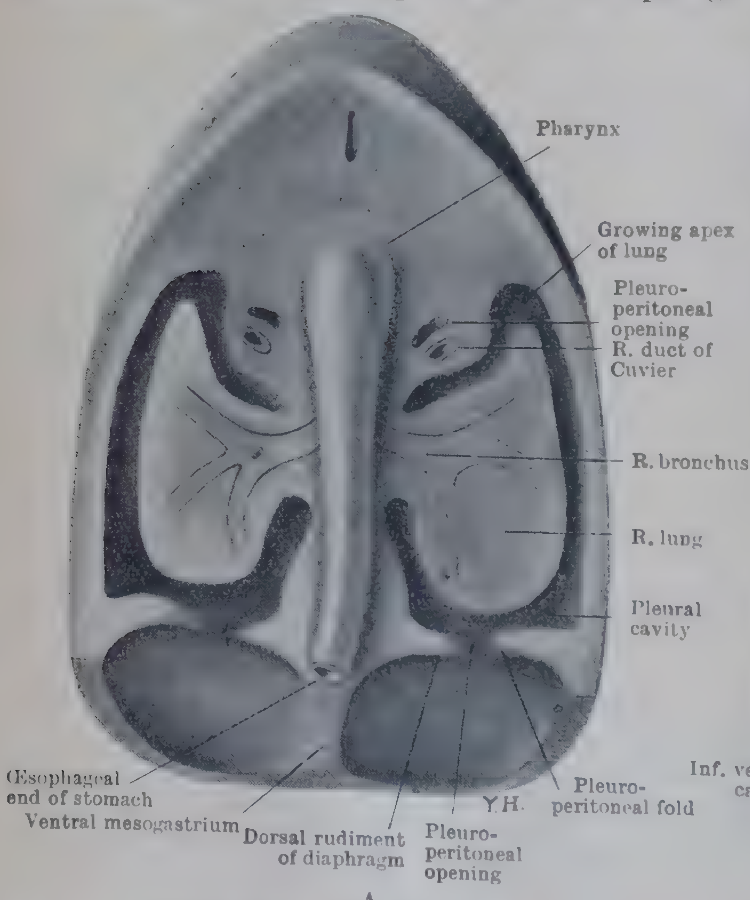
rudiments of the lateral parts of the diaphragm; they are connected ventrally with the septum transversum and grow medially until they fuse with the mesoderm of the side-wall of the fore-gut and with the dorsal mesentery (Figs. 109, 110). When this fusion is completed and the *pleuro-peritoneal opening* closed, the cavity of the portion of



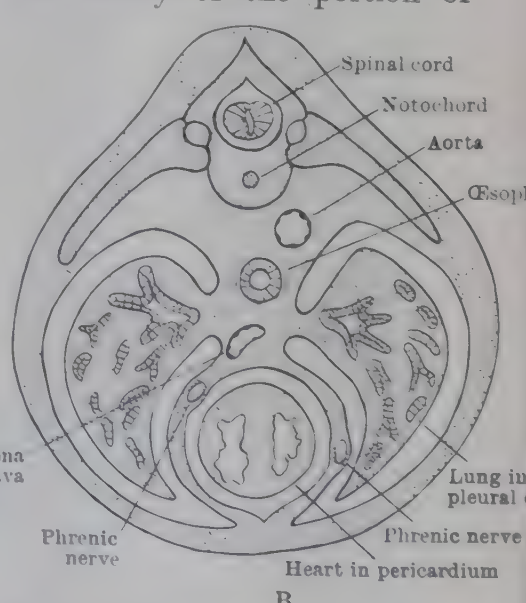


Fig. 110.—Schema of still later Stage of Differentiation of Cœlom. The pleuræ are separated from the pericardium, but still communicate with the peritoneum. A: from dorsal surface. B (after Patten, 1946): transverse section at the level of lung roots in A, showing ventral extension of the pleural cavities.

the cœlom surrounding the lung—the original pericardio-peritoneal canal—is

separated from the more caudal part of the cœlom, which now becomes the peritoneal cavity.

For some further details in the development of the pleural cavities see p. 724.

Formation of Diaphragm.—There are four main developmental parts of the diaphragm—a ventral, a dorsal, and a right and a left lateral.

The ventral part is formed from the *septum transversum*, which is gradually differentiated into a caudal, a middle, and a cephalic part. The caudal part is transformed into (1) the mesodermal tissue of the liver, which grows towards the abdomen, (2) the falciform and coronary ligaments, and (3) the lesser omentum. The cephalic part becomes the caudal or diaphragmatic wall of the pericardium. The middle part is transformed into the ventral portion of the diaphragm.

The dorsal part of the diaphragm is developed from the mesoderm of the dorsal mesentery of the fore-gut. Each lateral part is derived from the pleuro-peritoneal folds mentioned above. The two lateral portions grow towards the median plane till they fuse with the dorsal portion; but sometimes, especially on the left side, the fusion is not completed. The pleuro-peritoneal opening then remains unclosed (in the region of the *vertebro-costal trigone*, p. 452), and a portion of the abdominal contents may pass through it into the pleural sac, constituting a congenital *diaphragmatic hernia*.

For the origin of the muscular tissue of the diaphragm, see p. 555.

SUMMARY OF EXTERNAL FEATURES OF HUMAN EMBRYO AND FŒTUS AT DIFFERENT PERIODS OF DEVELOPMENT

First Month.—During the first **fourteen days** after fertilization the human ovum descends through the uterine tube, enters the uterus as a morula, and is transformed into a blastula which attaches itself to the uterine epithelium (Fig. 38) and penetrates into the decidua compacta (Fig. 39). The inner cell-mass differentiates into ectodermal and entodermal plates with which the amnion and the primary yolk-sac respectively become associated (Figs. 42-44); and when the secondary yolk-sac is formed the zygote consists of a large trophoblastic vesicle in which amnio-embryonic and yolk-sac vesicles are suspended by the mesoderm (p. 42). The embryonic area is indicated from the earliest stage by the contact of ectodermal and entodermal plates, but it is not until the 13th or 14th day, after the formation of the secondary yolk-sac, that it appears as a well-defined circular area about ·2 mm. in diameter (Figs. 47, 49, 50).

By the **fifteenth** or **sixteenth day** the caudal end of the embryonic area is indicated by thickening of the ectoderm and its fusion with the entoderm—the first stage in the formation of the primitive streak (Figs. 48, 50). About the **seventeenth day** the primitive groove, running caudally from the primitive node, has appeared; secondary mesoderm is spreading in the embryonic area from the primitive streak (now well-formed); and the allantoic diverticulum has grown into the body stalk (Fig. 111).

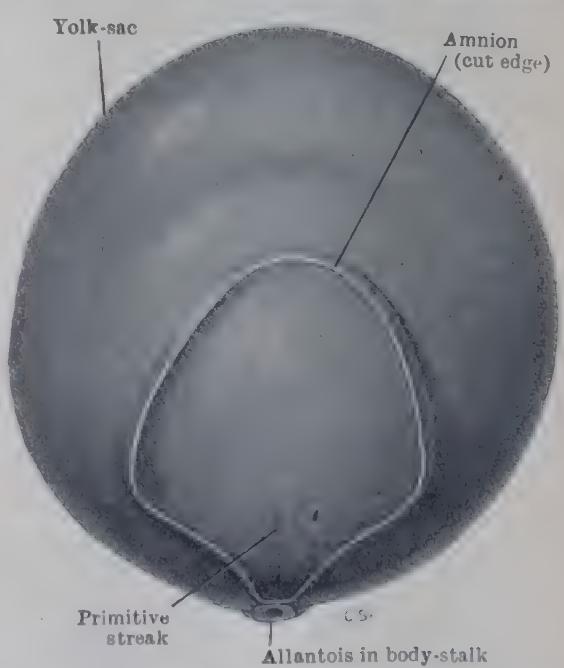

FIG. 111.—DORSAL VIEW OF HUMAN EMBRYO (MATEER) OF 17 DAYS. (After G. L. Streeter, *Carnegie Contrib. Embryol.*, 1920.) × 35. The amnion is cut away to show the embryonic area from above. The primitive streak is seen in the caudal part of the area and beyond that is a section of the body-stalk with the allantoic diverticulum in it.

By the **eighteenth** or **nineteenth day** the area, though variable in both size and shape, may be from 1 to 1·5 mm. long and 1mm. or less in breadth (Figs. 53, 112). The primitive streak is now fully developed with a very distinct primitive groove on its surface. The head-process is growing headwards from the primitive node and is progressively tunnelled by the archenteric canal. The tail-fold is carrying the primitive streak over the

caudal margin of the embryonic area, and the body-stalk, containing the allantois, appears to be bent dorsally at right angles to the region of the cloacal membrane (Fig. 54). There may be an indication of the formation of neural folds (Fig. 112).

By the **nineteenth** or **twentieth day** the embryonic area is still variable in size, but the length (1·5-2 mm.) is then definitely greater than the breadth. The floor of the archenteric canal has broken down, leaving the notochordal plate in the roof of the entodermal vesicle; and the neurenteric canal pierces the area towards its caudal end, with its dorsal opening between the caudal ends of distinct neural folds. The tail-fold is very evident; the head-fold has begun to form, and the pericardial region lies in the ventral wall of the rudimentary fore-gut (Figs. 60, 61, 70, 113).

By the end of the **third week** the head-fold and tail-fold are distinctly formed, the neural folds are well developed especially in the head-region, the neural groove is still completely open or just beginning to close, and the formation of mesodermal somites has begun (Fig. 114). The length of the embryo may now be about 2mm., but there is some variation in the relation of length to state of development at this stage.

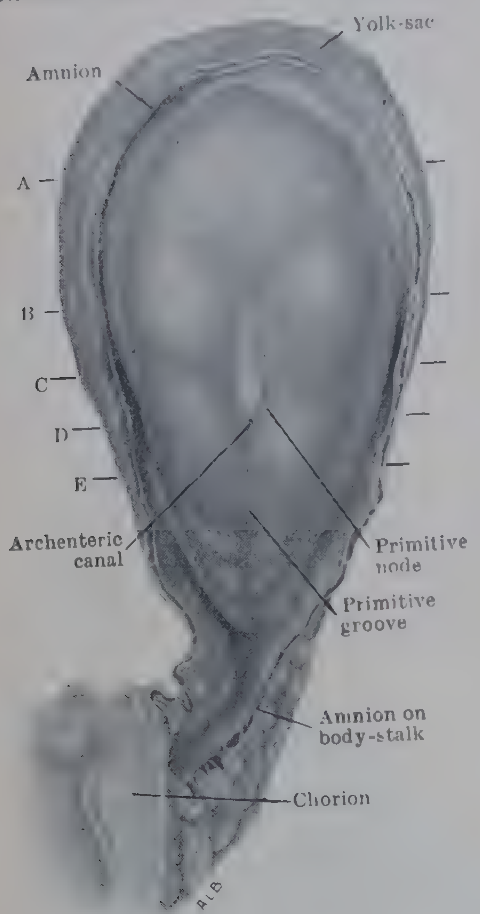

Fig. 112.—Dorsal View of Human Embryo of 18 Days. (After C. H. Heuser, *Carnegie Contrib. Embryol.*, 1932.) × 50.

The amnion is cut away to show the embryonic area now elongated (1·53 × 0·75 mm.) and with the caudal part slightly bent ventrally. The primitive node, with opening of archenteric canal, and primitive streak are seen in the caudal half of the area and there is an indication of commencing neural folds in the cranial half. Cf. Fig. 53; and for sections of this embryo, see Fig. 55.

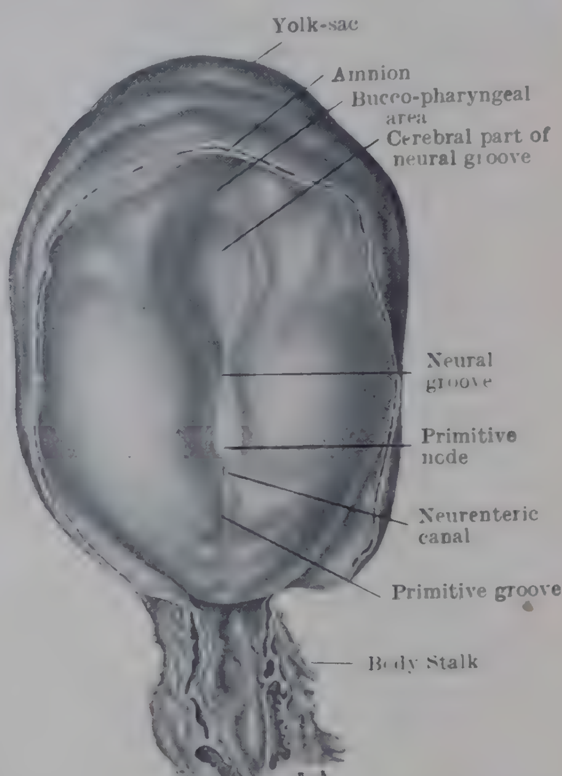

Fig. 113.—Dorsal View of Human Embryo of 19 Days. (After W. C. George, *Carnegie Contrib. Embryol.*, 1942). × 50.

The amnion is cut away to show the embryonic area (1·16 mm. long) with primitive node and streak, neurenteric canal and developing neural groove. Cf. Fig. 60.

In the next few days the primary parts of the brain begin to be evident, the neural groove closes except in the cephalic and caudal regions where the neuropores (p. 60) are seen, the mesodermal somites increase in number, and the cephalic region begins to bend ventrally as the cervical flexure forms (Figs. 115, 116).

By the end of the **fourth week** the length of the embryo is about 2·5-3 mm., the head is bent at right angles to the body, and appears flattened on account of the projection of the fore-brain. The number of somites increases to over twenty. The rudiments of the otic vesicles have appeared as slight depressions in the region of the hind-brain, and the cephalic and caudal neuropores are closed or closing. The yolk-sac is still relatively large and in free communication with the mid-gut. The pharyngeal arches and grooves are appearing in the wall of the fore-gut dorsal to the bulging pericardium (Figs. 75, 117).

Second Month.—During the **fifth week** the embryo attains a length of 5 to 6 mm.

The somites increase to thirty-eight or thirty-nine; the rudiments of the limbs appear and become quite distinct, the fore-limb in advance of the hind-limb; the otic vesicles sink into the interior of the head but remain connected with the surface by a narrow canal; the tail becomes a very definite appendage; and the bulgings caused by the optic vesicles are quite obvious on the surface of the head. The cervical flexure remains acute, and the head bends at right angles upon itself in the region of the mid-brain, forming the cephalic flexure, with the result that the frontal region is turned towards the tail (Fig. 118).

By the end of the **sixth week** the length of the embryo has increased to 11 or 12 mm.

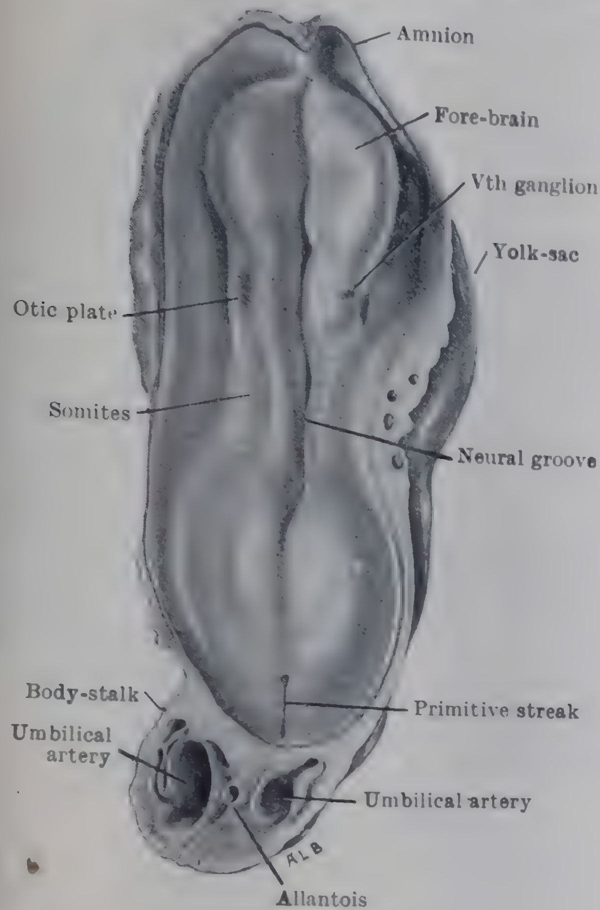

FIG. 114.—DORSAL VIEW OF HUMAN EMBRYO OF 21 DAYS. × 50. (After N. W. Ingalls, *Carnegie Contrib. Embryol.*, 1920.) The broad cephalic end of the neural plate is elevated with commencing formation of the brain. The neural groove is still open and its caudal end is enclosing the cephalic end of the primitive streak. The length of the embryonic area has increased to 1·4 mm. and somite formation has begun.

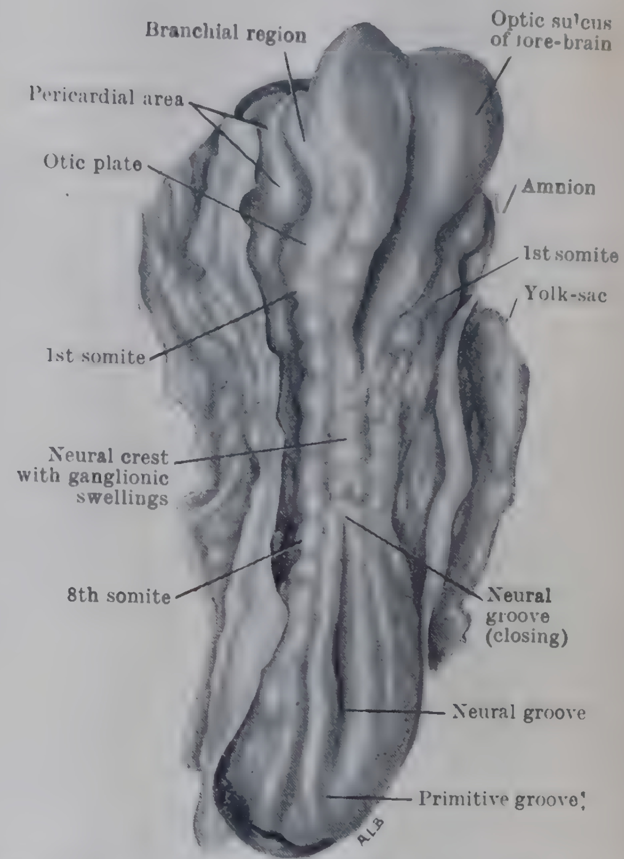

FIG. 115.—DORSAL VIEW OF 2·2 MM. HUMAN EMBRYO OF 22 DAYS. × 40. (After F. Payne, *Carnegie Contrib. Embryol.*, 1925.) The neural groove is closed in the future cervical region, the brain vesicles though still open are beginning to take shape, the site of origin of the optic vesicle is indicated, and there are 7 pairs of somites present.

(CR).[1] During this week the lens of the eye appears as a thickening of the surface-ectoderm, sinks into the interior of the eyeball, becomes a vesicle and separates from the surface. The three segments of the upper limb become visible, and the rudiments of the fingers appear. The lower limb is less advanced; the thigh segment is not distinct, and the rudiments of the toes are not yet visible. The third and fourth pharyngeal arches disappear from the surface and lie in the depths of the cervical sinus, overlapped by the caudal margin of the second arch (see p. 66) (Fig. 81). During the sixth week the head grows rapidly and becomes relatively very large in comparison with the trunk.

During this week also the olfactory pits appear between the median and the lateral nasal processes, and grow dorsally into the roof of the oral pit; the median process is divided into the two globular processes; and the maxillary processes of the mandibular arches, growing towards the median plane, fuse with the lateral nasal and the globular processes, so completing the lateral parts of the primitive upper lip (Figs. 76-77).

The nodular outgrowths which form the rudiments of the auricle appear on the margins of the first pharyngeal groove and begin to fuse together (Fig. 119).

By the **seventh week** the embryo has attained a length of 17-18 mm. (CR). The cervical

[1] CR indicates the crown-rump measurement which corresponds with the sitting-height (Mall, 1910).

flexure has begun to straighten. The rudiments of the eyelids have appeared. The globular processes have fused together, but there is still a distinct notch in the middle of the upper lip. The margins of the auricles are now well defined; the hands are folded medially; the tips of the fingers are free, and the palms rest on the upper part of the distended abdomen. The thighs and the toes have appeared, and the tail has begun to fuse with the caudal end of the trunk (Fig. 120).

At the end of the **eighth week,** when the embryo becomes a fœtus, it has attained a

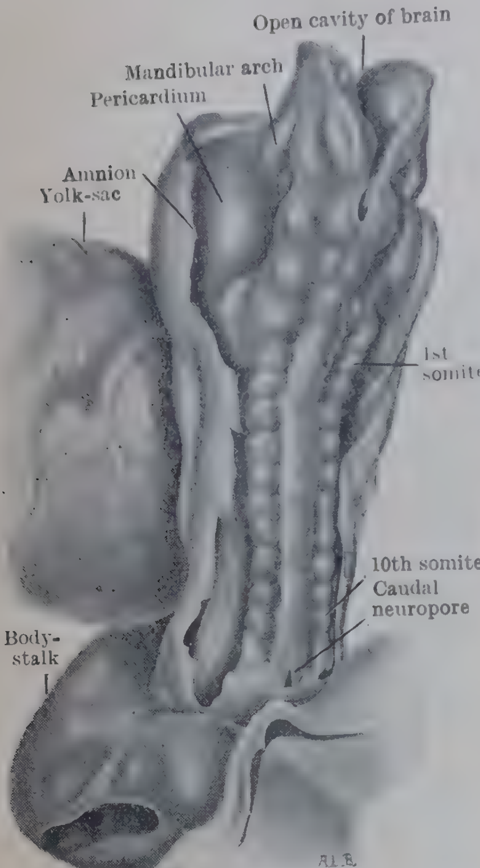

FIG. 116.—DORSAL VIEW OF 2·3 MM. HUMAN EMBRYO OF 23 DAYS. × 30. (After G. W. Corner, *Carnegie Contrib. Embryol.*, 1929.) The closure of the neural groove has advanced almost to the stage of cephalic and caudal neuropores. The three brain-vesicles are forming, the pericardium and the mandibular arch are evident, and there are 10 pairs of somites present.

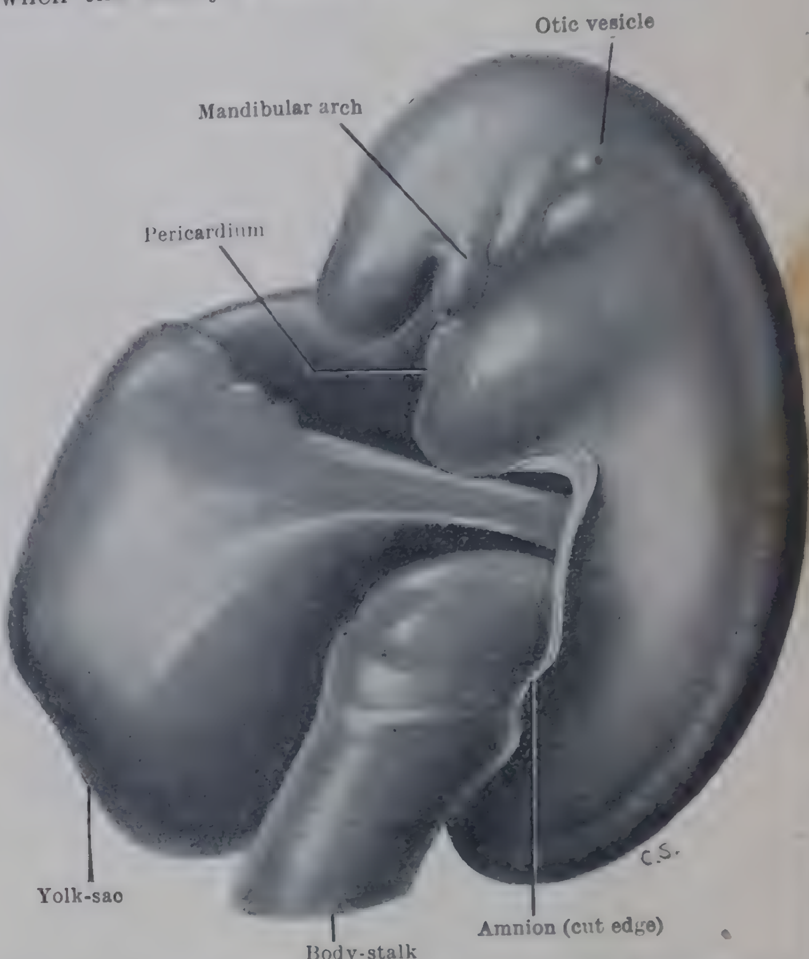

FIG. 117.—HUMAN EMBRYO, 2·5 MM. LONG, WITH TWENTY-THREE PAIRS OF SOMITES. × 34. (After Thompson, 1907.) The head is small and flattened; the optic vesicles project slightly from the fore-brain, and the position of the otic vesicle is indicated. The yolk-sac, still relatively large, is connected to the alimentary canal through the vitelline duct which, with the body-stalk, emerges from the umbilical orifice. The position of the somites is indicated by slight elevations of the surface. There is no trace of the limbs. For reconstruction of this embryo, see Fig. 75, p. 62.

length of about 25 to 30 mm. (CR). The auricles project from the sides of the head, the tail has almost disappeared from the surface, and the toes are free from one another. The external genital organs are developing and the genital tubercle is evident. The cervical flexure is now very slight, and although the head is still relatively large, the disproportion between it and the trunk has begun to decrease (Fig. 121).

Third Month.—The head grows less rapidly, and, though it is still large, it is relatively smaller in proportion to the whole body. The eyelids close, and their margins fuse together. The neck increases in length. The parts of the limbs begin to assume their proper proportions, and nails appear on the fingers and toes. The anal pit is formed and the external genital organs are sufficiently differentiated for the sex to be distinguished. The skin is a rosy colour, thin and delicate, and of firmer consistence than in the preceding stages. By the end of the third month the CR length of the fœtus is about 100 mm. (nearly 4 in.), and it weighs about 50 grams (2 oz.).

Fourth Month.—The skin is firmer, and fine, downy hairs (lanugo) are developed. The disproportion between the upper and lower limbs is less. A fœtus born at this period may live for a few hours. Its CR length is about 145 mm. ($5\frac{1}{2}$ in.), and it weighs 200 grams (7 oz.).

Fifth Month.—The skin becomes firmer, the hairs are more developed, and sebaceous

matter appears on the surface of the body. The lower limbs are still shorter than the upper, and the umbilicus is farther from the pubis. At the end of the month the CR length of the fœtus is 190 to 200 mm. (about $7\frac{1}{2}$ in.), and its average weight is 460 grams (about 1 lb.).

Sixth Month. — The skin is wrinkled and of a muddy, reddish colour. The hairs are stronger and darker. The deposit of sebaceous matter is greater, especially in the armpits and groins. The eyelashes and eyebrows appear. At the end of the month the CR length of the fœtus is 230 to 240 mm. (9-$9\frac{1}{4}$ in.), and its average weight is about 1 kilogram ($2\frac{1}{5}$ lbs.).

Seventh Month.—The skin is still a muddy-red colour, but it is lighter than in the previous month. The body is more plump on account of a greater deposit of subcutaneous fat. The eyelids have reopened. A fœtus born at this period is capable of living and may survive. Its CR length at the end of the month is about 250 mm. (11 in.), and its weight is about 1·5 kilograms (over 3 lbs.).

Eighth Month.—The skin is of a bright red tint and is completely covered with sebaceous deposit, which is thickest on the head and in the armpits and groins. The umbilicus is farther from the pubis, but it is not yet at the centre of the trunk. The CR length of the fœtus is 300 to 320 mm. (12-$12\frac{1}{2}$ in.), and its weight about 2 to 2·5 kilograms ($4\frac{1}{2}$-$5\frac{1}{2}$ lbs.).

Ninth Month. — The hair begins to disappear from the trunk, but it remains long and abundant on the head. The skin becomes paler, the plumpness increases, and the umbilicus reaches the centre of the trunk. During this month the nails reach

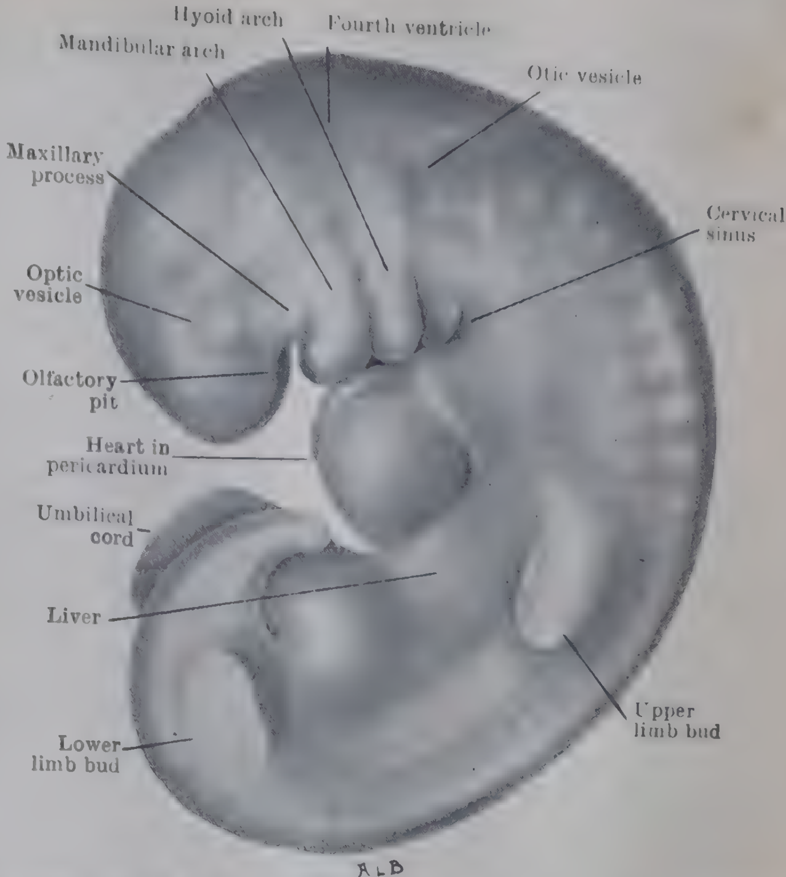

FIG. 118.—HUMAN EMBRYO, 5·5 MM. CR LENGTH. (After G. L. Streeter, *Carnegie Contrib. Embryol.*, 1945; Embryo No. 6830.) The limb-buds are now quite distinct (cf. Fig. 72, p. 58) and the upper limb is beginning to elongate and curve forward. The maxillary process has grown forward below the eye, and the cervical sinus is evident.

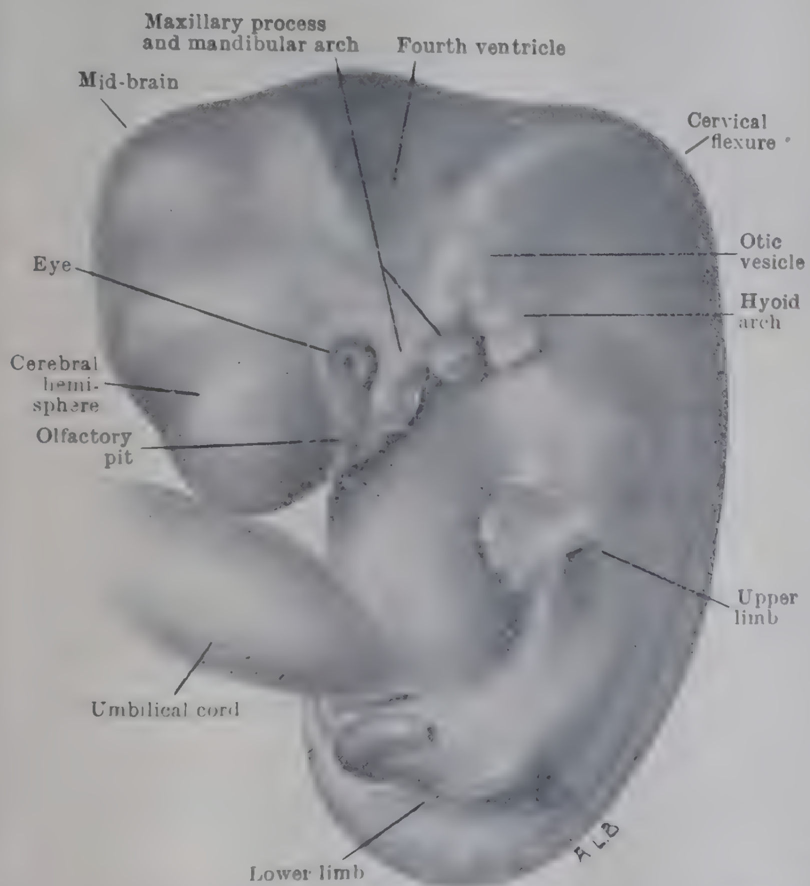

Fig. 119.—HUMAN EMBRYO, 13 MM. CR LENGTH. (After G. L. Streeter, *Carnegie Contrib. Embryol.*, 1948; Embryo No. 8101.) The limbs are bent ventrally and show differentiation into segments. The cervical sinus is closing and rudiments of the auricle of the external ear are present on the first and second arches. The pontine flexure of the hind-brain, the fourth ventricle and the olfactory pit are evident.

the ends of the fingers. At the end of the month, when the fœtus is born, its CR length is from 340 to 360 mm. ($13\frac{1}{2}$-14 in.), and it weighs from 3 to 3·5 kilograms ($6\frac{1}{2}$-$7\frac{1}{2}$ lbs.).

Age, Length, and Weight of Embryo and Fœtus.—The lengths and weights of embryos and fœtuses at increasing ages given in the foregoing summary are compiled from a number of sources. It must be understood, however, that they are only approximate, since embryos and fœtuses of the same length, or of the same weight, or even at the same stage of development, are not necessarily of the same age (Streeter, 1942). Moreover, it is usually impossible to calculate the *actual* age of an embryo (dating from the time of fertilization) and the age assigned (except in the case of some young embryos for which the data necessary for the calculation of fertilization-age are available) is then the *menstrual* age, dating from the first day of the last menstruation. Owing to the average time of ovulation in relation to the menstrual cycle, the menstrual age of the majority of embryos is probably at least fourteen days more than the actual age. The usual

Fig. 120.—Human Embryo, 18·5 mm. greatest length, about Seven Weeks Old. The abdomen is very prominent on account of the rapid increase of the liver. The digits of the hand and foot are distinct but not separated from one another. The margin of the auricle is completed. The eyelids have begun to form. Cf. Fig. 121a, p. 101.

Fig. 121.—Human Fœtus at the beginning of the Third Month. The cervical flexure is now slight. The upper limbs have assumed a characteristic position with the hands in front of the face, and the toes are free. The tail has almost disappeared, and the genital tubercle is evident.

method of calculating the duration of pregnancy by counting 280 days from the first day of the last menstruation gives in any case only the approximate date of parturition.

It should also be noted that the 'greatest length' of an embryo (excluding the lower limbs) depends upon the cervical flexure. While the head of the embryo is fully flexed the crown-rump measurement (CR) is less than the greatest length, but later the two measurements are the same.

Formulæ for the calculation of age from length have been devised, but it is more satisfactory to use tables and graphs (constructed from extensive data) from which the probable range of age can be read at a glance (Streeter, 1921).

FIG.—121A.—PHOTOGRAPH OF 21 MM. HUMAN EMBRYO IN AMNION AND CHORION. × 2·5.
For the form of the embryo, cf. Fig. 120; and note the position of the definitive yolk-sac between the expanding amnion and the chorion. (Carnegie No. 8537A; by special permission of Dr. George W. Corner.)

PLATE I.—RADIOGRAPH OF EIGHT-MONTHS FŒTUS (EVISCERATED) TO SHOW THE STATE OF OSSIFICATION OF THE SKELETON. THE RIGHT FOREARM IS SUPINATED, THE LEFT PRONATED.

Note the absence of ossific centres for the Carpus and the presence of centres for the Talus and Calcaneum (cf. Plate XVIII, Fig. 1, p. 273, and Plate XXVIII, Fig. 1, p. 321). Minute centres of ossification for the lower epiphysis of the right Femur and the upper epiphysis of the left Tibia are also faintly visible.

PLATE II

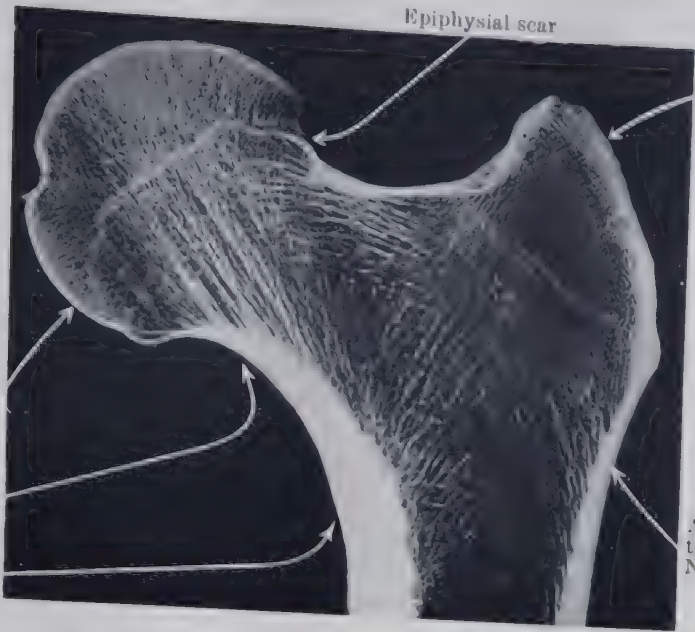
Fig. 1.—Photograph of Coronal Section of Upper End of Left Femur to show its Architecture.

Note how the compact bone of the Shaft thins out over the Greater Trochanter and the Head, and the manner of crossing of the different systems of lamellæ in the spongy bone.

Fig. 2.—Photograph of Sagittal Section of Calcaneum to show its Architecture.

Note the thin shell of compact bone and the arrangement of the lamellæ of the spongy bone in two main systems.

PLATE III



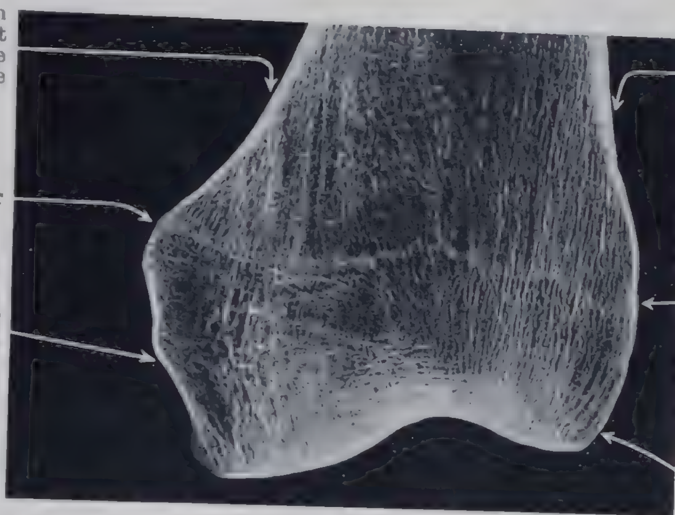


Plate III.—Radiographs of Coronal Sections of A. Upper End of Femur; B. Lower End of Femur; C. Upper End of Tibia, of a Woman aged 34.

Note the persisting epiphysial scars and the arrangement of the systems of lamellæ in the spongy bone.

PLATE IV

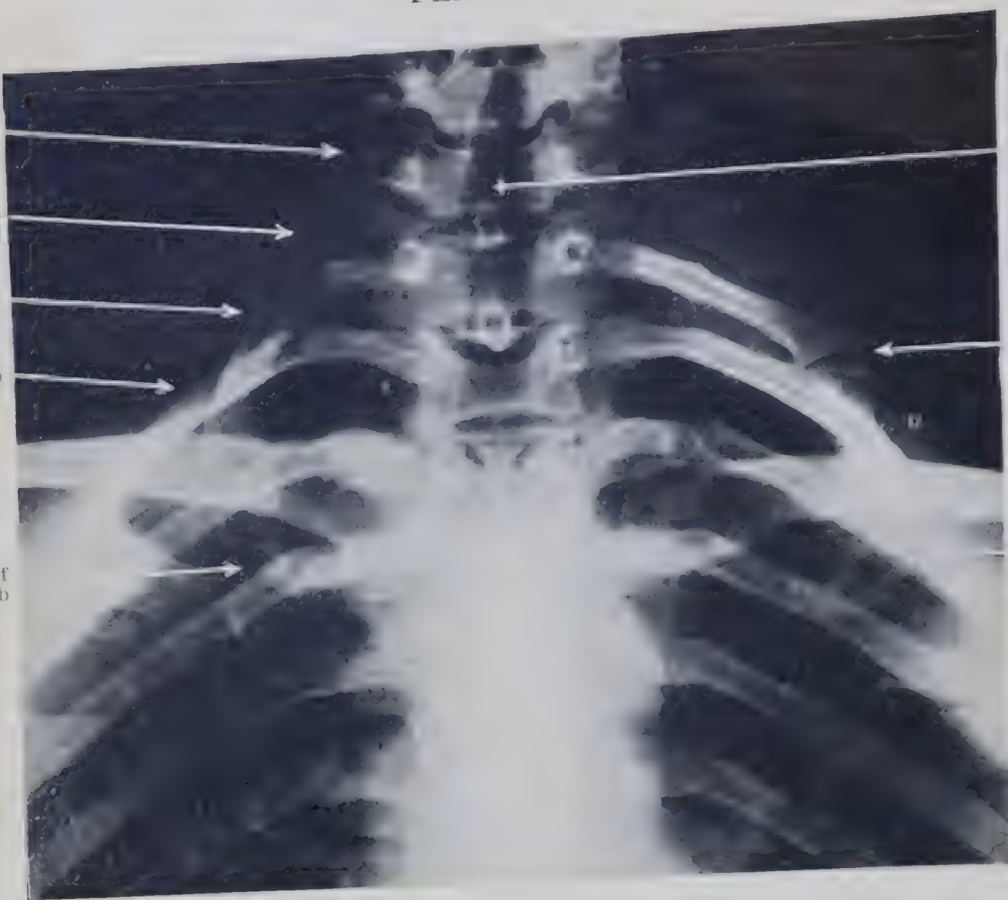

FIG. 1.—RADIOGRAPH OF CERVICO-THORACIC REGION OF WOMAN AGED 35, SHOWING A PAIR OF WELL-DEVELOPED CERVICAL RIBS.

Note the asymmetry of the cervical ribs and that the left one articulates with a projecting process of the first thoracic rib. For view of the right cervical rib on a larger scale see Plate LXVIII, Fig. 2, p. 721, which shows also more clearly the evidence of the presence of a " lobe of the vena azygos " in the right lung.

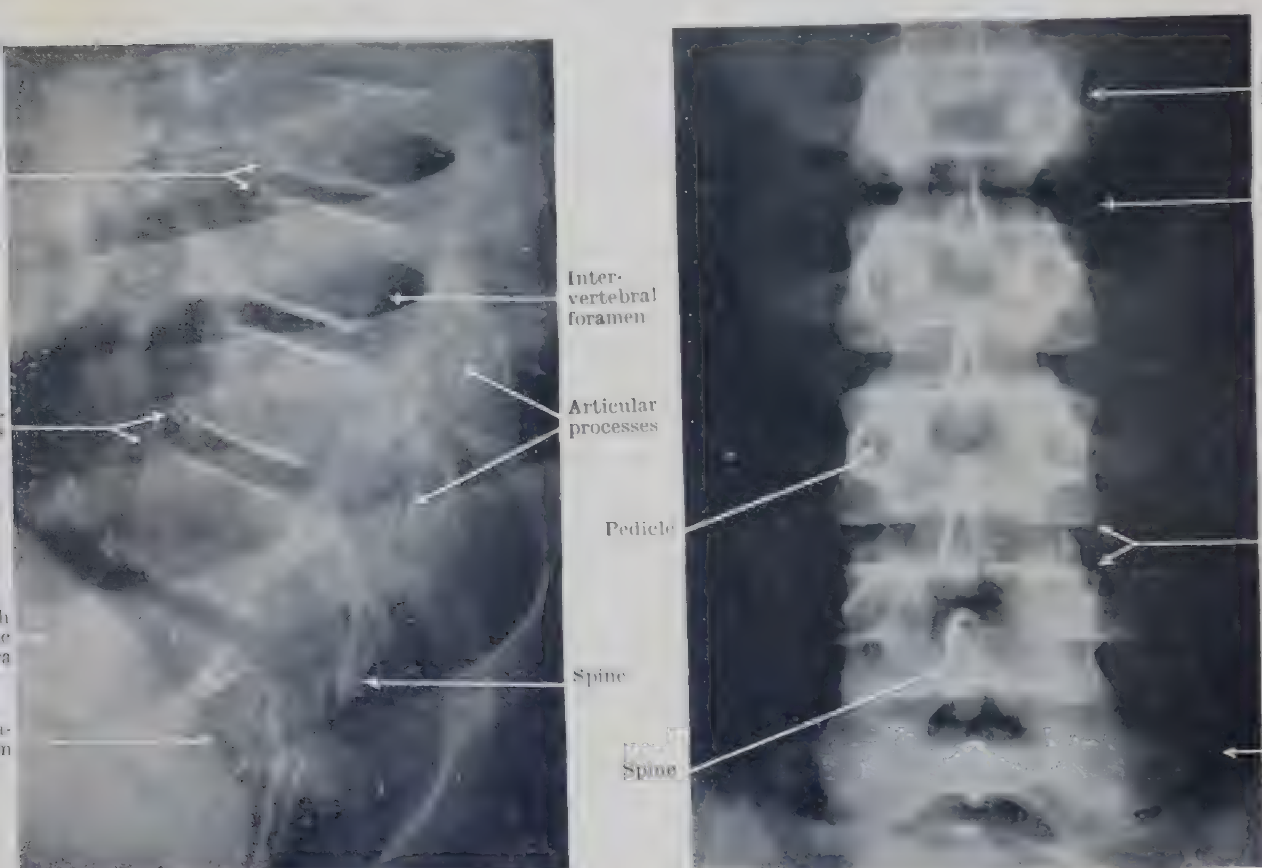

FIG. 2.—RADIOGRAPHS OF (A) THORACIC AND (B) LUMBAR VERTEBRÆ OF A GIRL AGED 12, SHOWING THE EPIPHYSES OF THE VERTEBRAL BODIES.

INTRODUCTION

BONES AND CARTILAGES

The body is supported by an internal framework or *skeleton* of **bones** [σκελετός (skeletos) = dried]. This skeleton accounts for about one-seventh of the body-weight in a man and rather less in a woman; and the bones are supplemented in many places by gristle or **cartilage**—more so in a growing person than in an adult.

Uses of Bones.—Bones give support to the softer tissues which surround them and in some cases form protective boxes or cages for internal organs such as, for example, the brain in the skull, the heart and lungs in the chest and the spinal cord in the backbone. They also act as levers to which muscles or their tendons are attached and can transmit either tensile or compression stresses without appreciable deformation.

In addition, the spaces found inside bones are used for the production of blood-cells, for these spaces contain bone-marrow in which the blood-corpuscles develop, and the bone-substance itself is a store of lime-salts upon which the body may draw when necessary.

Articulation of Bones (see also the Section on Joints).—Since a continuous rigid framework would prevent movement, the bony skeleton is divided into separate bones joined by softer tissues which are, as a rule, sufficiently flexible to allow movement to take place.

The union between two or more adjacent bones is called a joint or *articulation* (*articulus*, diminutive of *artus* = a joint) and the bones so united are said to *articulate* with each other at the joint. The surface of one bone which comes into direct relation with another at a joint is its **articular surface** and, when the bones can glide or rotate on each other freely, an actual space is present between them; the articular areas are then covered with an adherent layer of smooth glistening **articular cartilage**. The bone underlying the cartilage is also smooth so that the articular part of a dried bone is easily identified even although the cartilage has been removed. In other cases, where less movement is required, the union of adjacent bones is made by some form of connective tissue, such as fibrous tissue or cartilage, when the articular surface will usually be rough; or else the union may be made complete by fusion of the two bones so that movement is prevented. Movements at joints are controlled or produced chiefly by muscles which are attached to the bones, but the bones are held together by all the tissues which surround them. In the majority of cases fibrous tissue runs from bone to bone as thickened bands or ligaments (*ligamentum* = a band or bandage, from *ligare* = to bind). These ligaments or other soft tissues maintain the continuity of the skeleton and transmit tensile stresses when required. Compression stresses cannot be transmitted through ligaments of this kind and the articular ends of long bones are likely to be enlarged so as to distribute such stresses and provide a good bearing surface in any normal position of the joint.

Constituents of Bone.—On analysis, bone can be broken down into approximately equal parts of solids and water. The solids are partly organic matter (31 per cent)

and partly inorganic (69 per cent). The *inorganic matter* consists of various *mineral salts*, the chief of which is calcium phosphate. This makes up over 80 per cent of the mineral or inorganic matter, though not necessarily in such a simple form, and, because of its abundance, bones are one of the sources of phosphorus. The *organic matter* is *white fibrous tissue*. It consists of:—(*a*) fine fibres embedded in a little amorphous material, called 'ground-substance', which unites the fibres into interlacing bundles; (*b*) connective-tissue cells, called *bone-corpuscles*, placed in rows among the bundles of fibres. The ground substance is completely impregnated with the mineral salts and a bone which has been burned to destroy the connective tissue element (calcined) still retains its form, though it becomes brittle and inelastic and may crumble. On the other hand, if the mineral salts are removed from a bone by soaking it in dilute acid, the bone again retains its form completely but becomes flexible. It can be cut with a knife and a sufficiently long and thin bone can be tied in a knot. Bones are therefore not only hard but, because of the fibrous tissue, are also tough and elastic. This combination of organic and inorganic substances makes bones almost unique in that resistance to compression and extension is nearly equal (D'Arcy Thompson, 1942). In old age bones become more brittle owing to diminution of the elasticity of the fibrous tissue and not to any increase in the salts.

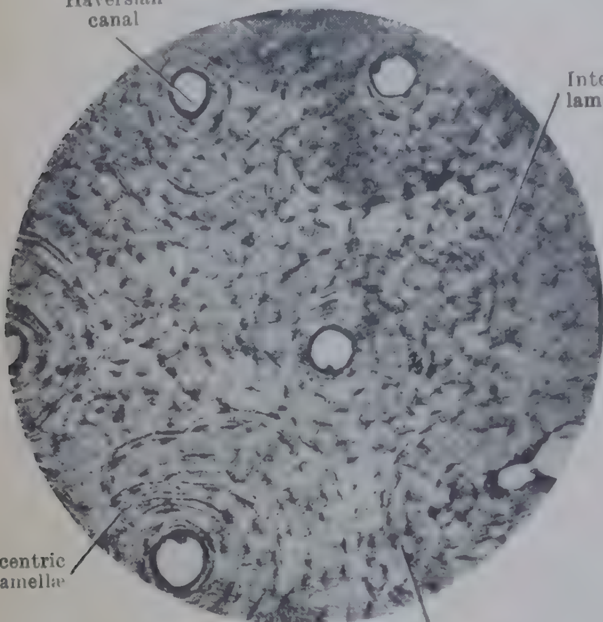

FIG. 122.—PHOTOGRAPH OF GROUND TRANSVERSE SECTION OF COMPACT BONE, showing Haversian systems (Haversian canal, concentric lamellæ, lacunæ, and canaliculi). × *c*. 75.

Structure of Bone.—There is only one kind of bone, but it may be either compact or spongy in texture (see Plate II, p. 104). **Compact bone** is hard and dense and forms the outer shell of a bone within its covering of periosteum (see p. 109). It is frequently thick and strong and is well seen when the shaft of a long bone, such as the thigh bone or femur, is sawn across. **Spongy bone** is also hard, but this is not so evident because it consists of thin intersecting lamellæ of bone substance with spaces between them, like a sponge (*lamella* or *lamina*—a leaf, blade, layer). This arrangement is well seen when the end of a long bone such as the femur is cut across. The spaces between the lamellae are filled with red marrow.

The **microscopical structure of bone** is essentially the same in the spongy and compact varieties and is closely associated with its mode of formation. Bone substance is laid down in two ways :—(a) Successive thin layers are formed under the periosteum. These lie approximately parallel with the surface and are called **periosteal lamellæ.** (*b*) Successive thin concentric layers are deposited around blood-vessels so as to form canals which therefore contain the blood-vessels as well as any lymph-channels, nerves and loose areolar tissue associated with them. The systems of tubular lamellæ so formed are called **Haversian systems** (after Clopton Havers who first described them in detail, 1691) and consist of three to ten or more concentric tubes, the **Haversian lamellæ**, which surround the central cavity named the **Haversian canal**. The cells associated with the laying down of bone are named **osteoblasts.** Numbers of them are trapped between the lamellæ during development and remain as **osteocytes** or **bone-corpuscles** in the substance of the bone. The minute cavities occupied by the bone-corpuscles during life are called **lacunæ** (*lacuna*—a pit, hole, or cavity) and, since the living cells are connected with each other by slender cytoplasmic processes, the substance of the lamellæ formed around them is penetrated by minute channels. These are called **canaliculi** and connect

neighbouring lacunæ with each other. The lacunæ of adjacent systems, however, seldom communicate. Bone is first laid down in its spongy form, but is thereafter continually changing its shape and structure by removal of bone already present and deposition of fresh bone arranged to suit new requirements. In consequence, the more recently formed Haversian systems have between them the remains of older Haversian systems or of periosteal lamellæ. These are termed **interstitial lamellæ**; periosteal lamellæ which lie nearer the surface and are unbroken by the Haversian systems are referred to as **circumferential lamellæ.** Bundles of collagenous fibres belonging to the surrounding fibrous tissue become incorporated in the periosteal lamellæ and calcified. These calcified bundles usually pass at right angles to the lamellæ, as though nailing them together, and are called the **perforating fibres** of Sharpey (1856).

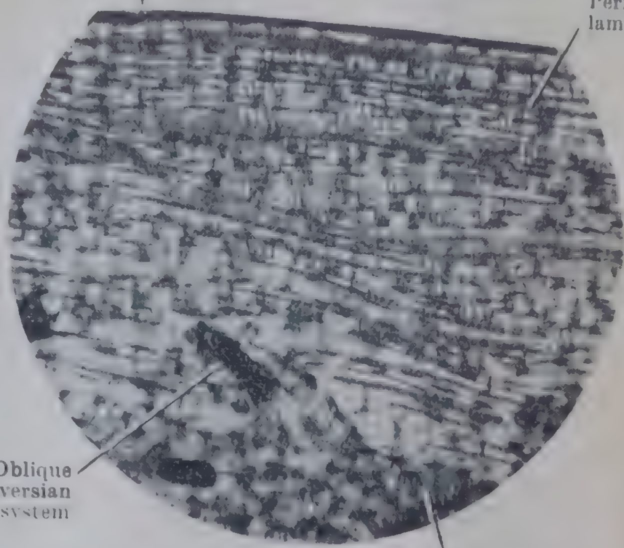

FIG. 123.—PHOTOGRAPH OF GROUND LONGITUDINAL SECTION OF COMPACT BONE, showing periosteal lamellæ parallel to surface above and Haversian systems cut obliquely below. × c. 75.

Architecture of Bone.—Although there is still doubt as to the actual mechanism—chemical, cytological, physical or mechanical, or a combination of these—which results in the absorption or deposition of bone, the resultant form and structure of any bone is peculiarly well adapted to its function of resisting mechanical stresses and is continually being modified to keep it so until ageing or decay leads to failure of the process.

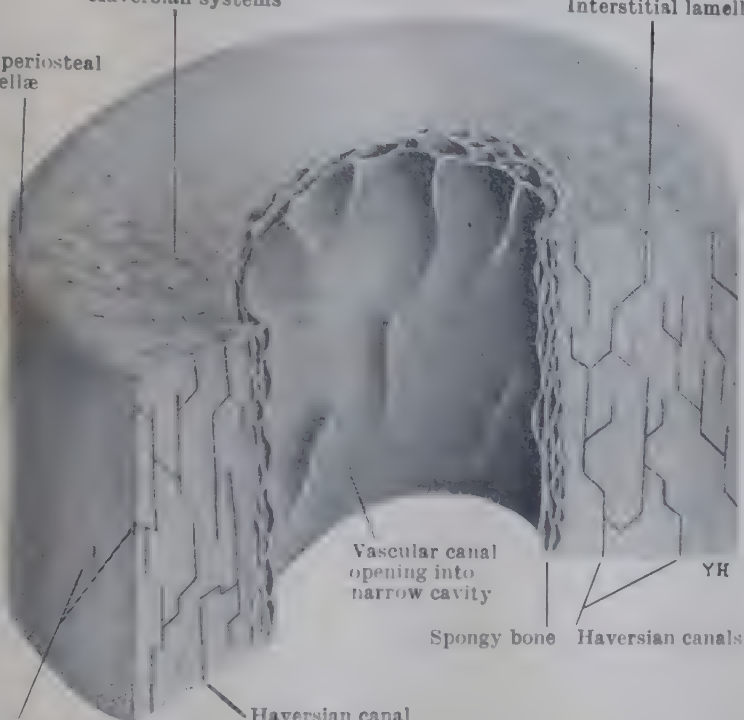

FIG. 124.—DIAGRAM TO ILLUSTRATE THE ESSENTIAL LAMELLAR STRUCTURE OF BONE. (After Le Gros Clark, 1945.) The Haversian systems are represented out of proportion in order to indicate schematically their arrangement in a long bone.

Two fundamental factors lead to strength and economy of material. The first of these is the intimate combination of mineral salts and fibrous tissue already mentioned. The other is the use of microscopic tubular lamellæ as basic units which resist bending equally in any direction and are hollow, to economize material where it is least required.

The sections of femur and calcaneum shown in Plate II, demonstrate the essential features of the architecture of bone. The bone-substance forms *macroscopic lamellæ*, or *trabeculæ*, running in definite directions suited to function. In the shaft of the femur (lower part of Fig. 1) the lamellæ are concentrated at the periphery and merge to form thick compact bone capable of resisting bending stresses while the interior is free of bone substance and constitutes the marrow-cavity. The upper end only of this cavity is shown in the illustration. In the upper end of the femur the lamellæ spring from the compact bone, diverge, and arch over to reach the head of the bone

and the greater trochanter. Other systems arch between the head and the trochanter or run from the surface of the head straight to the compact bone of the neck.

In the case of the calcaneum, or heel-bone, the heel is at the right lower corner of the illustration. Coarse lamellæ can be seen which transmit the weight of the body from the articular facets back towards the heel and forwards towards the ball of the foot. Other finer lamellæ curve forwards from the back of the heel to the lower part of the heel and to the front of the bone, intersecting the other systems and transmitting the pull of the tendon of the calf-muscles. In the space between these systems there is less stress and consequently a more open texture comparable to Ward's triangle in the neck of the femur (p. 298).

It must be emphasized that, to get a correct interpretation, the structural arrangements found in any bone must not be considered alone. Adjacent bones and soft tissues, particularly muscles, cause both tension and compression, which have to be taken into account. Also, it has to be borne in mind that conditions vary when joints are moved from one position to another (Carey, 1929) and effectively arranged lamellæ must be available for any normal position of the joint. The way in which lamellæ are arranged to transmit normal stresses from bone to bone is illustrated in Fig. 125 which may be compared with the radiographs in Plate III, p. 105. The classical example of bone-architecture is the arrangement found in the neck of the femur (see p. 297).

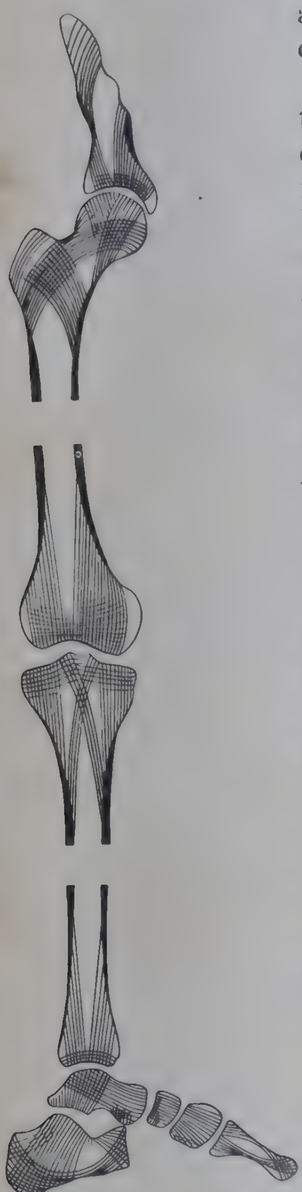

Fig. 125.—Diagram of the Architecture of the Bones of the Lower Limb. (After Meyer, 1867.)

Classification of Bones.—The bones are divided into four classes according to their shape: long, short, flat, irregular.

Long bones are found in the limbs, *e.g.*, the *humerus* or bone of the upper arm and the *femur* or thigh-bone. Small elongated bones, such as those of the fingers and toes, are called **miniature long bones**. Each long bone has a *shaft* and *two ends*. The **shaft** is a hollow, thick-walled rod of compact bone. The space inside is called the **medullary cavity**, and, when the bone is fresh, it is filled with soft, yellowish material known as *yellow marrow* [*medulla* = marrow]; the yellow colour is due to abundance of fat. Around the medullary cavity, inside the compact bone, there is a zone of coarse spongy bone. The medullary cavity serves not only for the lodgment of the marrow. Its presence saves bone-substance—with little diminution in strength, for up to a certain point a hollow cylinder is almost as resistant as a solid one of the same thickness and material. The shaft of a long bone is never quite straight but it is curved usually in more than one plane. To compensate for these curvatures there is a greater thickness of compact bony tissue in the concavities of the curves than elsewhere. The **ends** of a long bone are broader and thicker than the shaft. They consist of spongy bone covered with a thin layer of compact bone; the cavities in the sponge-work again economize in bone-substance and accommodate red marrow. The objects gained by the greater bulk of the end of the bone are :—(1) The surface for articulation is wider, and therefore movements at the joint can be regulated more precisely; (2) the chances of dislocation are diminished; (3) shocks received by the bone are diffused.

Short bones are more or less cubical in shape. They consist of spongy bone enclosed in a thin shell of compact bone. The short bones are the eight *bones of the wrist*, the seven *bones of the hinder half of the foot* and the *sesamoid bones.* A **sesamoid bone** is one which is developed in the substance of a tendon or sinew; the patella or knee-cap is by far the largest of these. They get their name from the resemblance that some of them have to sesame seeds.

Flat bones are such as the *ribs*, the *shoulder-blade*, and the bones of the *skull*

cap. They are thin rather than flat, for nearly all 'flat' bones are curved or bent. Each is made up of two plates of compact bone which enclose between them a layer of spongy bone. In the flat bones of the skull the layer of spongy substance is called the **diploë** [διπλόη (diploē) = a fold or doubling, a junction of two plates]; and in the diploë the marrow is largely replaced by venous blood-channels.

Irregular bones are of various shapes, and include all those that cannot be classed as long or short or flat. Many of the *skull-bones* are irregular, and so are the *vertebræ*. The thinner parts of irregular bones are like flat bones—two plates of compact substance with spongy substance between them. The bulky parts, especially in vertebræ, are like short bones, and consist of spongy substance surrounded with a layer of compact substance.

In the skull, most of the flat bones and many of the irregular bones have spongy substance between their two layers of compact substance, but in some of them the spongy tissue is invaded and replaced by cavities which contain air—the walls of the cavities being composed of compact bone. These cavities are **air-sinuses**; they give lightness to the bones and act as resonating chambers for the voice; they are extensions from the cavity of the nose, with which they are permanently in communication (Figs. 163-166) and their walls are lined on the inside with *muco-endosteum*, which is continuous with the muco-periosteum that lines the interior of the nose. Inflammation of the mucous lining of the nose in a "cold in the head" may extend to the lining of the sinuses and give rise to dull headaches. The air-spaces in the part of the skull called the mastoid temporal are extensions from the cavity of the tympanum or drum of the ear, and lie in the midst of spongy bone, replacing the marrow and some of the spongy substance. The bones of the skull which contain air-cavities are called **pneumatic bones** [πνεῦμα (pneuma) = wind or air].

Characters of Living Bone.—The following five points are to be noted with reference to a bone when it is living, or when it has been only recently removed from the body and has not been cleaned and dried.

(1) The articular parts of most bones are covered with a layer of **articular cartilage**; and, at those joints at which the bones are free to move, the articular cartilage is smooth to facilitate movement. But many of the bones of the skull, for example, have no articular cartilage: their articulating margins are rough and are united by fibrous tissue.

(2) The whole of the bone, except the articular part, is covered with a laminated membrane of fibrous tissue called **periosteum** [περί (peri) = around; ὀστέον (osteon) = a bone]. The periosteum is adherent to the bone owing to the number of blood-vessels and nerves which pass from the periosteum into the bone, and because numerous minute bundles of fibres, the *perforating fibres* of Sharpey, pass from the periosteum into the substance of the bone; within the bone the bundles are calcified like the rest of the bone, and 'nail' the bone-lamellæ together. The blood-vessels which carry blood to and from the bone and marrow lie in the periosteum before they enter the bone (arteries), and after they leave it (veins); if the periosteum is stripped off a living bone by accident or disease the underlying part of the bone may die owing to the loss of its blood-supply.

(3) The muscles, tendons, intermuscular fibrous septa [*septum* = a hedge, barrier, partition], and the ligaments are attached partly to the periosteum and partly to the bone directly. In muscles with fleshy attachments the muscle-fibres have microscopic tendinous ends which blend with the periosteum; some of the fibres of the tendons, the septa, and the ligaments blend with the periosteum, but a great many are prolonged into the bone as perforating fibres, and the tendons, etc., are therefore firmly attached to bone, being, in fact, in continuity with the non-calcareous part of it.

(4) The medullary cavity is filled with yellow marrow, and the cavities in spongy bone with red marrow.

(5) The cavities in spongy bone are lined with a delicate membrane of fibrous tissue called **endosteum** [ἔνδον (endon) = within]; and, in a long bone, the medullary cavity is lined with endosteum continuous with that in the ends of the bone. The endosteum is connected with the periosteum on the outside by means of the fibrous lining of the tunnels through which the blood-vessels pass.

Bone-Marrow.—Red and white blood-corpuscles are formed in the bone-marrow. After birth the marrow is the only normal source of the red corpuscles; and, in adults, the marrow

is the chief source of those varieties of white corpuscles that have distinctly stainable granules. Blood-platelets also are possibly formed in the marrow. In infants, red marrow pervades all bones. In the long bones, it is found not only in the spongy parts but also in the medullary cavity and even in the larger Haversian canals. It is gradually replaced by yellow marrow. At puberty the red marrow is found only in the spongy bone; and, as age advances, it is replaced by yellow marrow in the spongy bone of peripheral parts—distal ends of long bones and the lower part of the backbone (Piney, 1922). Red marrow persists in the sternum throughout life, and samples for examination are obtained clinically by *sternal puncture*. But, in certain diseases of the blood, the red marrow may increase, invade its former territories and replace the yellow marrow.

The **yellow marrow** is simple in structure. It is adipose tissue, and is the most purely fatty tissue in the body; but it still contains a few cells that give rise to blood-corpuscles.

The **red marrow** is the important blood-forming organ. It consists of a large number of cells contained in the meshes of a delicate sponge-work of reticular tissue in which numerous blood-vessels—chiefly veins—ramify and anastomose. The red marrow owes its colour to the red cells inside and outside the vessels. The cells are of different kinds:—(1) A large number of amœboid marrow-cells or myelocytes; (2) white blood-corpuscles; (3) erythroblasts; (4) red blood-corpuscles; (5) a few giant cells; (6) a few large fat-cells. The **marrow-cells** give rise to *white blood-corpuscles* by mitotic division. The **erythroblasts** are nucleated cells of two varieties—a larger and a smaller—and are reddish [ἐρυθρός (erythros) = red]. The larger give rise to the smaller by mitotic division. The smaller ones give rise to the *red blood-corpuscles* by losing their nuclei (probably by extrusion) and by becoming flattened discs. The **giant cells** resemble osteoclasts, and, indeed, are most numerous where bone is undergoing absorption, though they are not limited to such places.

The degenerated marrow found in the skull-bones of aged people is called *gelatinous marrow*.

The **blood-vessels** reach the yellow marrow through the canals in the thick, compact bone of the shaft, and they supply the bony substance on their way through it. To reach the red marrow they have to pierce only the shell of compact bone; they ramify in the red marrow, and send small twigs into the surrounding bone. Bone and fat are inactive tissues, requiring little blood; the blood-vessels in the part of the shaft that encloses the medullary cavity are therefore small and relatively few. Red marrow is an active tissue requiring a generous blood-supply; numerous blood-vessels of fairly large size therefore perforate the short and flat bones and the non-articular parts of long bones at and near their ends. The veins are larger and more numerous than the arteries; for the veins are the channels by which newly made blood-corpuscles are taken away from the marrow. Inside the spongy bone the veins are large blood-spaces enclosed by thin walls without muscular tissue.

The **nerves** that accompany arteries into the bone are probably *nervi vasorum*.

The **lymph-channels** of bone are cleft-like spaces in the areolar sheaths of the blood-vessels in the Haversian canals; and they end in the lymph-vessels of the periosteum. There are no lymph-vessels in the bone-marrow.

Appearances of a Dried Bone.—Bones used for study have been macerated and dried. In this process all structures attached to the bone, including periosteum and articular cartilage, are removed and the marrow and endosteum shrivel.

Though the articular cartilage is absent the **articular part** of a bone can still be identified. The articular cartilage that covers the upper and lower surfaces of the bodies of the vertebræ does not have a free surface but is adherent to a thick disc of fibro-cartilage (Fig. 313); and the part covered by the articular cartilage can be recognized by its peculiar appearance, which resembles unglazed porcelain. But in most bones the articular cartilage has a free surface which is smooth and glistening, and the bone covered by it is also smooth and polished; some other parts of the bone may be quite smooth but do not have the polished or glazed appearance. The numerous small apertures on the surfaces of a bone, except the articular surfaces, are the outer ends of the canals or tunnels through which the blood-vessels pass on their way to and from the bone-marrow and the substance of the bone. At the ends of a long bone, and on its shaft near the ends, these small foramina [*foramen*—a hole] are scattered, and are largest and most numerous near the margins of the articular surface. In the greater part of the shaft of a long bone the foramina are barely visible to the naked eye, but one is always relatively large and is called the **nutrient foramen**. Its position is fairly constant in different specimens of the same bone; the tunnel into which it leads is the *nutrient canal*; the vessels which pass through it are called the *nutrient artery* and *vein*, and they convey the blood to and from the yellow marrow and the substance of the shaft. The ends of a long bone have a double blood-supply—(1) from vessels that enter through their own non-articular surfaces; (2) from vessels that run into them from the adjoining parts of the shaft. In a dried bone, some of the foramina on the shaft near the end can be seen to be directed towards the end. It should be noted,

however, that no blood-vessels pass through the epiphysial plate of cartilage (see p. 116) from the shaft in the young bone (Harris, 1929).

On the exterior of bones there are many grooves and hollows, ridges, eminences, and projections. The depressions and elevations are chiefly for the attachment of muscles, tendons, and ligaments. The rough lines which often indicate the position of a muscle-attachment are made by fibrous tissue and, if present, show the position of its fibrous sheath or of fibrous septa within the muscle. For any one bone the markings vary in different bodies, but are sufficiently alike for a general description to be applicable to all. The **surfaces** of a bone are named usually from the direction in which they face; *e.g.*, a surface directed *forwards* is called the *anterior* surface. Sometimes surfaces are named according to their relative propinquity to a cavity; *e.g.*, the *outer* surface of a rib is the one farther away from the cavity of the chest. Some are named after neighbouring structures; *e.g.*, the *costal* surface of the shoulder-blade is the surface directed towards the ribs [*costa* = a rib]. The edge or ridge between two surfaces is called a **border** or margin, and is named from the direction in which it looks.

The depressions and elevations receive general names (most of which are in the list below) and special names according to their position or characters.

A student is often asked to say whether a given bone or other bilateral organ belongs to the right or the left half of the body. It is a ready means of testing whether he knows the broad, main features of the organ; for if a structure is held in the position it occupies in the erect body (*i.e.*, with its upper end upwards and its anterior surface facing forwards), then its lateral surface or end or border will look towards the side to which it belongs. If a student does not know enough about a structure to enable him to distinguish which is the upper part, which is the front, and which is the lateral part, there is little merit and no advantage in his knowing whether it is left or right.

Definition of Terms

The terms *median*, *medial*, *lateral*, etc., are explained on pp. 3 and 4.

Aditus. The entrance into a cavity. [*Aditus* = an entrance.]

Ala. A projection or a surface shaped like a wing. [*Ala* = a wing.]

Alveolus. A deep, narrow pit. [*Alveolus* = a small cavity.]

Antrum. A cavity or hollow filled with air and lined with mucous membrane in the interior of a bone. [Ἄντρον (antron) = a cave.]

Canal. A passage or tunnel; unlike the artificial watercourses of the same name, a canal has complete walls round about it.

Condyle. A smooth rounded eminence covered with articular cartilage. [Κόνδυλος (condylos) = a knuckle.]

Crest or *Crista.* A sharp, upstanding ridge of bone.

Epicondyle. A prominence or projection situated above a smooth articular eminence, though that eminence may not be called a condyle. [Ἐπί (epi) = above or upon.]

Facet. A small smooth area usually covered with articular cartilage. Nearly all smooth articular surfaces on bones are referred to at times as facets.

Foramen. A hole; it may be an aperture through which one can see, or it may be the end of a canal.

Fossa. A depression, usually broad and shallow. [*Fossa* = a ditch.]

Hiatus. A slit or gap.

Labium or *Lip.* The margin of a groove or a hollow; when a ridge or a border is thick its margins are called its lips.

Lamina or *Lamella.* A thin plate or sheet.

Ligula or *Lingula.* A projection shaped like a tongue.

Line or *Linea.* A low ridge, usually narrow.

Meatus. A short canal. [*Meatus* = a way, passage.]

Process. Any kind of projection or prolongation.

Sinus. A cavity in a bone lined with mucous membrane and filled with air; used with very different meanings in other systems. [*Sinus* = a curve, fold, interior, hiding place, bay, or gulf.]

Spina or *Spine.* A sharp-pointed projection.

Squama. A portion of bone shaped like a scale. [*Squama* = a scale.]

Sulcus. A groove or furrow.

Trochlea. A pulley or pulley shaped surface. [Τροχιλία (trochilia) = the sheave of a pulley.]

Tuber, *Tubercle*, and *Tuberosity* [*tuber* = a bump or swelling] are terms applied, without much distinction, to any kind of rounded swelling or eminence, large or small, smooth or rough. The term *tubercle*, with quite another meaning, is well known, owing to the endemic prevalence of disease caused by tubercle bacilli, but the origin of the term is the same. Tubercular diseases were so named because hard nodules or *tubercles* were found on the surface of affected organs.

Uncus. A part shaped like a hook. [*Uncus* = a hook or barb.]

Cartilage

Cartilage or gristle is present in many parts of the body. It is supplementary to bones, and in many situations it takes the place of bone. It is much

more abundant in a young animal than in an adult, for much of the cartilage present in the young animal is replaced by bone during the period of growth; but in many places cartilage persists throughout life. Cartilage is nourished by tissue fluids. Neither blood-vessels nor nerves have been found in the actual substance of cartilage, though blood-vessels are present in the clefts in the larger pieces. It is elastic, but is not hard like bone; for it consists of collagenous material impregnated with chondroitin sulphate, with only a trace of lime-salts. It is less yielding and pliable than tendons and ligaments, though it is cut more easily with a knife. Cartilage is covered with a fibrous membrane called **perichondrium**; the only exception is articular cartilage, which has a covering only on its margins. [Περί (peri) = around; χόνδρος (chondros) = cartilage.]

Classification of Cartilage.—There are three main varieties — hyaline cartilage; white fibro-cartilage; yellow fibro-cartilage.

Hyaline cartilage appears homogeneous to the naked eye and is glass-like in that it is bluish-white and translucent—hence the name 'hyaline' from ὕαλος (hyalos) = glass. It is, however, elastic and deformable by pressure and is easily cut with a knife or damaged by pressure over a small area. Hyaline cartilage is found mainly as a survival and continued growth of parts of the cartilage model which usually precedes bone in development (*vide infra*). This persistence of cartilage occurs, during growth, in *epiphyses* and between parts of a bone which ossify separately. It also occurs in the case of *articular cartilage*, which should not ossify, or else in parts which ossify late or not at all, such as the *xyphoid process* or the *costal cartilages*. Hyaline cartilage is found also in the respiratory system where it forms the cartilages of the *nose*, most of the cartilages of the *larynx* and the rings supporting the *trachea* and its branches, the *bronchi*. At birth a great deal of cartilage has been changed into bone already; but much of it still persists, especially at the ends of bones, and is gradually replaced by osseous tissue as growth goes on,

White fibro-cartilage consists of cartilage mixed with strong bundles of white fibrous tissue; it is therefore less homogeneous than hyaline cartilage and is tougher and more flexible; the fibrous tissue in it is most evident at its attachments to bone. It is found in the following situations:—(1) As *sesamoid cartilages* in a few tendons. (2) As *articular discs* in the joint between the lower jaw and the skull, the joint at each end of the collar-bone, and at the wrist joint. (3) In the shoulder joint and the hip joint, as a ring-like *labrum* attached to the rim of the articular socket of the shoulder-blade and the hip-bone. [*Labrum* = labium = a lip.] (4) In the knee joint, as two crescentic bodies called *semilunar cartilages*. (5) In the backbone as thick *intervertebral discs*, one between the bodies of each two vertebræ and attached firmly to both of them, uniting them together; these discs account for most of the white fibro-cartilage in the body; they are easily recognized between the bodies of the vertebræ on the sawn surface of a sirloin of beef. (6) A similar plate unites the two hip-bones at the *pubic symphysis*—that is, the joint in the median plane at the lower part of the front of the abdomen.

Yellow fibro-cartilage consists of cartilage containing bundles of yellow elastic fibres, but little or no white fibrous tissue. It is found in the *external ear*, in the *pharyngo-tympanic tube* (that is, the passage between the drum of the ear and the throat), and in some of the cartilages of the *larynx*.

Development of Bone

Bone is mesodermal in origin (p. 55) and develops as a sequel to the deposit of mineral salts in connective tissue, or in cartilage. The initial deposition of mineral salts is termed **calcification** which is to be distinguished from **ossification**, a term used to mean the process by which true bone is formed with its characteristic structure. When bone is formed directly in connective tissue it is referred to as **membrane bone** because of the membranous character of the tissue in which it develops. More frequently a preliminary foundation or model of cartilage is formed; this cartilage goes through the stages of calcification and ossification and is then referred to as **cartilage bone** to indicate its mode of development.

Formation of Cartilage Bone.—The first visible step is a closer aggregation of the mesodermal cells where the bone will develop. This aggregation of cells is the **rudiment** of a bone and the cells assume an appearance intermediate between fibrous tissue and cartilage, forming **pro-cartilage** which is gradually transformed into true hyaline cartilage. Each of the cells in the interior of the bone-rudiment enlarges, and as it does so it makes a thick *capsule* or envelope round about itself and then divides into two; each of the two enlarges, makes a capsule and divides; and so on—two new capsules being formed inside each older one. In that way the rudiment increases in size until a mass of tissue is formed consisting of cells—now called *cartilage-cells*—which are embedded in a dense substance of fused capsules made by the cells themselves and forming the **cartilaginous periblast** (or *matrix*—an unsuitable name.) The outermost part of the bone-rudiment is retained as the **perichondrium**, which consists of an outer layer mainly fibrous, and an inner layer mainly cells and blood-vessels. [Περί (peri) = around; βλαστάνω (blastanō) = grow; χόνδρος (chondros) = cartilage.]

Appearance of Ossific Centres.—The process of ossification begins at different dates in different bones, but nearly all the bones begin to be ossified during the second month of

intra-uterine life, and the date is fairly constant for any one bone in different subjects. The point in a bone where ossification begins is called a **centre of ossification**, and the centre is said to *appear* at such and such a date. Many of the bones are ossified from more than one centre. When several centres of ossification appear in a developing bone at widely separated dates, the first to appear is called the **primary centre** and the others are called **secondary centres**. By far the largest part of a bone is ossified from the primary centre. When ossification starts at more than one point in a bone about the same time, each is called a primary centre.

Ossification in Cartilage.—Ossification begins usually about the *middle* of a cartilage-bone. At that point there is a great *increase* both in the size of the cartilage-cells and in the amount of the substance around the cells; and the next step is the *deposition of lime-salts* in that substance. As the process spreads from the centre the *cartilage-cells* immediately ahead of the calcifying region *multiply* rapidly and become arranged in characteristic columns (Fig. 126); in that way the size of the 'bone' as a whole is increased—the multiplication and increase in a long bone taking place chiefly lengthwise. The deposit of lime-salts goes on till, in a little while, the

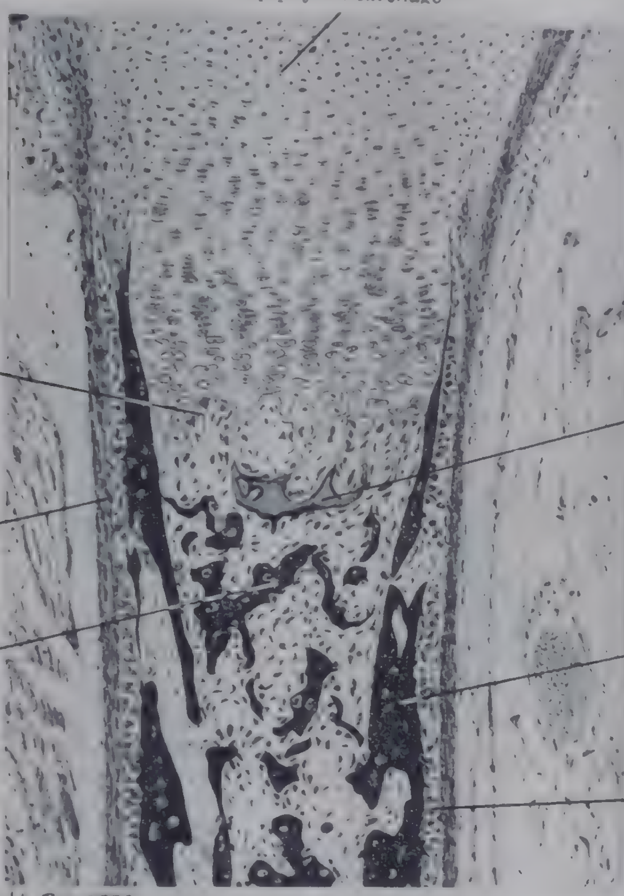

FIG. 126.—OSSIFICATION IN CARTILAGE (Le Gros Clark, 1945).

cartilage-cells become imprisoned inside the calcareous walls built around them, and, having their supply of nutriment cut off at the same time, they die and shrivel, leaving the *spaces* they occupied *nearly empty*.

This calcified cartilage is not bone, though calcification is part of the process of ossification; but while these changes have been taking place in the centre a similar change, which leads to the *production of true bone*, has been taking place on the outside of the cartilage. The cells of the deeper layer of the perichondrium have formed a clear *ground-substance* round about themselves; fibres have been laid down in that, and **bone** is produced by the deposit of lime-salts in the ground-substance between and among the cells and fibres, and, possibly, within the fibres themselves. The calcified cartilage in the interior is thus encased in bone formed by the perichondrium; the perichondrium, since it now surrounds bone, is called periosteum, and that bone is called **subperiosteal bone**.

The calcified cartilage is short-lived. Blood-vessels grow in from the deeper layers of the periosteum, and they are accompanied by more than one kind of cell. Some of these cells are called **osteoclasts** [κλάω (claō) = break, destroy]. They eat their way through the subperiosteal bone, making passages through it for the blood-vessels they accompany to run along; and when they come to the calcified cartilage they consume a great part of it and so enlarge the spaces in the interior. Other cells that accompany the blood-vessels are called *osteoblasts* or **bone-forming cells** [βλαστάνω (blastanō) = grow, produce]. They are the same kind of cells around which, and under the influence of which, the bone is formed underneath the periosteum; they form layers of bone on the calcified cartilage that the osteoclasts have so far left untouched, and

thus enclose the enlarged spaces with bony walls; the spaces become filled with marrow by the multiplication of fat-cells and other cells that accompany the blood-vessels. The remains of the calcified cartilage on which these layers of bone are laid down become in time destroyed by the osteoclasts, until no vestige of cartilage or cartilage-cells is left in the interior.

Both under the periosteum and in the interior some of the bone-forming cells are left in small lacunae between succeeding layers of bone; these lacunae are connected together by *canaliculi* through which nutritive material reaches the cells in them; the cells therefore survive, under the name of *bone-corpuscles*, as long as the bone lives.

It is not only the calcified cartilage that is destroyed by osteoclasts. The cavities in spongy adult bone are much larger than the cavities in newly-formed bone. This is because osteoclasts have removed a great quantity of the first-formed bone, so that several of the original cavities or spaces run into one. The strength of the bone, however, is maintained and increased because bone-forming cells lay down additional layers of bone on what remains of the original bone, and in that way the walls of the enlarged cavities are thickened. And it is not only in the bone which is formed in the cartilage that those changes occur; the original subperiosteal bone also is largely destroyed and is replaced by a second osseous deposit. If the horizontal diameters of the body of a vertebra of a new-born child are compared with the diameters of the body of an adult vertebra, it will be clear that only a small part in the centre of the adult bone is pre-formed in cartilage. The greater part in those diameters is formed by layer after layer deposited under the periosteum. In that subperiosteal bone the same process has gone on as in the centre—ingrowth of blood-vessels, excavation by osteoclasts, and a rebuilding and a strengthening of the remains by bone-forming cells; and that strengthening is especially marked in the last-formed layers in the adult bone so as to produce the compact bone at the surface.

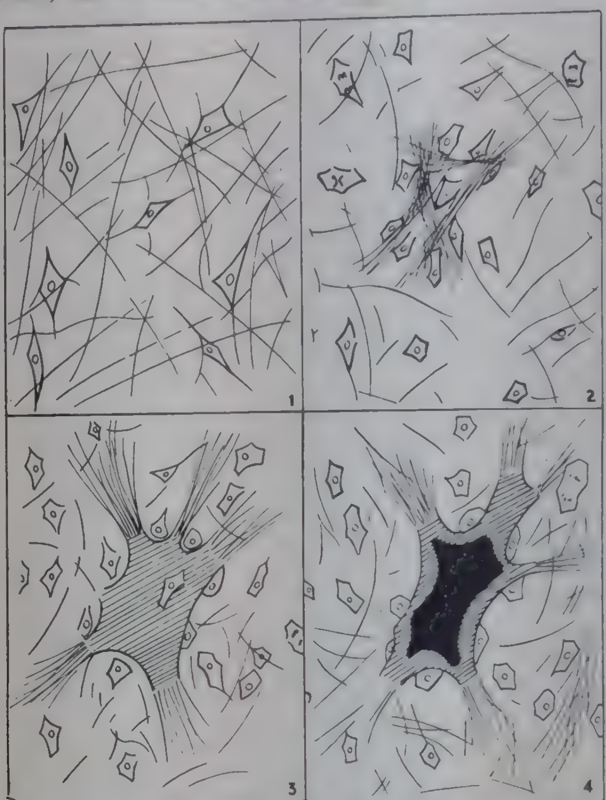

FIG. 127.—OSSIFICATION IN MEMBRANE (Leriche and Policard, 1926).

Schematic representation of the stages of formation of bone without the pre-formation of cartilage.

1. Oedema of connective tissue.
2. Multiplication of fibrils.
3. Deposit of pre-osseous ground-substance.
4. Deposit of lime-salts.

Some of the tissue which grows in with the blood-vessels from the periosteum becomes converted into the perforating fibres of Sharpey.

In bones that have a medullary cavity the osseous tissue which succeeds the calcified cartilage is entirely removed during the formation of the cavity; and, further, while new bone is being formed on the outside under the periosteum, osteoclasts are continually eating away the bony tissue next the medullary cavity in order to enlarge the cavity, both in length and width, until it attains adult size. In a bone like the femur none of the bony tissue present at birth and none that was created during early life is left at all, for the medullary cavity of the adult femur is larger than the whole femur of a child. Absorption of bone takes place also at the surface, especially at the ends of long bones—modelling them in order that their proper shape may be maintained as they grow.

The **Haversian systems** are produced in the following way:—Blood-vessels from the periosteum grow into the original subperiosteal bone, and the osteoclasts create long and relatively wide spaces around those vessels. The bone-forming cells then multiply and arrange themselves round the inside of the wall of the space, and produce layer after layer around the space, forming a series of concentric tubes, the innermost one enclosing the original space, now called the Haversian canal. As successive layers are produced, bone-forming cells are left between them as bone-corpuscles in lacunæ. Among the Haversian systems a few of the original layers of the subperiosteal bone or the remains of earlier Haversian systems survive as *interstitial lamellæ*; while, at the surface of the bone, the last-formed layers of subperiosteal bone are left unaltered as *circumferential lamellæ*.

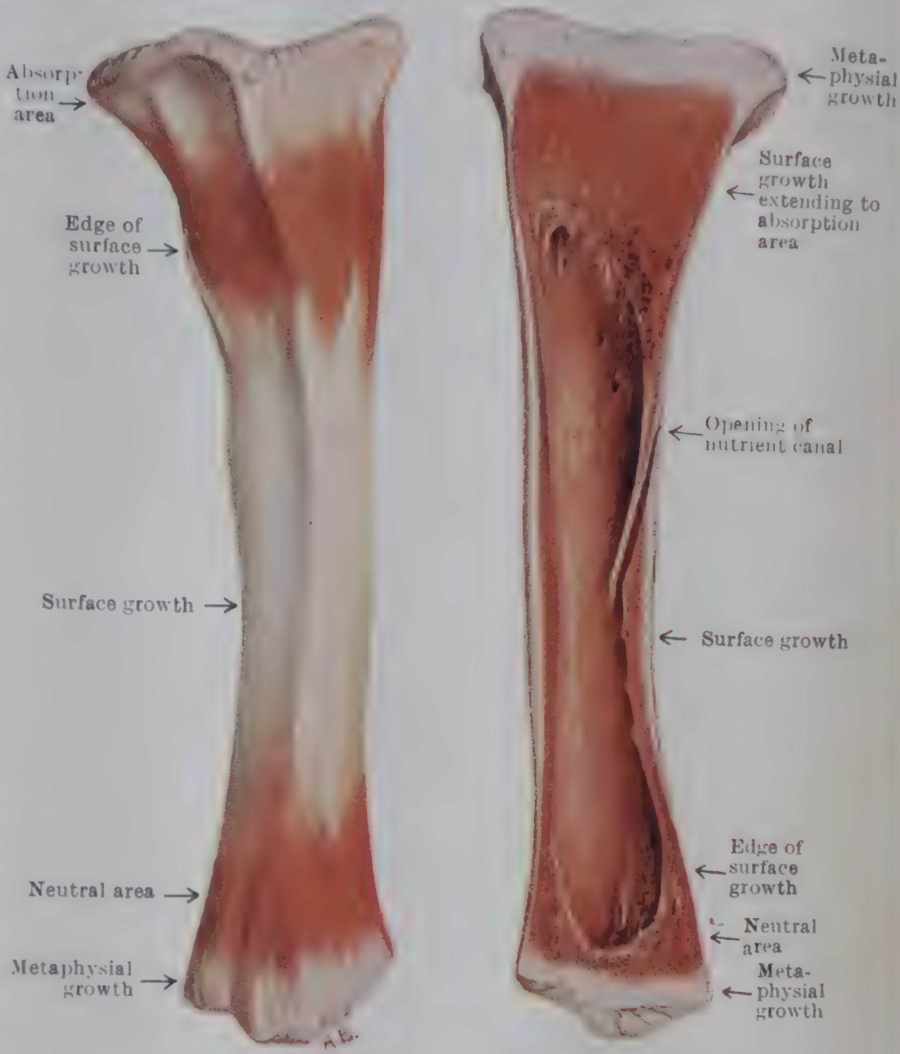
Ossification in membrane occurs in certain skull-bones, in the lower jaw-bone and in part of the collar-bone. The cartilaginous stage is missed out; in other respects the process of ossification is the same as in a cartilage-bone (Fig. 127). Osseous tissue is deposited in or underneath the outer layers of the sheet or membrane of mesoderm, which thereupon becomes periosteum; that is followed by excavation by osteoclasts and rebuilding by bone-forming cells—in the same sequence as in ossification under the periosteum of a bone pre-formed in cartilage.

Formation of Joints.—The mesodermal tissue between two developing bones becomes

converted into the structures that bind the two bones together, and these structures vary according to the class of joint. In a synovial joint—in which there is a cavity in the joint and the bones are free to move—the outer layers of the condensed mesoderm become converted into the *articular capsule* of the joint; the cells in the interior disappear and the *joint-cavity* is formed (Fig. 312). In certain joints the cells inside do not all disappear; those that remain give rise to the fibro-cartilaginous plates and the ligaments found in the interior of certain synovial joints. (See Section on Joints, p. 339.)

Growth of Bone.—The absorption of bony substance in some places and deposition of new bone in others which occur during development is continued thereafter to provide for growth. The process may be observed in bones taken from animals fed for suitable periods on substances, such as madder, which colour new bone as it is laid down (Figs. 128, 171). This continuation of controlled growth and absorption permits alterations in the shape of bones, alterations which are necessary if proper proportions and the correct relative position of individual parts of the bone are to be retained during growth.

The principles involved, with a review of the work of others as well as his own, are stated by Brash (1934) in his 'Struthers' Lecture and the student is referred to this and to the recent work by Lacroix (1949) for fuller discussion. One essential feature is that bone is laid down on or absorbed from a surface, whether this be an outer surface, the surface of a cavity, or the surface of a lamella in spongy bone. It can be seen that, if bone is laid down on one side of a given part of a bone and absorbed on the opposite side, the effect will be to move the part bodily in one direction. This will hold good whether the part is a projection or a hollow, the wall of a cavity such as the skull, or the whole thickness of part of a long bone.



A. Posterior aspect. B. Longitudinal section.

FIG. 128.—DIAPHYSIS OF TIBIA OF MADDER-FED PIG TO ILLUSTRATE THE MODE OF GROWTH OF A LONG BONE. (After Brash, 1934.)

The animal was $40\frac{2}{7}$ weeks old, and the madder had been omitted from the food for 30 days. The new bone added during that period is white, in contrast to the old, red bone.

The principle of surface-accretion as the only method by which a bone grows in size implies that there is *no interstitial growth* of bone as distinguished from interstitial changes in density which are constantly taking place. The proof that interstitial growth does not occur is threefold. (1) The experiment of inserting two metallic marks in the long bone of a living animal, as performed by John Hunter (1772) and others, shows that these remain the same distance apart as the bone grows in length; and metallic rings placed around the bone under the periosteum become embedded in the bone by surface-accretion and may be found later in the marrow cavity as that is enlarged by absorption. (2) If the long bones of a child show "lines of arrested growth"—transverse planes of greater density due to heavier calcification at the ends of a bone growing at a slower rate during an illness—repeated radiographic observation at increasing ages shows similarly that these remain the same distances apart as the bones grow in length (Harris, 1933). (3) The indirect madder method—colouring the bones completely and then omitting the dye for a definite period—leads to the same conclusion, since the increase in length is accounted for by the new white bone which appears at the ends and the increase in girth by the subperiosteal deposit (Fig. 128).

All three methods thus demonstrate that growth in length of a long bone occurs at the ends only; and measurements, which can be used to calculate the *rates* of growth (Payton, 1932), show that growth is greater at one end which, therefore, is termed the 'growing end' of the bone (p. 117).

Most bones grow in two dimensions by deposition of osseous tissue under the periosteum, and in the third dimension by transformation of cartilage into bone. For example, the body of a vertebra grows in breadth and in thickness by sub-periosteal deposit of bone, and in height by increase of cartilage at its upper and lower surfaces. A long bone grows in girth (*i.e.*, breadth and thickness) under the periosteum, and in length by increase of the cartilage at its ends. As growth takes place at the junction between bone and cartilage the bone which has been laid down is left behind to become part of the shaft. It has, however, been formed at a wide part of the bone and 'modelling absorption' must take place on the surface if the proper form of the bone is to be maintained.

Failure of modelling absorption may occur, rarely even in bones that appear to be normal in other respects (see Harris, 1933; Brash, 1934). Usually associated with abnormal bone-growth (Keith, 1920), the result is a characteristic club-shaped appearance of the ends of the bones; and it seems to have a genetic basis (Grüneberg, 1935). For a remarkable case in a child associated with "marble-bones" (Albers-Schönberg disease), see Lightwood and Williams (1939). In bones such as those of the skull which are developed in membrane, growth takes place under the periosteum mainly by deposition of new bone on the outer surface and absorption from the inner surface. Absorption or accretion will occur, however, wherever they are required to maintain the proper proportions of the bones.

Some short bones and some flat bones are ossified wholly from the **primary centre** of ossification. They continue to grow: (1) in the case of flat bones developed in membrane, until the bone-forming cells in the periosteum and in the tissue which separates the margins of bones cease to function as bone-forming cells; and (2) in the case of bones developed in cartilage, until the subperiosteal bone-forming cells cease to function and the cartilage-cells in the cartilaginous covering of an articular surface cease to multiply. At the articular part of a bone the multiplication of cartilage-cells and the process of ossification cease before the cartilage is all used up; a layer of articular cartilage is thus left, and it survives till death or until destroyed by disease.

All long bones and many others acquire **secondary centres** that appear in outlying cartilaginous parts into which ossification from the primary centre does not extend. Nearly all the secondary centres appear after birth, and the method of ossification from them is the same as from primary centres, except that the whole of the bone is formed within the cartilage, which, until growth ceases, enlarges by multiplication of its cells.

The part of a bone ossified from the primary centre is called the **diaphysis**. A part ossified from a secondary centre is called an **epiphysis**, and a secondary centre is therefore often called an *epiphysial centre*. ['Επίφυσις from ἐπί (epi) = upon, φύω (phyō) = make to grow.]

Ossification in the cartilage proceeds from the primary and secondary centres till only one part or two parts of the cartilage are left: (1) A thin plate, called the **epiphysial cartilage**, persists for a time between the diaphysis and the epiphysis (Fig. 306 A, p. 335); its edge at the surface of the bone forms the **epiphysial line**. (2) In a bone where the epiphysis is the articulating part the articular layer of cartilage survives.

So long as the epiphysial cartilage lasts the bone continues to grow on each side of it—that is, both diaphysis and epiphysis continue to grow—the rate of growth being much more rapid in the diaphysis than in the epiphysis, possibly owing to absorption of the epiphysis on its diaphysial side which counteracts the growth under the articular cartilage (Payton, 1933). The diaphysis continues to grow at the expense of the epiphysial plate, and this enlarging part of a diaphysis is sometimes called the *metaphysis*. To maintain the existence of the plate, the cells farther away from the diaphysis go on multiplying; but a time comes when they cease to do so, and the ossifying process in the diaphysis—invading the cartilage—uses it up. The diaphysis and epiphysis are then said to have joined or *fused*, and the bone ceases to grow in that situation. The epiphysis grows at the expense of the peripheral cartilage, whose cells multiply to maintain it; so growth goes on in the epiphysis until they cease to multiply—at about the same date as cessation in the epiphysial plate. If the epiphysis is on a non-articulating part of the bone—*e.g.*, iliac crest—the cartilage is all replaced by bone; but in bones where the epiphysis is articular, its outermost layer of cartilage remains.

Healthy periosteum, or endosteum, retains the faculty of producing new bone when required and absorption of bone continues to take place where necessary. Broken bones can accordingly be repaired and bones can be remodelled to meet increased exercise, or atrophy from lack of it. Harris (1933) points out that during growth in a long bone the longitudinal or primary trabeculæ are consolidated before the transverse or secondary trabeculæ are laid down and, in cases of atrophy, the transverse trabeculæ are in great measure absorbed before any changes occur in longitudinal trabeculæ. The length of the bone and the function of the joints and muscles are thus preserved.

Epiphyses (Figs. 229, 263).—The shaft of a long bone is developed from a primary centre, and the shaft is therefore the diaphysis. Every long bone has an epiphysis at one end; most of them have epiphyses at both ends; in some bones there are more than one epiphysis at the end, *e.g.*, the distal end of the humerus, the proximal end of the femur. When a long bone has an epiphysis at only one end, it is at the end at which there is the more movement. Most epiphyses are ossified from one centre, but some are ossified from more than one, and the different parts ossified from these separate centres coalesce before the union with the diaphysis, *e.g.*, the proximal end of the humerus. When there are more than one epiphysial centre at the end of a bone, and the parts ossified from these centres do not coalesce but join the shaft separately, each part is called an epiphysis, *e.g.*, the parts at the proximal end of the femur.

According to Parsons (1904, 1905, 1908) secondary centres of ossification fall into three classes :—(1) 'Pressure epiphyses', (2) 'traction epiphyses', related respectively to pressure at the articulating ends of long bones and to the pull of muscles, and (3) 'atavistic epiphyses' representing bony elements which have lost their independence in the course of evolution, *e.g.*, the secondary centres of the ischium and pubis and of the coracoid process of the scapula. The epiphyses of the trochanters of the femur are typical 'traction epiphyses'; but it should be noted that they do not necessarily depend upon the stimulus of muscle-action during the growth-period of an individual (Appleton, 1925).

Ossification of Epiphyses.—Post-natal changes in epiphyses of the long bones in the limbs may be separated into three main stages. (*a*) Secondary centres of ossification appear from the time of birth to 5 years of age. (*b*) Ossification continues to spread from these centres until the age of about 12 years in girls or 14 years in boys. (*c*) This is followed by a period from 12 or 14 years to 25 years during which the epiphyses fuse with the diaphyses and growth in length ceases as fusion occurs. This process is speeded up in girls at five years, and again at ten years (Wingate Todd, 1933, 1937), so that after these periods in particular the female is in advance of the male and the dates of epiphysial fusions in general are earlier.

Exceptions of some practical use include the appearance of a centre in the distal end of the femur in the last month of fœtal life. The proximal end of the tibia often develops a centre late in this month and the upper end of the humerus also may do so. A child is assumed to be at full-time if one of these centres is present. At the other end of the scale the clavicle, or collar-bone, has an epiphysis at its medial end which is exceptional in that its centre appears late (18-20 years) and fusion is delayed until between 25 and 30 years. A clavicle with an epiphysis present but unfused would be from a person between 18 and 30 years old.

As a general rule, when a centre of ossification in an epiphysis appears early the epiphysis fuses late and vice versa. The humerus, for example, is notable for the long period over which its stages of ossification are spread. A centre is present in the head shortly after birth and fusion of the epiphysis does not occur until the age of 18 to 21 years. The intermediate stages are marked by the comparatively late appearance of centres at the lower end of the bone and their correspondingly early fusion.

The end of a bone bearing an epiphysis which fuses late (or a single epiphysis for that bone) grows for a longer time and also grows more rapidly than the other end. It therefore contributes more to the length of the bone and is sometimes referred to as the "growing end". This differential rate of growth affects the course of the nutrient canals which are directed away from the growing end. This is because a nutrient artery maintains its position relative to the bone as a whole and, since the canal is formed by new bone laid down round the artery, the outer opening of the canal likewise retains its relative position. As growth proceeds at the "growing end", the nutrient artery and, with it, the nutrient foramen are displaced away from the slow-growing or stationary end of the bone and from the inner opening of the canal which itself is displaced in the same direction by absorption. The canal, therefore, becomes oblique as it grows, slopes away from the "growing end" and continues to point approximately to the site of the primary ossification centre.

Most of the epiphysial centres in the vertebræ and ribs and in the shoulder and pelvic girdles do not appear till puberty and fuse about the age of 25; this does not apply, however, to the fusion of the separate parts entering into the formation of the shoulder and hip joints. These conform more with the arrangement at the ends of long bones adjacent to them.

No student should ever attempt to memorize lists of dates of appearance of epiphysial centres or of fusion with the diaphysis, but a general knowledge is necessary. It is, for example, simple enough to group the dates of fusion of epiphyses in the long bones of the limbs. Using the figures given in this text and taking them according to their proximity to joints, the figures for the male are as follows :—Hip and ankle joint regions, 18 years; knee and elbow, 18-19 years; shoulder and wrist, 21 years. Fusion will take place earlier by two or three years in the female.

The most important of the epiphyses of a vertebra are those that cover the upper and lower surfaces of its body. In lower animals these epiphyses are thin plates; in Man they are flattened rings. These ring-like epiphyses do not fuse with the body of the vertebra till the full adult stage is reached, and that stage may not be reached till the 25th year or later; the back, therefore, goes on growing for a longer time than the limbs do, for the limb-bones have usually all ceased to grow before the 21st year.

For any one epiphysis, the date of appearance of its centre varies in different children by weeks or months, and sometimes by one or two years. The date of union varies even more, especially in the backbone; it is common knowledge that some people reach their full height in their teens while others do not do so till after the age of 25. The sequence of the dates of union and the intervals between them remain proportionately the same in different people (see Stevenson, 1924) and, therefore, if the first to join do so at an earlier age than usual, ossification throughout the body will be completed at an early age. Centres appear and union takes place earlier in girls than in boys. The dates given under the individual bones are approximate averages; those for most of the limb-bones are taken from the table compiled by R. S. Paterson (1929), but see also the tables compiled by Wingate Todd (1930) and H. Flecker (1932).

Separation of Epiphyses.—The cartilages and the opposed surfaces of diaphyses and epiphyses have pronounced elevations and depressions which fit into one another, so that the bones can withstand knocks and jars and twists. None the less, an epiphysis sometimes is broken off. When a limb of an adult is subjected to violence, a bone may be broken or put out of joint, but while the bones are growing there is an added danger: an epiphysis may be damaged or

break away. When that happens, the epiphysial cartilage is often injured so that the bone ceases to grow at that part after diaphysis and epiphysis have reunited. When a bone is broken near one end in a young person, it may be either an ordinary fracture or a separation of the epiphysis. It is important to recognize at the outset which it is; and it is important, therefore, to remember the period at which epiphyses usually join. Moreover, in a negative radiograph of a young person an epiphysial cartilage appears as a dark line, and that line may be mistaken for a line of fracture if it is forgotten that there is an unjoined epiphysis in the region. (In an adult, even though the epiphysis fused long ago, the position of the epiphysial line may still be indicated in a negative radiograph by a thin, white line known as the "*epiphysial scar*"—Pl. III.)

Epiphyses can be seen in radiographs and in the skeletons of relatively young people and young animals in museums. They can be seen at home also: epiphysial plates of vertebræ can be seen in a sirloin of young beef; epiphyses of limb-bones can be found in a leg of lamb.

THE SKELETON

The human body is divided into the following parts: the **head** and **face**; the **neck**; the **trunk**, subdivided into the chest or *thorax* and the belly or *abdomen*; a pair of **upper limbs**; and a pair of **lower limbs.** The abdomen is further divided into a larger upper part called the *abdomen proper*, and a smaller part called the *pelvis*, situated below and behind the abdomen proper, between the two hips. The bones in the head, face, neck, and trunk are 80 in number in the adult and constitute what is called the *axial skeleton*. Excluding the small sesamoid bones, which are inconstant in number, there are 32 bones in each adult upper limb and 31 in each adult lower limb, and they constitute the *appendicular skeleton.*

The bones in the adult **axial skeleton** are—(*a*) the backbone or vertebral column; (*b*) the breastbone or sternum; (*c*) 12 pairs of ribs; (*d*) the skull, including the lower jaw-bone or mandible; (*e*) the hyoid bone; and (*f*) 3 pairs of tympanic ossicles.

The **vertebral column** is the fundamental part of the skeleton; it is common to all the great *vertebrate* class of animals, namely, fishes, amphibians, reptiles, birds, and mammals. It is situated in the median part of the back of the body and extends through the whole length of the neck and the trunk. The **sternum** lies in the median part of the front of the thorax. The twelve **ribs** make up the framework of the side and front and back of each half of the thorax. The **skull** is the skeleton of the head and face, and the **mandible** supports the lower part of the face. The **hyoid bone** lies in the front of the neck below the mandible and the tongue. The **tympanic ossicles** are little bones situated in the drum of the ear or tympanic cavity.

The bones of the **appendicular skeleton** are summarized in the sections on limbs.

VERTEBRAL COLUMN

The vertebral column or backbone is a long, curved pillar (Fig. 140) composed of a number of units, called **vertebræ,** which are placed in a series one above the other and are connected together by discs of fibro-cartilage and by ligaments. The bulky part of each vertebra is its anterior part and is its *body* (Fig. 131). The most posterior part of a vertebra is a projection called its *spine*, whence arose the names 'spine' and 'spinal column' used as synonyms for backbone. The spines can be felt in the floor of the median furrow that begins at the nape of the neck and ends between the buttocks.

In the **child** there are 33 separate vertebræ, but in the **adult** vertebral column there are only 26 separate bones, for the lowest nine vertebræ are fused together to form two single bones; the upper one is the *sacrum* and consists of 5 fused vertebræ; the lower is the *coccyx* and consists of 4 fused vertebræ (Fig. 141). The vertebræ are classified in five groups from above downwards:—

Child.		*Adult.*		
Cervical vertebræ	7	Cervical vertebræ	7	True or movable vertebræ
Thoracic ,,	12	Thoracic ,,	12	
Lumbar ,,	5	Lumbar ,,	5	
Sacral ,,	5	Sacrum	1 = 5	False or fixed vertebræ
Coccygeal ,,	4	Coccyx	1 = 4	
	33		26	

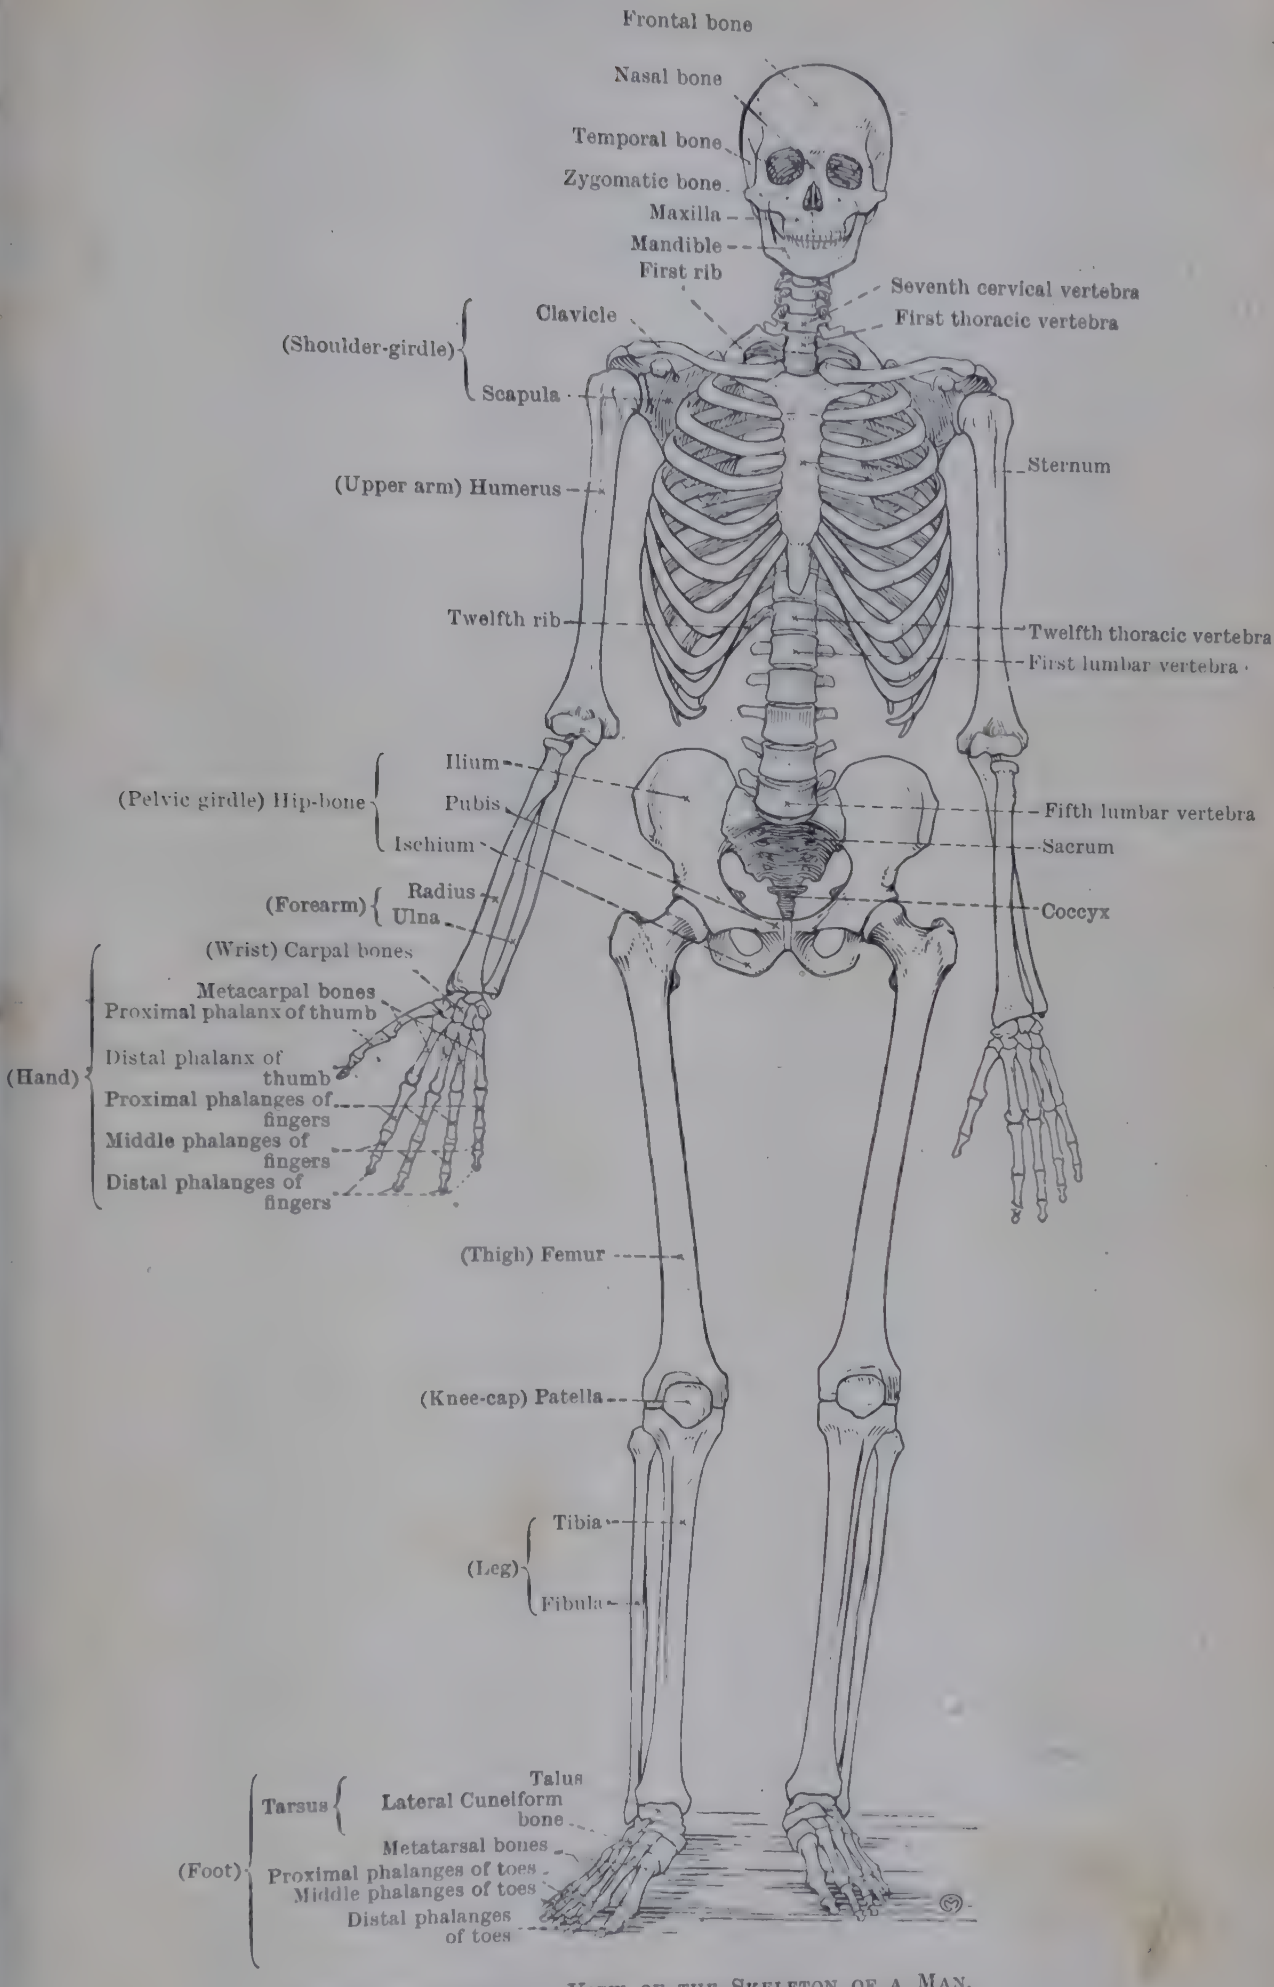


FIG. 129.—ANTERIOR VIEW OF THE SKELETON OF A MAN.
The bones of the left forearm and hand are in the position of pronation.

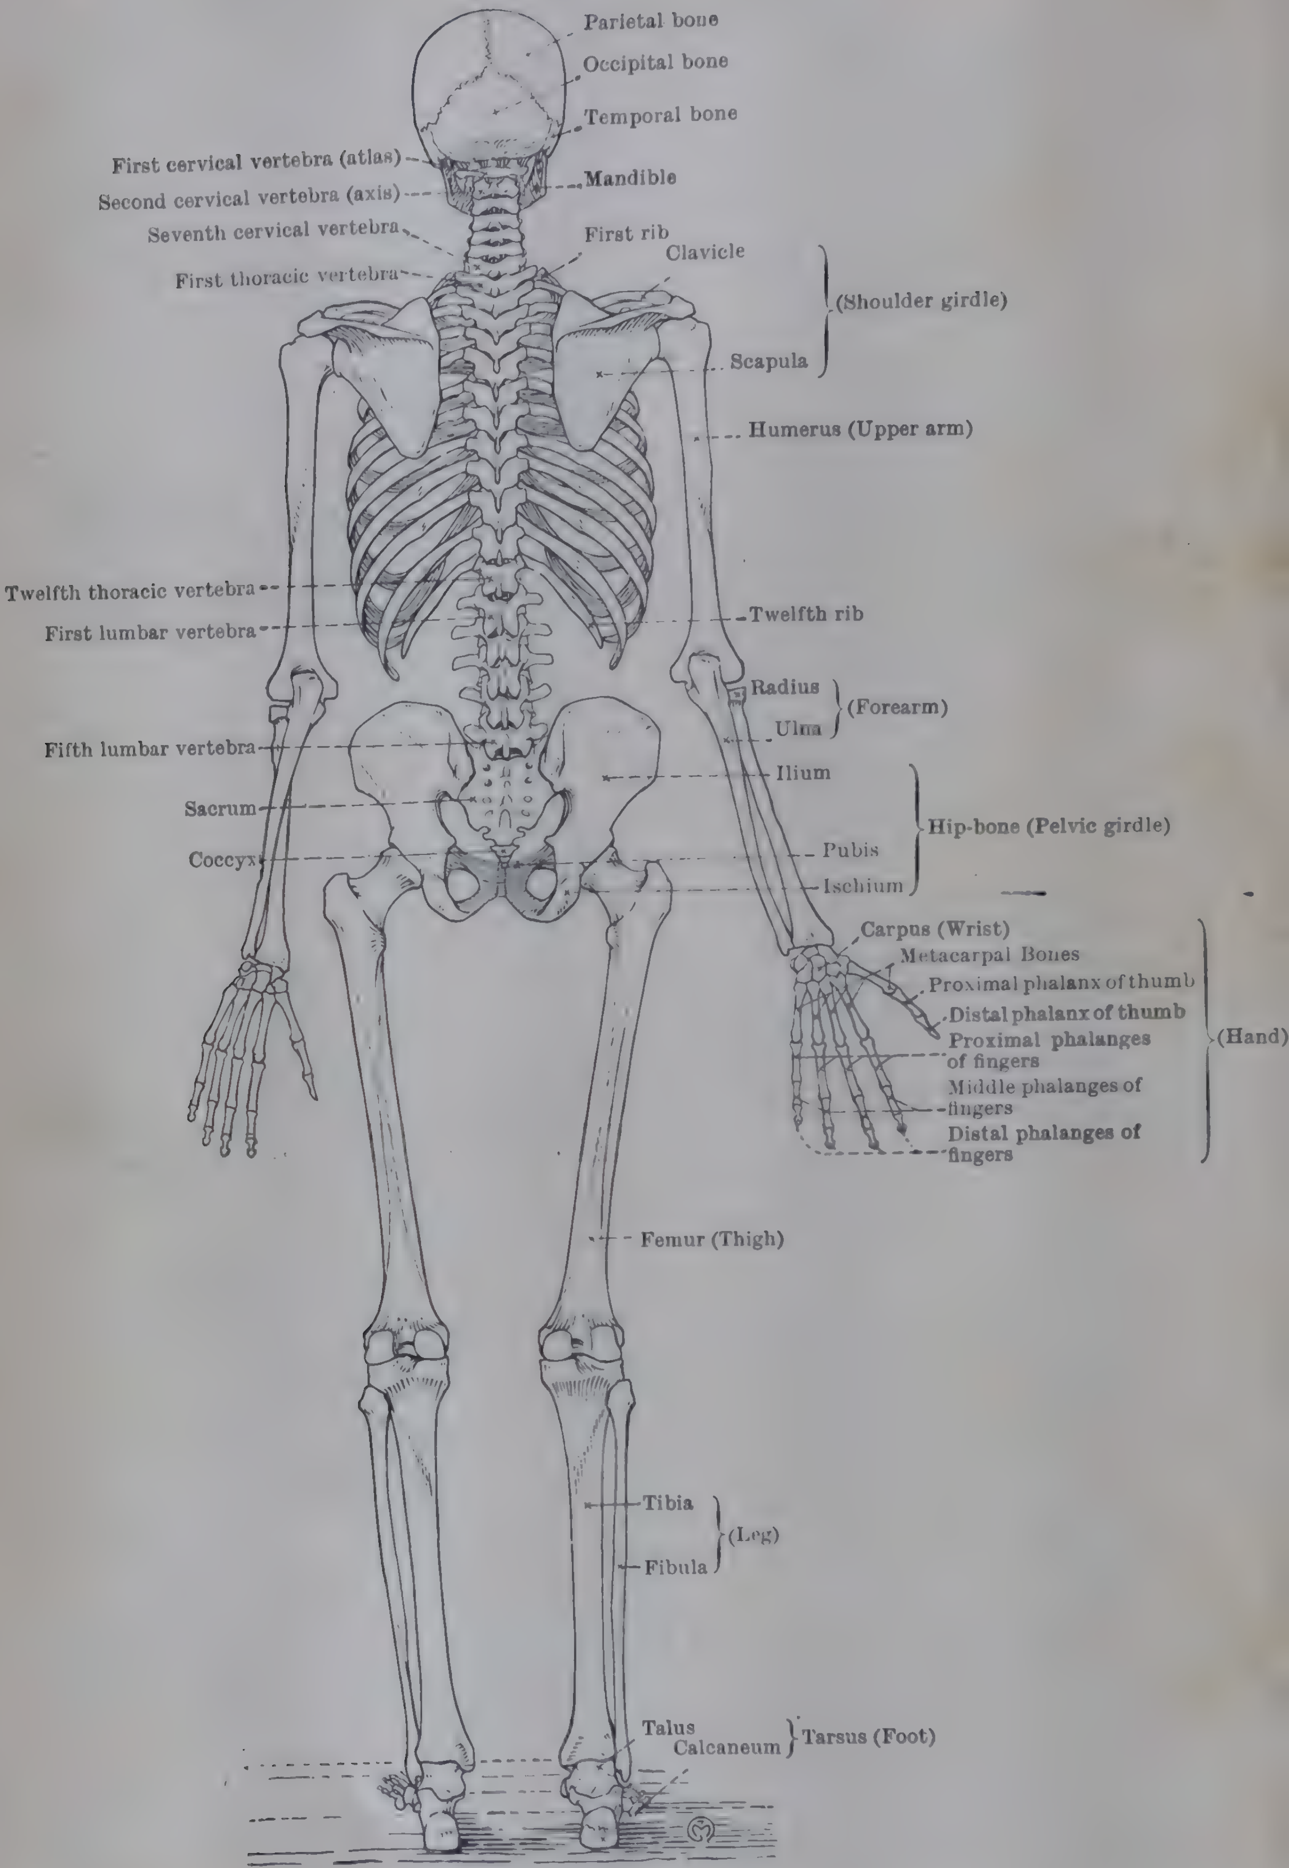

Fig. 130.—Posterior View of the Skeleton of a Man.
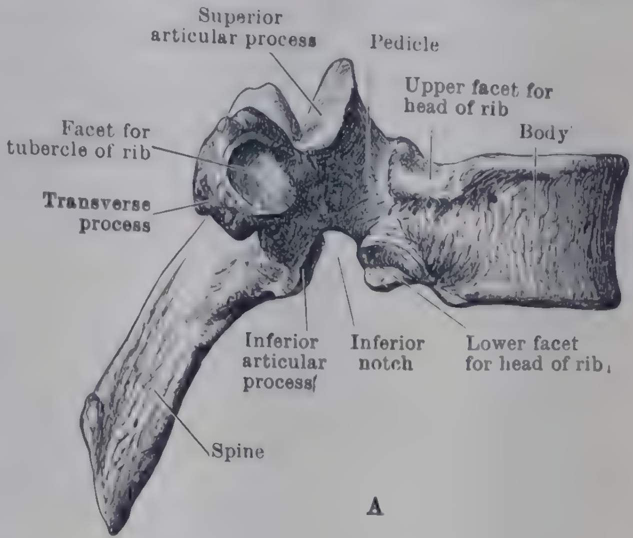
The bones of the left forearm and hand are in the position of pronation.

Vertebræ belong to the class of *irregular* bones. Most of them have characters in common, but the vertebræ of each group have also special characters that distinguish them from those of the other groups; and, while each vertebra has the distinctive characters of its own group, many of them have their own special features by which they can be recognized at a glance.

A Typical Vertebra (Fig. 131).—It is usual to select a vertebra from the *middle* of the *thoracic* region as a type. The beginner can pick out a thoracic vertebra from among the others because it has articular *facets* on the sides of the body. Only a thoracic vertebra has these facets; and those in the middle of the thoracic region have long spines. The main parts of a vertebra are a *body* and an *arch* which enclose a large hole called the *vertebral foramen*. Various processes jut out from the arch, namely, the *spine*, a pair of *transverse processes*, and two pairs of *articular processes*—superior and inferior.

The **body** is the bulky, anterior part. The **vertebral foramen**, behind the body, is large enough to admit a finger; when the vertebræ are in column the series of vertebral foramina makes a long tunnel, or *vertebral canal*, for the lodgment of the spinal cord. The **vertebral arch** consists of four essential parts which bear the processes named above. These parts are a pair of *pedicles* at the sides of the foramen, and a pair of *laminæ* at the back; the two laminæ fuse together in the median plane. When the vertebræ are in column there is, on each side, a row of holes, called the *intervertebral foramina*, between the pedicles; a spinal nerve passes through each intervertebral foramen. The **spine** projects backwards and downwards from the junction of the two laminæ; its downward slant enables the beginner to distinguish the upper part of the vertebra from the lower; the tip of the spine is the only part of a vertebra that is *easily* felt in the living person, and, owing to the slope, it is at the level of the body next below. The other processes are at or near the junction of the pedicles with the laminæ; the **transverse processes** are the large projections that jut out from the sides of the arch; **superior articular processes** project upwards from the side of the arch; the **inferior** pair project downwards and articulate with the superior pair of the vertebra next below; in the thoracic vertebræ they are less distinct than the superior pair and are on the laminæ near the pedicles.



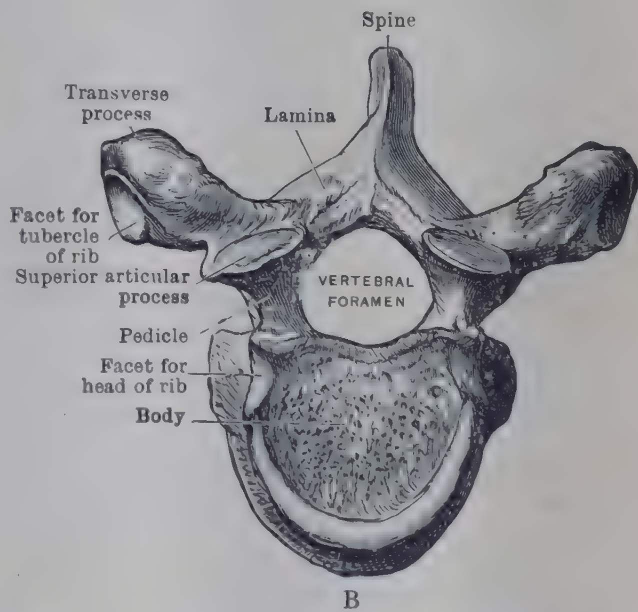


FIG. 131.—FIFTH THORACIC VERTEBRA, (A) as viewed from the right side, (B) as viewed from above.

The **body** has an *upper* and a *lower* surface; a *posterior* surface, which forms the anterior boundary of the vertebral foramen; an *anterior* surface, which merges into the *right* and *left* sides, so that the three form a continuous surface which is highly convex from side to side and slightly concave from above downwards. The upper and lower surfaces are separated from the bodies of the vertebræ immediately above and below by thick *discs* of fibro-cartilage (which, at the same time, bind the bodies together); and two long fibrous ribbons, called the *anterior* and *posterior longitudinal ligaments*, lie on the front and the back of the bodies and are attached to them and to the discs throughout the series of movable vertebræ.

The **pedicles** of the arch project backwards from the back of the body and are continuous with the laminæ posteriorly. The upper and lower borders of each pedicle are slightly concave, forming the floors of notches called the **superior** and **inferior vertebral notches**; in the thoracic and lumbar regions the superior notch is very shallow, for the pedicle springs from the upper part of the body. The pedicles are the only parts of two contiguous vertebræ that are not united by ligaments; they are separated by the **intervertebral foramen**, which is bounded *above* and *below* by the pedicles, *posteriorly* by the articular processes of the two vertebræ, *anteriorly* by the upper of the two bodies in the thoracic and lumbar regions and by both bodies in the cervical region. These foramina form a linear series on each side, transmitting the spinal nerves and vessels on their way from and to the spinal cord.

The **laminæ** are plates of bone that slope towards each other from the posterior ends of the pedicles and fuse together in the median plane behind the vertebral foramen. [*Lamina* = a plate, a leaf.] Their posterior surfaces are covered with muscles. Laminæ of contiguous vertebræ are united by flat, fibro-elastic bands, the *ligamenta flava* [*flavus* = yellow] which are attached to their borders, to the rough lower parts of their anterior or inner surfaces and to the upper parts of their outer surfaces.

The **vertebral canal**, formed by the series of **vertebral foramina**, is bounded *anteriorly* by the bodies of the vertebræ, the discs, and the posterior longitudinal ligament, *posteriorly* by the laminæ and the ligamenta flava, *at each side* by the pedicles—between which there are the intervertebral foramina. The canal *contains* the spinal cord and its membranes, the roots of the spinal nerves, vessels which supply the spinal cord and the vertebræ, and a quantity of loose, semi-liquid fat. The canal is widest in the regions where the vertebral column is most movable—the neck and the loins.

Each **spine** has a median ridge superiorly, but widens out inferiorly into a surface bounded by a pair of ridges; and each ridge may end in a little tubercle at the tip. The spines are united by *interspinous ligaments*, which lie in the interval between each two, and *supraspinous ligaments*, which pass from tip to tip, forming a continuous band from the sacrum to the neck; in the neck they form a wide sheet called the *ligamentum nuchæ* [*nucha* (derivation uncertain) = the nape of the neck]. The ligamentum nuchæ is set as a median partition between the muscles of the two sides of the back of the neck and is attached superiorly to a median ridge, the external occipital crest, on the posterior part of the base of the skull. Numerous muscles are attached to the spines.

The **transverse processes** give attachment to numerous muscles, and are connected with those of the vertebræ above and below by weak fibrous bands called *intertransverse ligaments*. In a typical thoracic vertebra each transverse process articulates with a rib and has a facet on the front of its free end for that articulation. It is connected to ribs by ligaments.

The **articular processes** project upwards and downwards from a pair of *articular masses* which are thickened parts of the pedicles and laminæ at and near their junction. The **superior processes** have smooth articular surfaces on their posterior aspects. The **inferior processes** are not so prominent; they are surfaces rather than processes in cervical and thoracic vertebræ, and look forwards to articulate with the superior pair of the vertebra below. The margins of the articulating surfaces give attachment to the *joint-capsules*; and the non-articulating parts give attachment to muscles.

Structure.—All parts of a vertebra consist of spongy bone enclosed in compact bone. The compact bone is thinner in the body than in the other parts; it is thickest at the notches, the inner tables of the laminæ and the upper edge of the spine. The cervical vertebræ are denser in structure than those of the other regions. *Vascular foramina* are very small in the arch and processes; they are numerous and large on the front, sides, and back of the body; the largest is on the back and transmits a vein.

Cervical Vertebræ

Cervical vertebræ constitute the bony axis of the *neck* and form a very flexible part of the vertebral column [*cervix* = neck]. By their small size and uneven surface-contours they can be identified as cervical at a glance; but their special distinctive character is that each of them has three holes in it—the large **vertebral foramen** in the middle, and a smaller hole at each side, called the **foramen transversarium** because it is partly bounded by the transverse process. The foramina transversaria form a vertical series on each side, and the *vertebral artery* runs through the upper six of them. In most cervical vertebræ the **transverse process** has two tubercles at its free end called the *anterior* and *posterior tubercles* of the transverse process. The free ends are little more than an inch from the median plane, and can be felt as an uneven bony resistance when pressure is made on the side of the neck. The lower border of the *third* vertebra is at the level of the upper border of the thyroid cartilage—the prominence in the front of the neck known as the laryngeal prominence or "Adam's apple". The *sixth* vertebra is at the level of the cricoid cartilage—the rounded bar felt in the front of the neck below

the thyroid cartilage; the anterior tubercle of its transverse process is called the *carotid tubercle* because the carotid artery can be compressed against it.

The first and the second vertebræ are greatly modified to allow free movement of the head, and the seventh also has special characters, but the other four are very much alike and are regarded as typical cervical vertebræ.

A Typical Cervical Vertebra.—The **body** is small and is wider from side to side than from before backwards in the proportion of 3 to 2. It is lipped up at the sides on the upper surface and correspondingly bevelled off on the lower surface; between the lip and the bevel of contiguous vertebræ there is a small synovial joint at the side of the intervertebral disc. The posterior surface is flat, and it is pitted near its centre by holes for veins. The anterior surface is flat in the middle for the attachment of ligaments, and depressed at its side for muscular attachments; its lower part juts downwards and overlaps the disc below; the upper margin of the surface may be slightly bevelled.

The **vertebral foramen** is triangular with rounded angles; and it is large in order that the spinal cord shall not be compressed in the movements of the neck, and also because the cord is thicker in the neck than it is lower down. The **pedicles** are short and rounded; they project sidewards as well as backwards, and that contributes to the width of the vertebral foramen and to its triangular outline. The superior and inferior **vertebral notches** are nearly equal in depth.

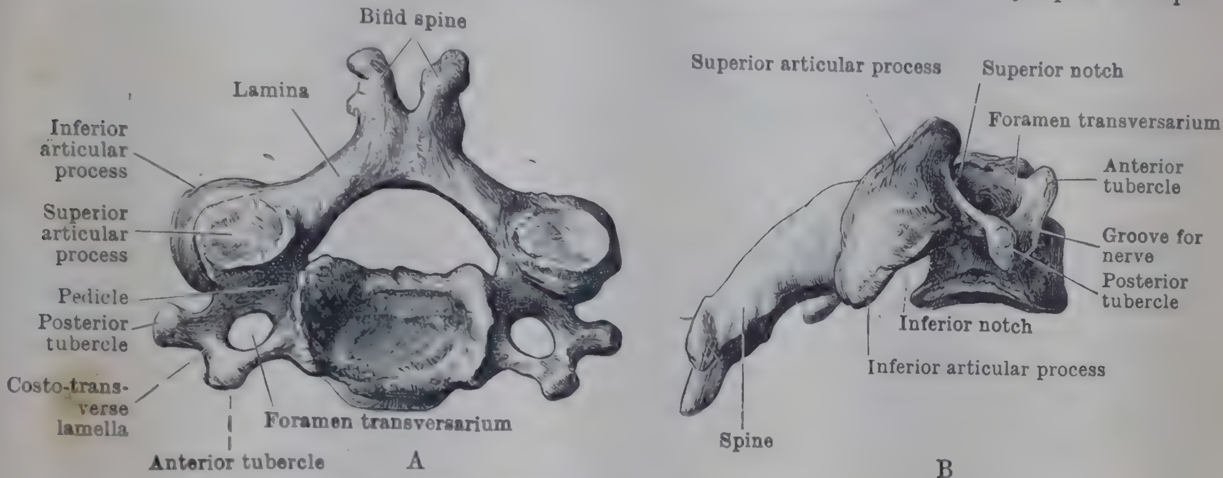

FIG. 132.—FOURTH CERVICAL VERTEBRA, (A) from above, and (B) from the right side.

The **laminæ** are thinner than in other regions, longer in their horizontal measurement, and narrower from above downwards.

The **spine** is short, and it overlaps the spine below; it is compressed from above downwards, and the median ridge is blunt and ill-defined; the free end is bifid, because the pair of lateral ridges end in prominent spurs for the attachment of muscles—the spurs of the sixth being, however, short or absent.

The **articular masses** are large, and the series of them are built up to make a pair of rounded pillars behind the transverse processes; shallow, horizontal grooves on the sides of the third and fourth are for the accommodation of the posterior primary rami of the corresponding cervical nerves. The **articular processes** are merely the upper and lower parts of each articular mass; their articular surfaces are sloping and are nearly flat; the upper pair look backwards and upwards; the lower pair look in the opposite direction.

The **transverse processes** are short and inclined slightly downwards and forwards. Each has two distinct parts or roots—an anterior and a posterior. The *anterior root* corresponds to a rib and is sometimes called the *costal process*; it springs from the side of the body and ends laterally as the *anterior tubercle*. The *posterior root* is the true transverse process; it springs from the arch at the front of the articular pillar, and it ends laterally as the *posterior tubercle*. Near their free ends the lower margins of the two roots are united by a curved bar of bone called the *costo-transverse lamella*. The posterior tubercle is farther from the median plane than the anterior tubercle is—jutting beyond the plane of the lateral surface of the articular pillar. The upper border of the anterior root is about the level of the upper surface of the body, and may be even higher. In the third it is at a higher level than the posterior root, and the costo-transverse lamella therefore slants downwards and backwards. In the fourth the anterior root is higher at its upper border and its costo-transverse lamella also is oblique, but the lower border is almost at the same level as the lower border of the posterior root. In the fifth and sixth the roots are nearly at the same level, and the lamella is therefore horizontal, but in the sixth the roots are farther apart and the lamella therefore longer.

The **foramen transversarium** is bounded by the side of the body, the pedicle, the two roots of the transverse process and the costo-transverse lamella; in some vertebræ it is divided into two by a spicule of bone. Except in the seventh, it transmits the vertebral artery surrounded by a network of veins and a plexus of sympathetic nerves derived from the inferior cervical ganglion. The cervical nerves, on emerging from the intervertebral foramina, lie behind the vertebral artery, where each one divides into an anterior and a posterior primary ramus; the posterior

ramus turns backwards above the posterior root of the transverse process across the side of the articular pillar; the anterior ramus runs laterally and lies on the costo-transverse lamella.

The **atlas** or **first cervical vertebra** is a ring of bone. It has no body and no spine; for the median part of the body has been detached from it and is fused with the upper surface of the body of the second vertebra, and a spine has not been developed on it because it would hamper the backward movement of the head. The two bulkier parts of it are called the **lateral masses**; they are united by an **anterior arch** and a **posterior arch**, of which the posterior is much the longer. A **transverse process**, enclosing a **foramen transversarium**, projects sidewards from each lateral mass. The transverse processes are farther apart than those of other cervical vertebræ; the tip of each is an inch and a half from the median plane, and is the bone felt by the finger pressed into the hollow below the ear. The lateral masses rest upon the second cervical vertebra, and they support the skull—hence the name "atlas". Their upper and lower surfaces are readily distinguished, for the *lower* facets are fairly flat, while the facets on their *upper* surfaces are kidney-shaped and concave. The upper facets articulate with the occipital condyles at the sides of the foramen magnum of the skull (Fig. 156).

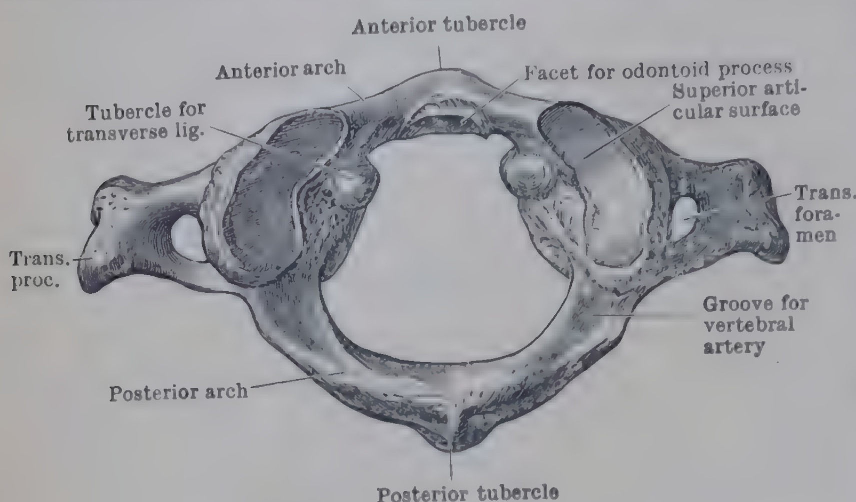

Fig. 133.—The Atlas from above.

The **anterior arch** is short and is compressed from before backwards. The facet seen on the middle of its posterior surface is for articulation with a part of the second vertebra called the odontoid process. On the middle of its anterior surface the **anterior tubercle** of the atlas forms a smooth eminence which gives insertion to the upper ends of the longus cervicis muscles. A continuation of the anterior longitudinal ligament is attached to the *lower margin* of the arch. The anterior atlanto-occipital membrane stretches upwards from the *upper margin* to the anterior margin of the foramen magnum (p. 172).

The **posterior arch** is twice as long as the anterior arch, and it is tilted slightly upwards. It springs on each side from the back of the lateral mass and the posterior root of the transverse process, and it represents the pedicles and laminæ of a typical vertebra. On the middle of its posterior surface the **posterior tubercle** of the atlas forms a small projection, which corresponds to a spine and gives origin to a pair of small muscles named the recti capitis posteriores minores. On the *upper surface* of the arch, close to each lateral mass, there is a broad, oblique groove in which the vertebral artery lies as it runs from the first foramen transversarium to the foramen magnum. The first cervical nerve lies in the groove below the artery. The remainder of the upper surface or border gives attachment to a thin fibrous posterior atlanto-occipital membrane which stretches upwards to the posterior margin of the foramen magnum and also upwards and laterally to fuse with the capsule of the joint between the lateral mass and the skull. The infero-lateral margin of the membrane therefore bridges across the groove for the vertebral artery and is sometimes ossified, converting the groove into a foramen. The *lower margin* of the arch is connected with the laminæ of the second vertebra by the first pair of ligamenta flava.

The **transverse processes** are longer and stronger than those of other cervical vertebræ, for they give attachment and leverage to the muscles that rotate the head. The free end—though often tuberculated and sometimes bifid—corresponds only to the posterior tubercle of a typical cervical transverse process. The anterior root and tubercle have been absorbed into the front of the lateral mass (where they may be identified as a slight swelling), and the bar of bone that bounds the foramen anteriorly corresponds to a costo-transverse lamella. The free end is a little below the tip of the mastoid process of the temporal bone, but is slightly medial to and in front of that process. The prominent, anterior part of the tip is the bone felt in the hollow below the ear. Each process gives origin to the following muscles—the rectus capitis lateralis, the obliquus capitis superior and slips of the levator scapulæ and scalenus medius—and insertion to the obliquus capitis inferior and a slip of the splenius cervicis.

The **lateral masses** correspond to the pedicles and to the lateral parts of the body of a typical vertebra—the parts that bear the synovial joints. Owing to the shortness of the anterior arch, the lateral masses are closer together in front than behind; and their upper and lower

surfaces slope so markedly that the medial surface is of much less depth than the lateral surface. The *lower surface* of each is oblique, nearly circular, and is slightly concave when denuded of cartilage; it articulates with the second cervical vertebra, and the capsular ligament of that joint is attached to the rough, slightly grooved circumference of the lateral mass above the articular margin. The *upper surface* articulates with the occipital condyle. Almost the whole upper surface is occupied by the articular facet, but there are narrow, depressed areas laterally and medially—the medial part usually presenting a vascular pit; posteriorly, it juts as a prominent tubercle that overhangs the groove for the vertebral artery. The facet, like the whole lateral mass, is nearer its fellow in front than behind. To fit the occipital condyle, it is kidney-shaped, concave (especially antero-posteriorly), and slopes downwards from the lateral to the medial edge. The 'hilum' or notch is on the medial side; but it may be notched on both sides, and is sometimes divided into two parts. The capsular ligament of the joint is attached well beyond the articular margins—to the front of the lateral mass, to the overhanging tubercle at the back, and to the outlying margins of the rough depressions at the sides. The *anterior surface* is slightly undulating, and gives origin to the rectus capitis anterior; it merges into the front of the anterior arch and the transverse process, and, near the transverse process, it presents a diffuse, low tubercle or swelling that represents the anterior root and tubercle of the typical cervical transverse process. The *lateral surface* gives origin to the transverse process, and is slightly excavated by the vertebral artery. The *posterior surface* is connected with the posterior arch; it is convex from side to side and grooved horizontally by the vertebral artery above the arch and by the anterior primary ramus of the second cervical nerve below the arch. The *medial surface* is small and uneven, and is seldom sharply marked off from the upper surface; its most conspicuous feature is a smooth, round *tubercle* for the attachment of the *transverse ligament* of the atlas, which stretches from one lateral mass to the other across the back of the odontoid process and keeps it in place against the anterior arch. The hole surrounded by the lateral masses and the arches is divided by the transverse ligament into two parts—an anterior, which holds the odontoid process, and a posterior, which is the vertebral foramen and contains the spinal cord and its membranes.

The **second cervical vertebra** is called the **axis** and is the thickest and strongest of the cervical vertebræ. It is easily distinguished, because a thick process called the **odontoid process** stands up from the upper surface of the body. The **spine** is thick compared with other cervical spines; it can be felt two or three inches below the *external occipital protuberance, i.e.*, the knob in the median line where the back of the head joins the neck. The spine is the first bony resistance encountered by the finger drawn downwards from the protuberance.

The **axis vertebra**, when looked at from the front, is relatively long in its vertical measurement, because of the upstanding odontoid process and because the lower part of the front of the body juts downwards very considerably. The **odontoid process** [ὀδούς (odous,

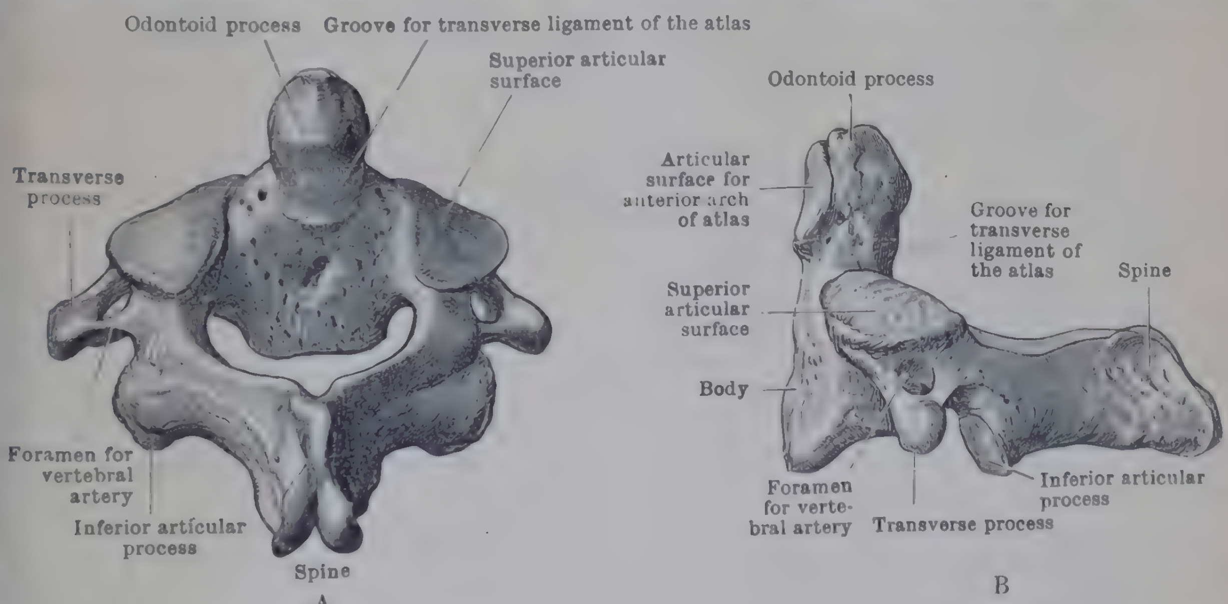

FIG. 134.—AXIS VERTEBRA: (A) from behind and above, (B) from the left side.

genetive odontos = dens = a tooth] is the median part of the body of the atlas fused with the body of the axis. When the first two vertebræ are fitted together the odontoid process lies in the anterior compartment of the ring of the atlas, and, if the atlas is looked at from above, the whole of what is really its body is then seen—its own pair of lateral masses and the odontoid process of the axis. The upper part of the anterior surface of the odontoid process is smooth for articulation with the back of the anterior arch of the atlas; its posterior surface near its

root also is smooth and even grooved for contact with the transverse ligament. Its top is pointed. A weak band of fibres, the apical ligament, stretches from the apex to the anterior margin of the foramen magnum; and a pair of strong bands, the alar ligaments, stretch from the sides of the apex to tubercles on the sides of the foramen magnum. When the head is turned from side to side, the atlas, carrying the skull, pivots round the odontoid process (hence the name *axis*), and the movement is limited by the alar ligaments.

The **inferior vertebral notches** are deep; the **superior** are absent; the **laminæ** are thick. The **spine** is deeply grooved on its lower surface and keeled on its upper surface. It is thick and broad because of the number of muscles attached to it. The most important of these muscles are the rectus capitis posterior major and obliquus capitis inferior (which move the head) and a great part of the semispinalis cervicis, which is inserted into it and bends the neck backwards. The **transverse processes** are the smallest of the series, the free end representing only the posterior tubercle. The anterior root is absorbed into the anterior surface of the upper articular part of the bone, and the anterior tubercle is either absent or is only a slight roughness near that surface. If the second and third vertebræ are placed together and looked at from the side, the change in the transverse process is obvious. The anterior boundary of the **foramen transversarium** is then seen to be chiefly the bar of bone that corresponds to the costo-transverse lamella of the third vertebra. The foramen is a short canal directed laterally as well as upwards, because the transverse process of the atlas is more laterally placed. The **inferior articular surfaces** are situated on typical *articular processes*. The **superior articular surfaces** are not situated on processes at the junction of the pedicles and the laminæ, but are placed on the body and the pedicles; they articulate with the lower surfaces of the lateral masses of the atlas, and through them the weight of the head is transmitted from the lateral masses to the bodies of the vertebræ below. The joints between them and the lateral masses of the atlas, and also those between the lateral masses and the occipital condyles correspond to the small joints between the bodies of the cervical vertebræ at the sides of the intervertebral discs; the first and second cervical nerves issue therefore behind the joints that connect the atlas with the skull and with the axis, while other spinal nerves issue through the intervertebral foramina in front of the joints formed by the articular processes.

The **seventh cervical vertebra** is distinguished from the others because its **spine** is long, and is not bifid but is thickened at its free end; the end of the spine is the upper of the two prominences at the root of the back of the neck, and on that account the seventh vertebra is called the *vertebra prominens*. The *posterior root* of the **transverse process** is a relatively wide triangular plate whose base or medial attached edge may reach almost as high a level as the top of the superior articular process, and its free end (*i.e.*, the posterior tubercle) is in line with the tip of the first thoracic transverse process. The *anterior root* is slender and the *anterior tubercle* is often absent; but the anterior root is sometimes large and separate, forming a **cervical rib** (Pl. IV, p. 105, Fig. 1). The **foramen transversarium** is usually small, for it does not transmit the vertebral artery; it transmits the posterior of the two vertebral veins when there are two of these veins instead of one; on one or both sides it may be double.

Thoracic Vertebræ

Thoracic vertebræ lie in the posterior wall of the chest with 12 pairs of ribs attached to them [θώραξ (thōrax) = a cuirass]. They are of medium size, and increase in size from above downwards; their distinctive character is that they all have facets on their sides for articulation with the heads of ribs (see Figs. 131 and 135). The **body** of each of the upper eight articulates with two pairs of ribs—the pair with which it corresponds numerically and the pair below. For example, the body of the **first** articulates with the heads of the *first* pair of ribs and the upper part of the *second* pair; the **second** body with the lower part of the heads of the *second* pair and upper part of the *third* pair; and so on to the **eighth** body, which articulates with part of the *eighth* pair of ribs and part of the *ninth* pair. The bodies of the lower four articulate only with the ribs with which they correspond numerically.

The upper ten have a facet on each **transverse process** for articulation with the tubercle of the corresponding rib (see Fig. 147). The lower two do not have facets on the transverse processes. The thoracic transverse processes are thick, their posterior surfaces lie under cover of the muscles of the back, and their tips are a little more than one inch from the median plane. The **spines** are long and sloping, especially in the middle of the series, where the slope is so steep that the spine is almost vertical. In the upper and lower vertebræ the spines are shorter and slant very little in comparison. The lower can be distinguished from the upper by the

large size of the bodies. The tip of the spine of the *first* thoracic vertebra is the lower of the two knobs felt at the root of the back of the neck. The spine of the *third* is at the level of the spine of the scapula where it joins the medial border, and that point is easily found in the living body. The spine of the *seventh* is at the level of the inferior angle of the scapula (Figs. 130, 151).

The first two thoracic vertebræ and the lower four have special characters by which they can be distinguished individually; the other six belong to a common type; but when the whole series are from the same skeleton they are easily placed in their proper order, if the gradual changes in appearance are noted.

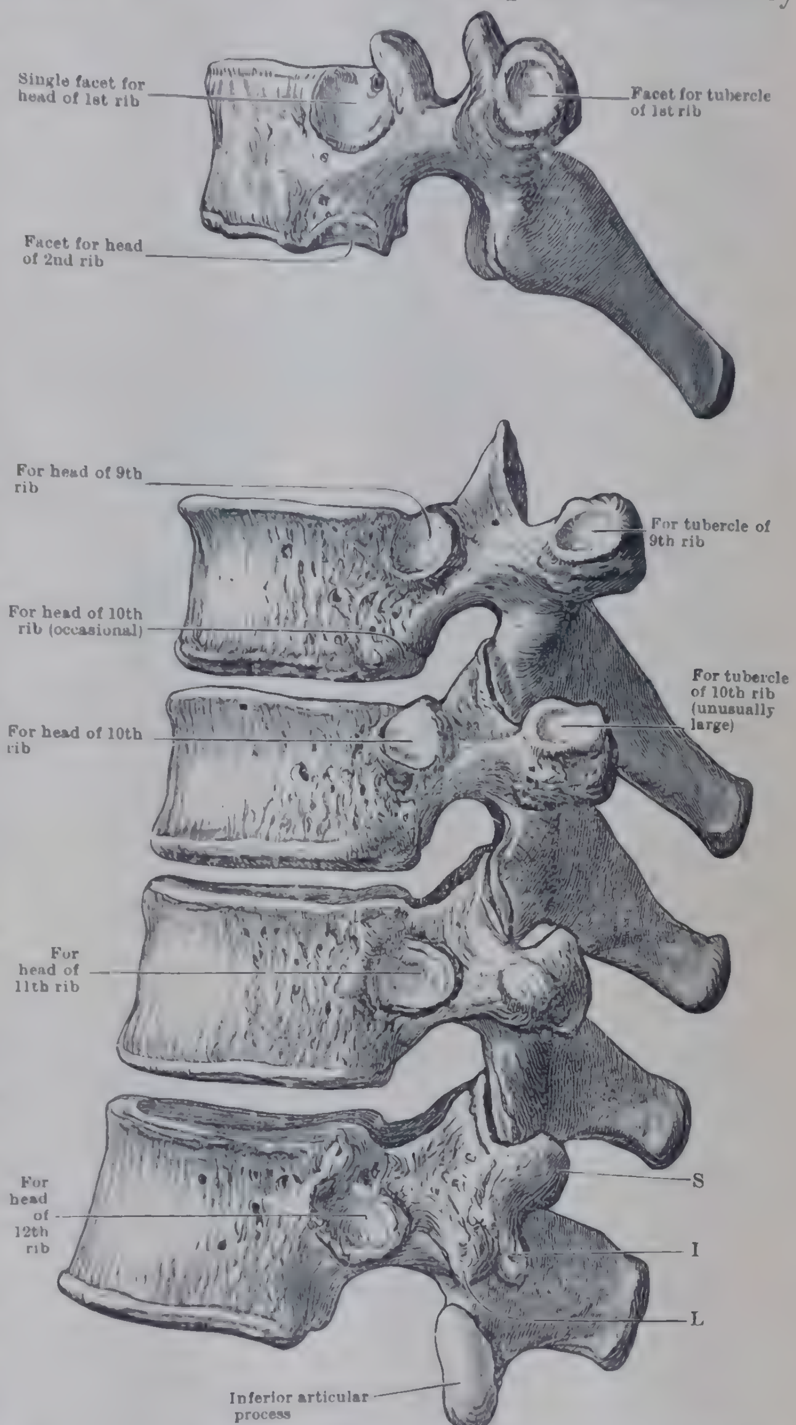

Fig. 135.—Left Side of the First, Ninth, Tenth, Eleventh, and Twelfth Thoracic Vertebræ.

S. Superior, I. Inferior } tubercles correspond to { Mamillary, Accessory } of lumbar.
L. Lateral tubercle = posterior part of root of Transverse

A Typical Thoracic Vertebra (Fig. 131).—The *upper* and *lower surfaces* of the **body** are almost flat, and are heart-shaped in outline. The *posterior surface* is slightly concave from side to side; it is slightly deeper than the *anterior surface* to conform with the curvature of the backbone in the thoracic region (p. 135). There are two unequal *facets* set far back at the widest part on each side of the body, the larger one at the upper border and the smaller at the lower border. The lower facet of one vertebra is directly above the upper facet of the vertebra next below; the two facets, together with the side of the intervertebral disc, make a socket for the head of the rib that corresponds numerically with the lower of the two vertebræ.

The **pedicles** increase in thickness from above downwards. Each is compressed from side to side; it passes more directly backwards than in the cervical and lumbar regions, and is inclined upwards. It springs from the body nearer the upper border than the lower; the **superior vertebral notch** is therefore shallow, and the **inferior** is deep. Owing to the direction of the pedicles, the **laminæ** are narrow, but they are deep and overlap the laminæ below; such overlapping is called *imbrication* [*imbrex* = a tile]. The **vertebral foramen** is smaller than in the cervical and lumbar regions, as there is less movement and less danger of compressing the spinal cord. The small size of the foramen and its circular outline are due to the direction of the pedicles and the narrowness of the laminæ.

The **spine** is long, slender, and three-sided, and its ridges converge on its free end, which is slightly thickened; it slopes so as to overlap the spine below. The **transverse processes** are long, thick, and rounded, and are inclined backwards and upwards. The free end of each is clubbed, is roughened for muscular and ligamentous attachments, and bears on its anterior surface a *facet* for articulation with the tubercle of the rib of corresponding number; owing to the backward inclination of the process, the facet looks sidewards rather than forwards, and in the lower members it looks upwards as well; the process is connected with the corresponding rib by a

joint-capsule and by the lateral and inferior costo-transverse ligaments. It is connected with the neck of the rib below by the superior costo-transverse ligament. The *superior articular surfaces* are flat, and look backwards and slightly upwards and sidewards; they are situated on distinct **articular processes**. The *inferior articular surfaces* are situated partly on the lower parts of the laminæ near the pedicles, and partly on short **articular processes** that jut downwards from the laminæ. Their direction is the opposite of that of the superior surfaces and the articular surfaces lie concentrically so as to allow movement round the axis of rotation of the bodies as well as flexion and extension

The *body* of the **first thoracic vertebra** resembles that of a lower cervical vertebra in general outline, and also in that the postero-lateral part of the upper surface is raised up as a prominent lip which makes the superior vertebral notch deeper than that of any other thoracic vertebra. The body departs from type in its costal facets also; it has a complete, full-sized facet on each side near the upper border for the whole of the head of the first rib, and a small facet at the lower border for the upper part of the head of the second rib. The superior articular processes are wider than those of a typical vertebra and are less upright, and they encroach on the upper surfaces of the transverse processes.

The **second** often resembles the first, but the large facet at the upper border is not quite complete, and its superior vertebral notch and articular process conform to type.

The **ninth** has only one facet on the body; it is at the upper border—encroaching on the pedicle—and is incomplete; it is for articulation with the lower part of the head of the ninth rib. There may be a small facet at the lower border also, in which case the ninth would be a typical vertebra, and the tenth would resemble a ninth. Occasionally, the facet on the ninth is complete; in that case the eighth would resemble a ninth, and the ninth would not be readily distinguished from a tenth unless it was known that they both belonged to the same skeleton. The facet on the transverse process is on its upper surface rather than on the front.

The **tenth, eleventh**, and **twelfth** have *large bodies* resembling those of lumbar vertebræ, and each of them has only one pair of facets for the heads of ribs. The facet is large and complete, and is more on the pedicle than on the body; it is for articulation with the head of the rib of corresponding number. The facet on the *tenth* is near the upper border, while that on the *eleventh* is lower down; the tenth has a small facet on the upper surface of the transverse process, and the eleventh has none; those two, therefore, can usually be distinguished, though it is not always easy when they are from different skeletons. The **twelfth** is easily identified. Its *transverse processes* are each replaced by three small tubercles. Its costal facet is on the middle of the pedicle—or lower. The articular surfaces of the *inferior articular processes* look in a lateral direction, while in other thoracic vertebræ they look forwards. In some skeletons the inferior articular processes of the eleventh resemble those of the twelfth, but the transverse processes of the eleventh are not replaced by tubercles. The inferior articular facets, which face laterally, will limit rotation of the vertebral column by locking against the superior facets of the vertebra below.

Lumbar Vertebræ

Lumbar vertebræ lie in the loins or "small of the back" [*lumbus* = the loin]. They are the only bones that belong exclusively to the *abdomen proper* which is less supported by bone than any other part of the body. Their *large size* distinguishes them at a glance from cervical vertebræ and most thoracic vertebræ; the *thin transverse processes* and *hatchet-shaped spine* distinguish them (all except the fifth) from the bulky lower thoracic vertebræ. The negative distinctive characters common to all lumbar vertebræ are the *absence* of a foramen in the transverse process and the *absence* of facets for ribs.

The **bodies** are about an inch in depth; they are almost two inches wide at their widest part, and structures that lie alongside the bodies are therefore about an inch from the median plane; and the tips of the **transverse processes** are rather more than an inch and a half from the median plane. The **umbilicus** is opposite the disc between the bodies of the *third* and *fourth*. The *fourth* is at the level of the *highest* part of the **iliac crest** (Fig. 150), and the *fifth* is at the level of the *tubercle* of the **iliac crest**. The **laminæ** droop considerably below the level of the pedicles, so that, though the spine is nearly horizontal, its posterior edge is at the level of the lower part of the body of its own vertebra and the upper part of the body next below. The laminæ do not overlap (Fig. 151); there is an interval between the spines and laminæ of two contiguous lumbar vertebræ through which an instrument can be passed into the vertebral canal in a living person—the operation being called *lumbar puncture*. Lumbar vertebræ measure about three inches from the posterior border of the spine to the front of the body, and therefore account for a large part of the antero-posterior diameter of the trunk about the level of the umbilicus.

The fifth lumbar vertebra has distinguishing features of its own; the others belong to a common type, though there are minor differences among them.

A Typical Lumbar Vertebra.—The **body** is large; its *upper* and *lower surfaces* are nearly flat and have a slight resemblance to a kidney in outline; the *posterior surface* is slightly concave, and, in the lower three, is less in depth than the *anterior*, in conformity with the curve of the lumbar part of the backbone, which is convex forwards; the greater part of that convexity is, however, accounted for by the fact that the intervertebral discs are thicker in front than behind.

The **pedicles** are short, thick, and horizontal, with a slight lateral inclination, and are compressed sideways. They spring from the upper part of the body; therefore the **superior vertebral notches** are shallow and the **inferior** are deep. The **laminæ** are thick and uneven; they droop considerably below the level of the pedicles but do not imbricate. The **vertebral foramen** is triangular in outline with rounded corners; it is larger than in the thoracic region owing to the larger size of the body, but smaller than in the cervical region as the pedicles are less oblique.

The **spine** is large and hatchet-shaped, and, owing to a great exaggeration of the median ridge, is almost horizontal. The **superior articular processes** are broad and uneven. The posterior border of each process is smooth, rounded, and slightly enlarged, and is called the *mamillary process* [*mamilla* = a nipple]. The articular surface is on the medial side, is concave from before backwards and faces medially and slightly backwards so as to prevent much rotation. The **inferior articular processes** project downwards from the lower part of the laminæ, and are pointed at their lower ends. They fit in between the superior processes of the vertebra below; they are therefore closer together than the superior pair, and the articular surfaces look in a lateral direction and are convex. The line of the joint is therefore almost in a sagittal plane; but sometimes, in the lower members, the articular surfaces have a lessened convexity and look forwards as well as sidewards; the superior processes of the next vertebra are correspondingly altered, and the result is that the line of the joint is oblique or nearly transverse, and the inferior processes are nearly as far apart as the superior.

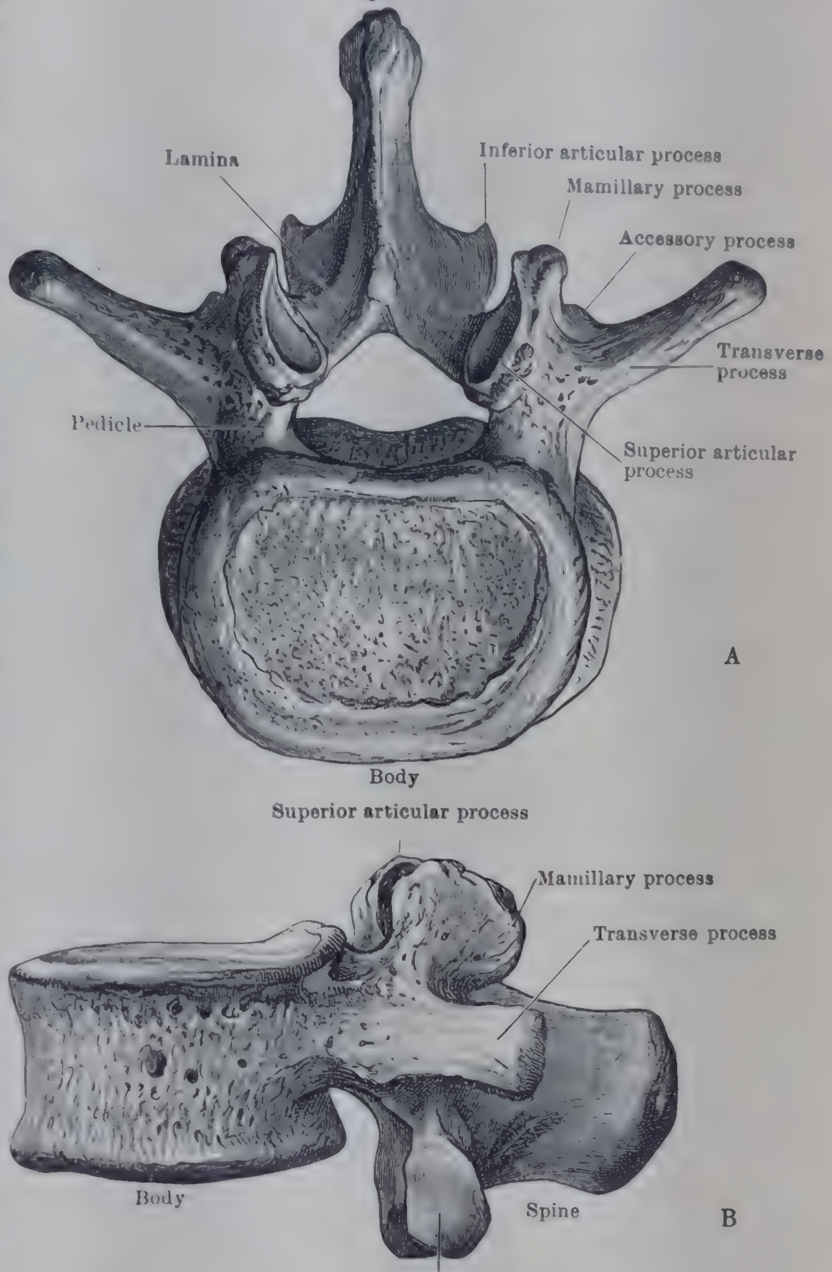

FIG. 136.—THIRD LUMBAR VERTEBRA, (A) from above, and (B) from the left side.

The **transverse processes** are long, thin and compressed from before backwards, and they incline slightly backwards and upwards. In the lower vertebræ they spring from the pedicle as well as from the junction of pedicle and lamina, and the superior vertebral notch extends as a shallow groove on to the root of the process. On the back of each root there is a little tubercle called the *accessory process*. The mamillary and accessory processes and the posterior part of the root of the transverse process correspond to the transverse process of a thoracic vertebra, as may be seen if the last two thoracic vertebræ and the first lumbar vertebra are placed together in order; almost the whole of the transverse process of a lumbar vertebra is the homologue of a rib, and occasionally the first one is separate as a **lumbar rib**.

Certain minor differences among lumbar vertebræ may be noted. The body of the first may be deeper behind than in front, and these measurements may be equal in the second, while the others are deeper in front than behind. The third transverse process is usually the longest, and the others are shorter in this order 4th, 2nd, 1st, 5th. But these differences are inconstant, and it may be impossible to attach a number to one of the upper four unless the

others are present. Progressive differences are then obvious. From above downwards, the bodies widen, the pedicles thicken, the articular processes are farther apart, the mamillary processes become less prominent, and the length of the whole articular column is reduced. The spines increase in depth to the third and then diminish.

The **fifth lumbar vertebra** is usually the largest of the lumbar vertebræ, though its body is usually of less depth than the fourth. The front of the **body** is usually much deeper than the back. The **spine** is small, and its corners are rounded off. The transverse process is short, thick, and conical; its root is attached to the junction of lamina and pedicle and also to the side of the pedicle or even to the side of the body. A strong ilio-lumbar ligament stretches from its tip to the adjoining part of the iliac crest. The **inferior articular processes** are as wide apart as the superior, or even wider, for they have to articulate with the widely separated superior articular processes of the sacrum. Their articular surfaces are less convex than in a typical vertebra and look forwards as well as sidewards—sometimes more forward than sidewards.

Sacrum and Coccyx

The **sacrum** is a large bone made up of the five sacral vertebræ, which are fused together in order to increase the stability of the pelvis [*os sacrum*; the "sacred" bone—called *luz* in ancient times—supposed to resist decay and to be the seed from which the body was to be resurrected]. It lies below the small of the back, almost horizontally, in the dorsal wall of the pelvis between the two hip-bones where it can be felt as an uneven bony surface. It forms by far the greater part of the dorsal wall of the cavity of the pelvis and is held in place by exceedingly strong ligaments. Shaped like an inverted triangle, it possesses a wide upper end or **base**, a small lower end or **apex**, right and left **borders**, a rough, uneven **dorsal surface**, and a relatively smooth **pelvic surface**.

The **pelvic surface** is concave and looks downwards and forwards; it presents a large median column of bone separated from a smaller mass on each side by a vertical series of four holes. The median column consists of the **bodies** of the five sacral vertebræ and the ossified intervertebral cartilages all fused together. The block of bone on each side is the **lateral mass** of the sacrum. The four pairs of holes are the **anterior sacral foramina** and the anterior primary rami of the upper four pairs of sacral nerves issue through them. When the coccyx has fused with the sacrum there are five pairs of foramina.

The **base** is directed forwards and upwards. In the middle there is the upper surface of the **body** of the first sacral vertebra; its prominent anterior border forms the *promontory* of the sacrum. On each side of the body there is a wide, spreading surface called the **ala** of the sacrum; it is the upper end of the lateral mass. The promontory and the anterior borders of the two alæ form the posterior part of the brim of the true pelvis. The **vertebral foramen** is the large opening behind the body and leads into the *sacral canal*. The **superior articular processes** are the pair of upstanding projections at the sides of the vertebral foramen.

The **apex** is the lower surface of the body of the fifth sacral vertebra.

Each side or **border** of the sacrum is very thick above and much thinner below. The upper part is a sharply defined area that has some resemblance to an ear and is therefore called the **auricular surface**; it articulates with a corresponding auricular surface on the hip-bone to form the *sacro-iliac joint*. The thinner, lower part of the border, as it is traced downwards, turns abruptly towards the body of the fifth vertebra, where it ends; the point where the change of direction takes place is called the **inferior lateral angle** of the sacrum.

The **dorsal surface** is very rough and uneven, and is convex. In the median plane there is a row of **spinous tubercles**; they are the spines of the sacral vertebræ, and may be united by ossified ligaments into a median crest. The second spine or spinous tubercle is opposite the middle of the sacro-iliac joint, and, when the body is erect, it is at the same level as the promontory of the sacrum and the posterior superior iliac spine of the hip-bone. About an inch lateral to the median plane there is a vertical row of four **posterior sacral foramina**; they are opposite the anterior foramina, and transmit the posterior primary rami of the upper four sacral nerves. The posterior parts of the vertebral arches of the lower two or more sacral vertebræ are absent; the row of spines therefore does not reach the lower end. The lowest complete vertebral foramen is the lower end of the sacral canal;

it is an oblique opening; and its margins are prolonged downwards to the fifth vertebra and end as two blunt projections called the **sacral cornua**.

The chief contents of the **sacral canal** are the roots of the sacral and coccygeal nerves, the filum terminale and the lowest parts of the dura mater and arachnoid mater. The lower end of the sacral canal gives exit to the fifth pair of sacral nerves, the pair of coccygeal nerves and the filum terminale. (Dura mater and arachnoid mater are the names given to the outer two of the three membranes that surround the spinal cord; they are continued downwards around the roots of the nerves as far as the second piece of the sacrum. The innermost membrane is called the pia mater; the filum terminale is a long, slender glistening thread continued

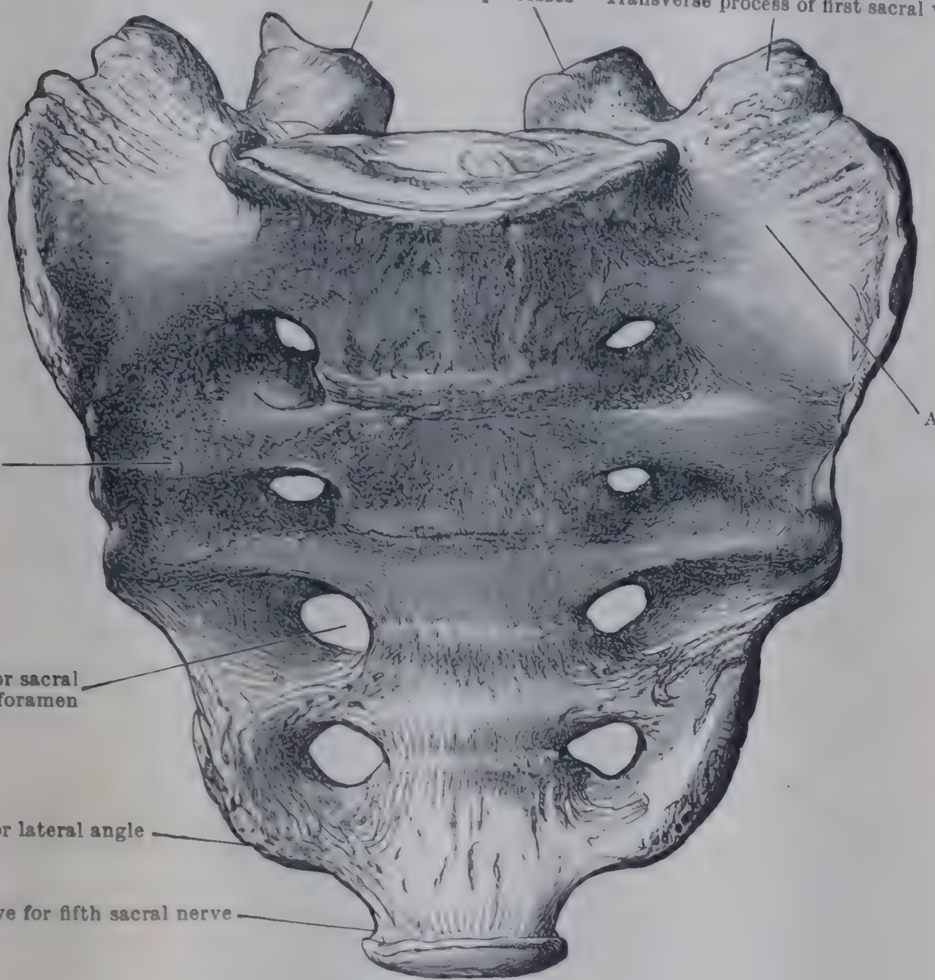

FIG. 137.—THE SACRUM (pelvic view).

downwards from the lower end of the pia mater and it ends by blending with the periosteum on the back of the coccyx.)

The **coccyx** is the lowest part of the backbone and has a fancied resemblance to the bill of a bird [κόκκυξ (coccyx) = a cuckoo] It lies in the floor of the groove between the buttocks a little above the anus, and, at the same time, in the dorsal wall of the pelvis below the sacrum. It is made up of four small incomplete vertebræ fused together, and, like the sacrum, it is triangular in outline with the apex below. It has a base, an apex, a pelvic surface, a dorsal surface, and a pair of borders. The **first vertebra** is much the largest; its *upper surface* is the **base** of the coccyx and articulates with the apex of the sacrum; from its **dorsal surface** a pair of processes called the **coccygeal cornua** project upwards; and from each border a **transverse process** juts out. The lower three vertebræ are mere nodules of bone, usually diminishing in size from above downwards. Occasionally the coccyx consists of three or of five pieces instead of four.

The **pelvic surface** of the **sacrum** is concave from above downwards, and slightly concave from side to side also, the degree of concavity varying greatly in different specimens. Four *transverse ridges*, which are the edges of ossified intervertebral discs, indicate that there are five

bodies in the median column. The bodies diminish in width and thickness from above downwards and to a varying extent in depth; and, if a sagittal section is made, the remains of the discs are found between them. The four pairs of **anterior sacral foramina** are at the ends of the transverse ridges; they also diminish in size from above downwards and a short, shallow groove extends from the foramen on to the lateral mass. Each foramen transmits the anterior primary ramus of a sacral nerve, a branch of a lateral sacral artery, and an accompanying vein. The **lateral mass** is made up of the *transverse processes* of one side all fused together, including, as in the cervical region, a *rib element* in front and a *true transverse process* behind. The costal elements make up the larger part of the lateral mass (Fig. 144), especially in the upper three segments which articulate with the ilium.

The median sacral artery with its companion veins, runs down the middle of the pelvic surface of the sacrum and ends on the pelvic surface of the coccyx. The sympathetic trunk runs down

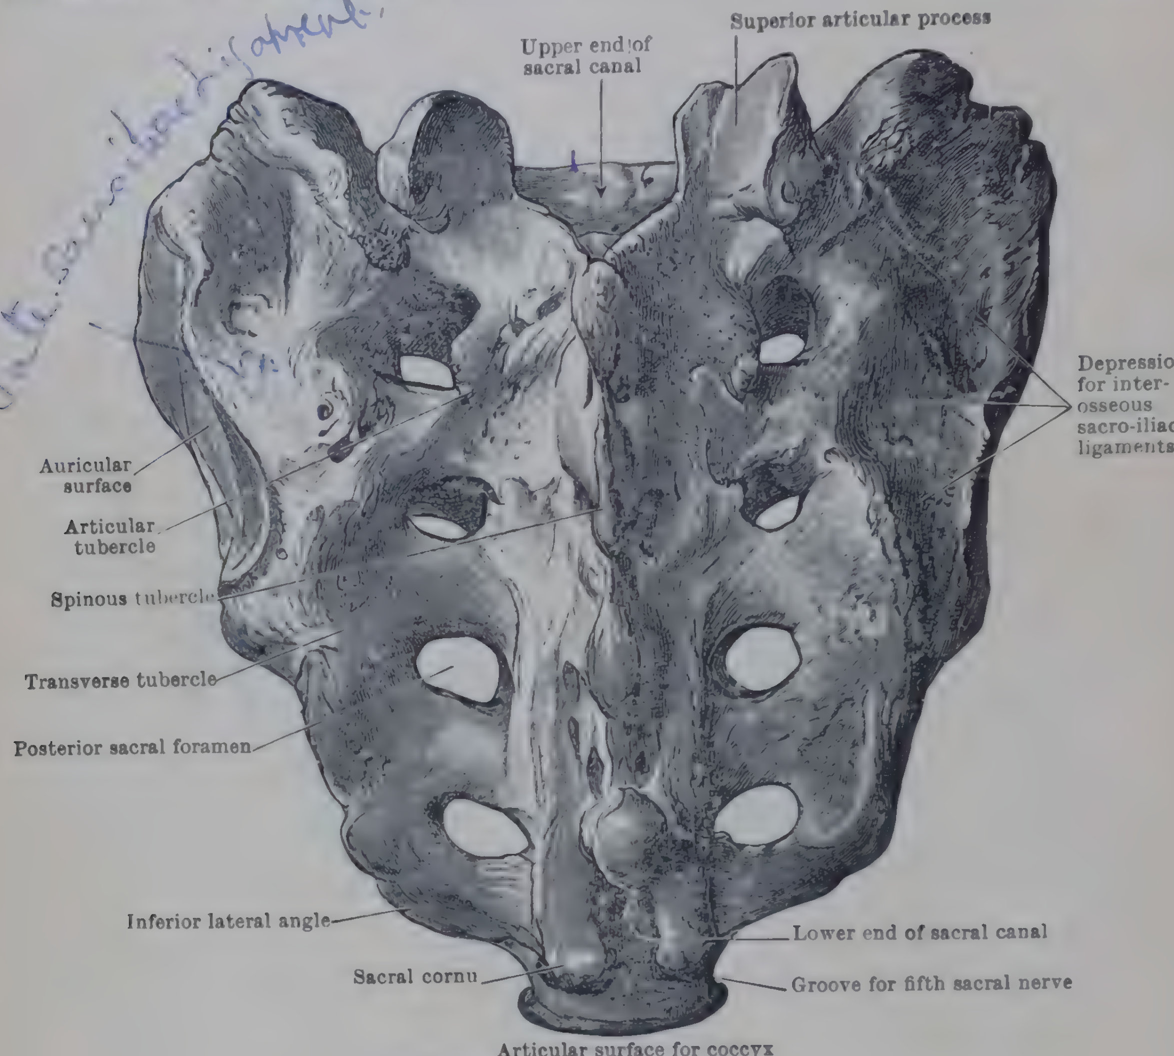

FIG. 138.—THE SACRUM (dorsal view).

across the medial parts of the anterior sacral foramina and joins its fellow of the other side on the front of the coccyx. The greater part of the piriformis muscle arises from the middle three pieces of the sacrum between the anterior foramina. The rectum is closely related to the pelvic surface of the coccyx and the lower half of the sacrum. The bodies above that are clothed with peritoneum.

On the **base** of the sacrum the constituent parts of the first sacral vertebra may be made out fairly clearly. The upper surface of the **body** resembles the body of the fifth lumbar vertebra in outline; it is bound to that body by the lowest intervertebral disc and the lower ends of the anterior and posterior longitudinal ligaments. The **vertebral foramen** is large, sloping, and triangular. The **superior articular processes** stand up from the sides of the vertebral arch. Their articular surfaces are concave; they look medially and backwards, and they articulate with the inferior articular processes of the fifth lumbar vertebra, to which they are bound by articular capsules. The **laminæ** are connected with the laminæ of that vertebra by the lowest pair of ligamenta flava. The **pedicle** is the part between the superior articular process and the body, and it may be marked off from the ala by a pit, or, in rare cases, by a foramen. It is the lower boundary of the intervertebral foramen through which the fifth lumbar nerve issues. The vertebral notch is on the root of the pedicle, and it is continuous with two grooves: the one groove is for the posterior primary ramus of the nerve, and it runs backwards between the articular process and the lateral mass; the other is for the anterior primary ramus and runs forwards to the side of the body, whence the anterior ramus, running downwards, forwards, and sidewards,

sometimes makes a shallow groove on the ala. The **ala** is the transverse process; its posterior part is the *true transverse process* and may be marked off from the rest by a slight depression; the postero-lateral angle of the ala is the tip of the true transverse process and may be marked off from the margin in front of it by a notch. The ala is continuous with the floor of the iliac fossa of the hip-bone when the bones are articulated; the lumbo-sacral ligament and some fibres of the iliacus are attached to it. Its lateral margin is the anterior or upper boundary of the auricular surface.

The **apex** is attached to the body of the first coccygeal vertebra by an intervertebral disc and by the anterior and the deep posterior sacro-coccygeal ligaments.

The **lateral border** is curved sinuously as it is traced from base to apex, for the third piece of the sacrum is rather wider than the second, and the border turns abruptly towards the body of the fifth piece. The **auricular surface** belongs to the upper two or three pieces; it is uneven and usually rough, though it is the articulating surface at a synovial joint; its inequalities fit into reverse inequalities of the auricular surface of the hip-bone, so that very little movement is possible at the joint. The anterior and lower parts of the joint-capsule are together called the anterior sacro-iliac ligament, which is attached to the convex margin of the auricular surface; the posterior or upper part is the interosseous sacro-iliac ligament, which is very thick and strong, and is attached to the concave margin of the surface and to the wide, uneven depression above and behind it. The pelvic surface of the upper part of the sacrum is wider than the dorsal surface, and the auricular surface slopes accordingly; in the articulated pelvis the sacrum is therefore the reverse of the keystone of an arch; the interosseous ligaments of the two sides are the principal factors in holding it in place.

The thinner, lower part of the lateral border gives attachment to part of the sacro-tuberous ligament; the upper parts of the sacro-spinous ligament and coccygeus muscle are attached to the side of the fifth piece in front of the sacro-tuberous ligament; and the **inferior lateral angle** is connected with the transverse process of the coccyx by the lateral sacro-coccygeal ligament.

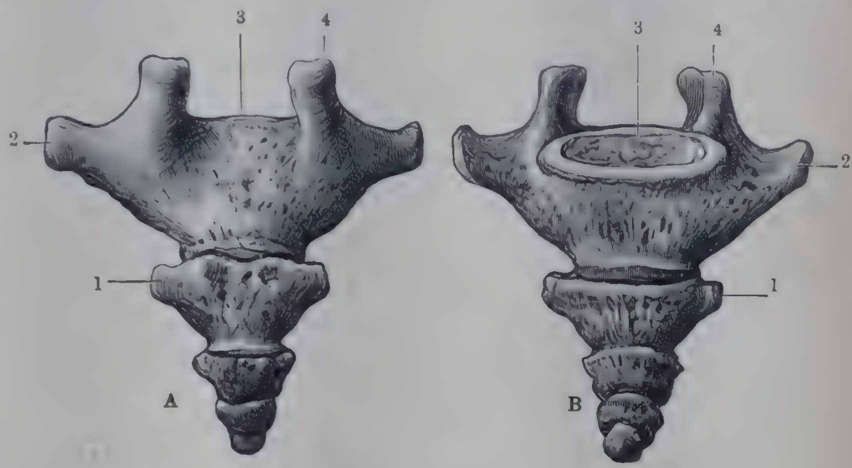

FIG. 139.—THE COCCYX.
A. Dorsal Surface. B. Pelvic Surface.
1. Transverse process. 2. Transverse process. 3. For Sacrum. 4. Cornu.

The **dorsal surface** is directed upwards and backwards. The ridge of **spinous tubercles** varies greatly in its degree of prominence; its upper end gives attachment to a supraspinous and an interspinous ligament that connect it with the lowest lumbar spine, and the lower part of the lumbar fascia is attached to each lip of the ridge. At each side of the root of the ridge there is a rough plate of bone made up of the laminæ united by ossified ligaments. Lateral to that plate there are the four **posterior sacral foramina**; they diminish in size from above downwards, and each one transmits the posterior primary ramus of a sacral nerve, accompanied by small terminal branches of the lateral sacral vessels. At the medial margin of each foramen there is a small projection which is called an **articular tubercle** because it represents the inferior and superior articular processes of two contiguous sacral vertebræ fused together. The lowest of the series is the **sacral cornu**, which represents an inferior articular process of the fifth sacral vertebra; the two sacral cornua are connected by ligaments with the coccygeal cornua. Lateral to the posterior sacral foramina, on the back of the lateral mass, there is a row of **transverse tubercles** which represent the tips of the fused true transverse processes. The sacro-spinalis muscle arises from the spinous and transverse tubercles, and the multifidus from the uneven surface that separates these two rows of tubercles. The short posterior sacro-iliac ligament is attached to the first and second transverse tubercles (the first being the postero-lateral angle of the ala); the long posterior sacro-iliac ligament to the third tubercle; part of the sacro-tuberous ligament to the fourth and fifth; fibres of the gluteus maximus arise from the back of the sacrum, but they spring from these ligaments and the lumbar fascia rather than from bone.

The **sacral canal** is the lowest part of the vertebral canal. It lies between the united bodies and the united laminæ. Its upper part is triangular; its lower part is flattened from before backwards. On each of its two margins there is a series of four large apertures that correspond to **intervertebral foramina**; they transmit the upper four sacral nerves, and each one divides into two parts which end as an anterior and a posterior sacral foramen. The canal *contains*: (1) a quantity of soft fat in which there lie small arteries and fairly large, thin-walled veins, (2) the roots of the sacral and coccygeal nerves, (3) the filum terminale, (4) the lower part of the spinal dura mater and arachnoid mater down to the level of the second spine. The lower part of the posterior wall of the canal is deficient owing to the absence of the laminæ and spine of the fifth vertebra and, very often, of the fourth also. The lower opening of the canal, or *hiatus sacralis*, is therefore very oblique. It is closed by a thick membrane, called the superficial posterior

sacro-coccygeal ligament, which extends from its upper and lateral margins to the back of the coccyx. The hiatus transmits the filum terminale and the primary rami of the coccygeal and fifth sacral nerves.

The coccygeal cornua correspond to pedicles and superior articular processes. In specimens in which the sacrum and coccyx are fused together the ligaments that connect the sacral and coccygeal cornua may be ossified, and so also may be the ligaments that connect the inferior lateral angles of the sacrum with the transverse processes of the coccyx; in such a specimen there are a *fifth pair* of intervertebral foramina and corresponding sacral foramina.

The back of the first piece of the **coccyx** gives attachment to the filum terminale, and a few fibres of the gluteus maximus. Its margin gives attachment to the lower parts of the sacro-tuberous ligament, the sacrospinous ligament, and the coccygeus muscle, in that order from behind forwards. The posterior fibres of the levator ani muscle are inserted into the side of the lower pieces; the sphincter ani externus and the ano-coccygeal body are attached to its apex.

Sexual Differences.—In the male the curve of the sacrum is fairly uniform and is deepest opposite the third piece. In the female the sacrum is flatter above and more sharply bent forwards below. In the female the auricular surface may be limited to the first two pieces; in the male it includes the third partly or wholly. The female sacrum is shorter and wider (in accordance with a shorter and wider pelvic cavity) and the alæ form nearly two-thirds of the width of its base. Its pelvic surface looks more downwards than in the male. The coccyx is more movable in the female and less liable to be fused with the sacrum, and the first piece of the coccyx more often fails to fuse with the second piece than in the male.

VERTEBRAL COLUMN AS A WHOLE

The **vertebral column** is about 28 inches (70 cm.) long in a man and 24 inches (60 cm.) in a woman; and it is said to diminish nearly half an inch during the day. The discs account for nearly one-fourth of its length. In a man, approximate measurements for the different regions are: cervical, 5 in.; thoracic, 11 in.; lumbar, 7 in.; sacrum and coccyx, 5 in. The length increases up to the age of twenty-five or more; it diminishes in old age owing to reduction of the thickness of the discs and to exaggeration of the curve in the thoracic region. The proportion of its length to the whole length of the body is—3 : 4 at the third week of intra-uterine life; about 3 : 7 at birth; and 3 : 7·5 in a young man.

The column can bear a weight of nearly 7 cwt. without crushing, and a tearing strain of nearly 3 cwt. Its weakest part is between the second and third cervical vertebræ but the part most liable to injury is at the twelfth thoracic, for at that level the column has the smallest transverse width (Fig. 141), and is acted upon by the longest leverage. The important factor, however, is that this region lies at the junction of relatively fixed and freely movable parts.

The vertebræ are joined together by the discs between the bodies and by the ligaments that connect the body, laminæ, and processes of one vertebra with corresponding parts of its two immediate neighbours, so making a strong column for the support of the trunk and neck and a pedestal for the head. It is a flexible and resilient column for, although the vertebræ are firmly bound together, a little movement is possible between each two (with the exception of the segments of sacrum and coccyx). The sum of the movements between each two over the whole movable part of the column is considerable. The vertebræ derive their name from the rotary movements between them. [*Vertere* = to turn.]

The column of **bodies** is the chief axis of support and the bodies increase in size with the increasing weight carried from above down to the sacrum where the body weight is transmitted to the pelvic girdle. Below that level the sacrum tapers rapidly. The **vertebral arches** close in the vertebral canal, in which the spinal cord lies in safety; the **articular processes** permit movement but also control its direction and help to limit its range; the **spines** and **transverse processes** are levers to which muscles are attached.

Curvatures.—**At birth** the column has two **primary curvatures**, both concave forwards. The lower one, made by the sacral and coccygeal vertebræ, begins to appear at the fifth month of intra-uterine life and accommodates the pelvic viscera. The upper one includes all the rest of the column, and is present from the earliest period. The **sacro-vertebral angle** is formed where the two curves meet, at the junction of the last lumbar vertebra and the first sacral. It is more acute in the female than in the male.

In the adult the assumption of an erect posture has produced two **secondary**

curvatures, convex forwards, in the cervical and lumbar regions. The alternating curves, in conjunction with the intervertebral discs and the muscles, provide considerable elasticity to the upright column. The original primary curve, concave forwards in both thoracic and lumbar regions, is a characteristic feature in the quadrupeds. The pronounced lumbar curve characteristic of the human vertebral column is associated with an erect posture during life and a pronounced alteration in the mechanics of the vertebral column. The curvatures are maintained partly by the shape of the vertebral bodies, partly by the shape of the intervertebral discs, and partly by the tension of the soft parts such as the ligaments and, particularly, the muscles. Any attempt to reconstruct the spinal curvatures from dried bones is rendered difficult or impossible by the absence of the intervertebral discs; but it must be remembered that an increased range of movement during life, or an habitual posture, may result in misleading conclusions. Habitual squatting, for example, may give rise to compression of the anterior parts of the vertebral bodies and suggest a flattening of the lumbar curve which did not exist during life except as a transient phenomenon.

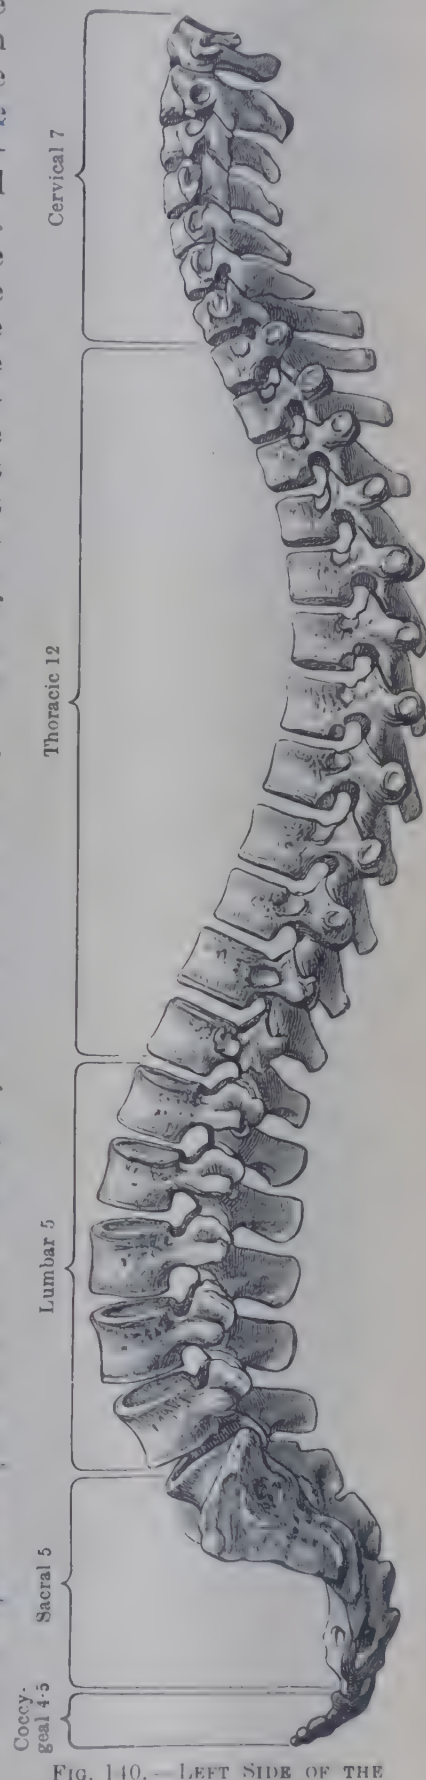

Fig. 140.—Left Side of the Vertebral Column.

The **cervical curvature** is convex forwards. It begins at the atlas, culminates at the fifth cervical, and, at its lower part, merges into the thoracic curve; the lower border of the second thoracic vertebra is taken as the level where the two curves meet, for that is the level of the upper border of the breastbone, and the upper two thoracic vertebræ lie, therefore, in a sense, in the neck. The cervical curvature is the least marked of the four curves and is undone when the neck is bent forwards. It is a *secondary* or *compensatory* curve and is due chiefly to the shape of the discs. It begins to be formed two or three months after birth, when the child begins to lift its head up from the chest; and it becomes further developed at the eighth or ninth month, when the child begins to sit upright. The **thoracic curvature** is concave forwards. It is deepest at the sixth thoracic vertebra, and extends to the twelfth, where it merges into the lumbar curve. It is a primary curve and is due to the shape of the bodies of the vertebræ. The **lumbar curvature** is convex forwards. It is more pronounced in women than in men, and in youth than in the elderly. It culminates opposite the umbilicus, between the third and fourth lumbar vertebræ or at the fourth, and it extends to the sacro-vertebral angle. It is a *secondary* or *compensatory* curve, due chiefly to the shape of the discs. It begins a year after birth, when the child, adopting the erect attitude, lifts up its trunk, straightens out its lower limbs and begins to walk; it makes its first appearance immediately above the sacro-vertebral angle, and gradually extends upwards as the lower limbs come more into use. The **sacrococcygeal curvature** is the original lower *primary curve* and is concave downwards and forwards.

Besides having those four curvatures the column of bodies is often slightly convex towards the right side in the thoracic region. That **lateral curvature** may

be due to the greater muscularity and use of the right upper limb, for it is said to be convex towards the left in left-handed people; but much more probably it is due to the pressure that the upper part of the descending aorta exerts by its pulsations on the left side of the bodies of the middle four thoracic vertebræ, and in the rare cases in which the aorta is on the other side of these vertebræ the curve is convex towards the left. When the lateral curvature is well marked there are compensatory curves, in the opposite direction, above and below it.

The curvatures of a line drawn along the tips of the spines are not repetitions of the curvatures of the bodies, owing to the varying length and obliquity of the spines; and lateral curvature of the spines may be greater or lesser in degree than that of the bodies. Occasionally one or more spines may be deflected very considerably to one side without corresponding rotation of the body towards the opposite side and without any sign of past disease or of recent accident.

Curvatures of the backbone may become accentuated and distortions may occur as a result of weakness, disease, or accident. With advancing years the column loses its flexibility and resilience and becomes more set and rigid, In many skeletons evidence of ‘ rheumatic ’ osteo-arthritis is seen in the ‘ lipping ’ of the margins of the vertebræ and rough ridges and protuberances here and there.

The following points may be noted in the vertebral column :—

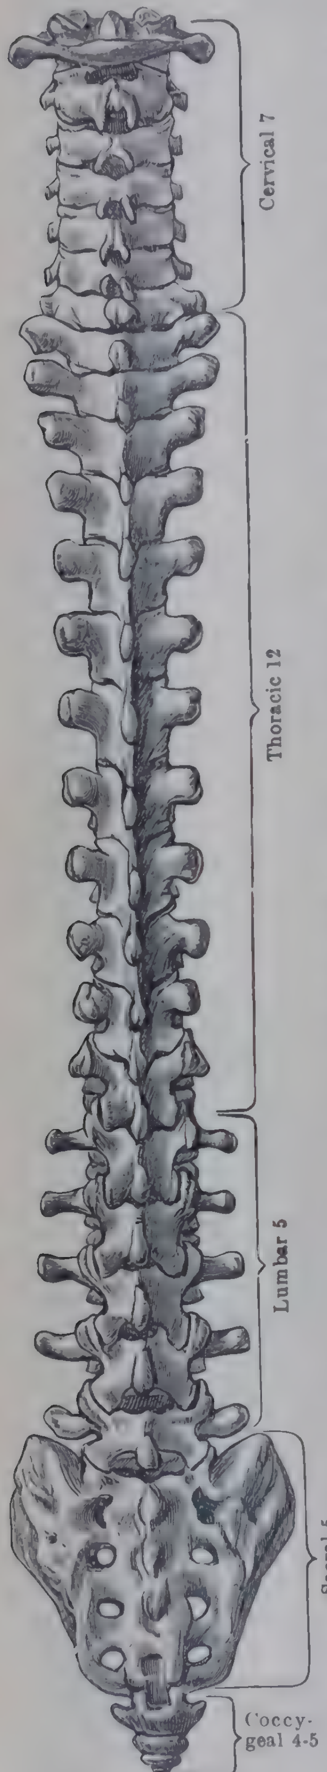

FIG. 141.—VERTEBRAL COLUMN FROM BEHIND.

When viewed from the Side.—(1) The four curvatures. (2) The antero-posterior diameters of the **bodies** increase gradually down to the *second lumbar*, and then gradually diminish. (3) The **costal facets** on the sides of the bodies, from the first thoracic downwards, gradually take up a position farther back till that on the twelfth is more on the pedicle than on the body. (4) The **intervertebral foramina** increase in size from above downwards. (5) The **transverse processes** of *cervical* and *lumbar* vertebræ are in front of the articular processes, while those of *thoracic* vertebræ, which do not incorporate a rib element, are behind and have more of a backward inclination. They are between the intervertebral foramina in the *cervical* region, and behind the foramina in the *thoracic* and *lumbar* regions; the change of characters is abrupt between cervical and thoracic regions, and more gradual between thoracic and true lumbar transverse processes. (6) Owing to the direction of the **articular surfaces** the clefts of the joints between the articular processes are visible in the cervical and thoracic regions, but not in the lumbar region. (7) The length and slope of the **spines** vary, and there is consequent lack of conformity between the curves of the spines and those of the bodies; the slope of the spines, though varying greatly, is always downwards, increasing in obliquity down to the seventh thoracic and then diminishing; in most lower animals the spines slope towards an ‘ anticlinal ’ vertebra situated in the hinder part of the thoracic region. (8) The antero-posterior diameter of the *lumbar vertebræ* is much greater than that of the others.

When viewed from the Front.—(1) The lateral curvatures, when present. (2) The column is widest at the base of the sacrum; the **bodies** increase in width from the second cervical to the first thoracic and diminish slightly from the first to the fourth; they increase gradually from the fifth thoracic to the first sacral, below which there is progressive diminution in width. (3) The side-to-side convexity of the bodies is sharper in the middle thoracic region than elsewhere. (4) In the vertical diameter the body of the second cervical vertebra is deeper than those of the lower five, which are nearly equal in depth; below that there is gradual increase in depth down to the third or fourth lumbar; the fifth lumbar is usually of less depth than the other lumbar vertebræ; in different skeletons any one of the thoracic vertebræ may be of less depth than the one above it. (5) The **transverse processes** of the *atlas* are outstanding and are wider apart than the next five pairs, the tips of which are at nearly equal distances from the median plane; those of the *seventh* are almost as long as the first thoracic; they gradually diminish from the

first thoracic to the twelfth, where they are mere tubercles; they are outstanding again in the lumbar region and vary in length, and though the third is usually the longest, its tip is not necessarily the farthest from the median plane, owing to the greater width of the fourth and fifth vertebræ as a whole. (6) The *sacrum* and *coccyx* rapidly diminish in width from above downwards, but there is little difference between the second and third pieces of the sacrum, and the third is usually the wider; the diminution is very sudden below the inferior lateral angle of the sacrum, and, again, below the transverse process of the coccyx.

When viewed from the Back.—(1) Differences in the lengths of the **transverse processes** as seen also from the front; in the cervical region they are hidden by the articular processes, so that only the posterior tubercles are visible; the transition from thoracic transverse process to lumbar mamillary and accessory processes is well seen. (2) The **articular processes** of the lower six cervical vertebræ are at equal distances apart, and are wider apart than those of the thoracic vertebræ; the distance gradually diminishes from the first thoracic to the first lumbar, below which it increases; the joint-clefts between articular processes are clearly visible in the lumbar region, less so in the cervical region, and not at all in the thoracic region. (3) The **laminæ** overlap in the thoracic region; in the lumbar region there are intervals between them; in the cervical region they overlap very slightly when the neck is straight, but there are intervals between them when the neck is bent forwards, and there is always a fairly wide interval between the atlas and the second vertebra, and also between the atlas and the skull. The widest inter-laminar gaps are between atlas and axis, fourth and fifth lumbar, and fifth lumbar and sacrum. (4) The different characters of the **spines** are seen, and their lateral curvatures or deflections, if present. (5) The **vertebral groove** is the wide furrow alongside the spines; it is shallow in the neck and the loins, where its floor is the laminæ and inferior articular processes, and deep in the thoracic region, where its floor is the laminæ, inferior articular processes and transverse processes.

OSSIFICATION OF VERTEBRÆ

A typical vertebra is ossified from three primary centres and five epiphyses. The **primary** centres are one in the *body* and one in each half of the *vertebral arch* (called also the *neural arch*); the **secondary** centres appear—one at the tip of the *spine*, one at the tip of each *transverse process*, and multiple centres (which soon coalesce) in the cartilage on the upper and lower surfaces of the *body*.

The *primary centres* for the **arch** appear gradually from above downwards, appearing first in the upper cervical region about the seventh week of intra-uterine life and reaching the sacrum about the twentieth week. They appear at the roots of the articular processes; the arch and its processes are ossified from them, and also the postero-lateral parts of the body—the parts of the body which, in thoracic vertebræ, articulate with the ribs.

The *centre* for the *centrum*, *i.e.*, the median, larger part of the **body**, appears dorsal to the notochord, first in the lower thoracic region about the tenth week; the process spreads up and down till by the twentieth week centres have appeared in all the bodies except in the last two pieces of the sacrum, where they may not appear till the thirtieth week, and in the coccyx, where they do not appear till after birth. Occasionally a body has a pair of centres which coalesce, but may fail to do so, and the body may ossify therefore as two separate halves—or one half only may ossify.

At birth the vertebra is in three pieces—the median, larger part (the *centrum*) of the body and the two parts ossified from the centres for the arch. The laminæ are not osseously united; the spine is cartilaginous. The median part (centrum) of the body is joined to each postero-lateral part by a plate of cartilage; the joint is called the *neuro-central joint*.

FIG. 142.—OSSIFICATION OF VERTEBRÆ.

The union of laminæ begins in the lumbar region soon after birth, and, spreading upwards, is completed in the cervical region early in the second year, but is deferred in the sacrum till between the seventh and tenth years. After fusion of the laminæ the ossifying process extends into the spine. The union of the body and arch, *i.e.*, the disappearance of the neuro-central joint, begins in the neck in the third year, and, spreading downwards, is completed in all regions in the sixth or seventh year.

The *secondary centres* appear at **puberty**, and the epiphyses formed from them fuse with the rest of the bone at 25. The epiphyses on the body are in the form of flat rings on the circumferential part of the upper and lower surfaces (Fig. 143 and Pl. IV, p. 105, Fig. 2); the centres for each ring appear at the edge of the cartilage; they vary in number and soon unite to form one circular centre. In the thoracic region the epiphysis on the tip of a transverse process includes part of the articular facet.

	Centres for arch.	Centre for body.	Laminæ unite.	Arch joins body.	Epiphyses appear.	Epiphyses join.
Cervical . .	7th week	15th week	Early 2nd yr.	3rd year	Puberty	25th year

Coccygeal . .	*none*	1st year to puberty	*none*	*none*	*none*	*none*

In many of the vertebræ the ossification departs from type.

In the **cervical region** the bifid tip of the **spine** has a *pair* of epiphyses.

Atlas Vertebra.—A primary centre for each half of the vertebral arch, including the lateral mass, appears at the seventh week. The two halves unite posteriorly in the third year, and their union may be preceded by a secondary centre in the cartilage between them. The anterior arch is cartilaginous at birth. One centre (or a pair) appears in it during the first year, and it fuses with the lateral masses about the seventh year. It includes the anterior part of the upper articular surface of the lateral mass. The epiphyses on the transverse processes unite about 18.

22. Centre for lower part of odontoid process.
23. Neuro-central joint.
24. Inferior epiphysial ring.
25. Single or double centre for body.

Atlas.

26. Posterior arch and lateral masses ossified from a single centre on each side. In this figure the posterior arch is represented complete by the union posteriorly of its posterior elements.
27. Anterior arch and portion of superior articular surface ossified from single or double centre.

Thoracic vertebra.

28. Centre for transverse process.
29. Centre for spine.
30. Centre for vertebral arch on each side. The arch is here shown complete posteriorly.
31. Centre for body.

Axis Vertebra.—A primary centre for each half of the vertebral arch appears in the seventh week; one or two for the lower part of the body early in the fifth month; a pair appear side by side for the upper part of the body and the lower part of the odontoid process later in the fifth month, and fuse during the seventh month. *At birth* the vertebra is in four bony pieces which unite between the third and sixth years. An epiphysis for the top of the odontoid process appears between the third and sixth years and fuses before 12; another appears on the lower surface of the body at puberty and fuses about 25.

The **sixth** and **seventh cervical vertebræ** may have separate primary centres in the costal processes; these join the rest of the bone about the fifth year. Sometimes in the seventh it does not join but forms a cervical rib.

Lumbar vertebræ have additional epiphyses on the *mamillary processes*. The **first lumbar vertebra** may have a separate primary centre for its *transverse process*, and it may remain separate as a **lumbar rib**. The **fifth** may have two primary centres in each half of the arch; the two parts of each half are then united by a plate of cartilage set obliquely between the superior and inferior articular processes. Its transverse process may have two epiphyses.

Sacrum.—**Primary centres** appear between the third and eighth months. One centre for each centrum and one for each half of the vertebral arch, and one for the costal element on each side in the upper three or four vertebræ. The costal parts fuse with the arches at the fifth year. The arches fuse with the centra a little later. The halves of the arches unite posteriorly between the seventh and tenth years. The segments of the lateral mass fuse together at puberty. **Epiphysial centres** appear on the upper and lower surfaces of the bodies at puberty; the epiphyses fuse with the bodies and the bodies fuse together from below upwards between 18 and 25. Numerous epiphysial centres appear on the ends of the costal and true transverse

processes at 18 (Fawcett, 1907). From them are formed an epiphysis which covers the auricular surface, and another which completes the margin below the auricular surface.

The **coccyx** is cartilaginous at birth. Each segment has one **primary** centre. They appear, from above downwards, between the first year and puberty. Fusion between segments takes place from below upwards, but is very variable. Epiphyses on the surface of the bodies and in the cornua have been described.

VARIATIONS IN VERTEBRÆ

Variation in number is due usually to the coccygeal vertebræ being reduced to three or increased to five or even six. Variations in other regions may occur through increase or reduction or rearrangement among the regions; the formula may be altered therefore in several ways, as follows :—

Cervical	7	7	7	6	7	7	7
Thoracic	13	12	12	13	13	12	12
Lumbar	5	6	4	5	4	6	4
Sacral	5	5	5	5	5	4	6
Coccygeal	4	4	4	4	4	4	4
	34	34	32	33	33	33	33

In addition to such numerical variations as the above, it is not uncommon to find that the right or left half of a vertebra has been suppressed or intercalated (Brash, 1915), a condition which necessitates a compensatory curvature elsewhere in the column (Brailsford, 1948).

Atlas.—One or other of the arches may be incompletely ossified or may have a facet for articulation with the margin of the foramen magnum. The foramen transversarium may be incomplete owing to absence of the anterior part of the transverse process. A bar of bone may bridge across the groove for the vertebral artery. The upper articular facet may be divided. The transverse process may be bifid ; and it may articulate with an occasional projection, called the *par-occipital process*, that juts from the jugular process of the occipital bone. The atlas may be partially fused with the occipital bone or with the second cervical vertebra.

Axis.—It may be fused with the atlas or with the third vertebra. The odontoid process may articulate with the basi-occiput. It may be bifid or double, or it may be a separate bone called the **os odontoideum**. Fusion of a detached odontoid process with the anterior arch of the atlas has been recorded. Its apical part may be partially or completely detached. The foramen transversarium may be incomplete, owing to imperfect development of the posterior part of the transverse process.

Nodules representing ribs have been seen once or twice in the **fourth** and **sixth** cervical vertebræ. The **seventh** has a cervical rib fairly often (Pl. IV, p. 105, Fig. 1). One of its foramina transversaria may be absent.

The **first thoracic vertebra** may have its transverse process connected with the neck of the first rib by a bar of bone ; the posterior part of its arch may be separate. The facets on the body of the **ninth** are variable. The **tenth** may have no facets on its transverse processes ; and its spine may be shorter than that of the eleventh. The inferior articular processes of the **eleventh** may resemble those of the twelfth, and the superior processes of the **twelfth** correspondingly resemble those of a lumbar vertebra. Suppression of the right or left half of a lower thoracic vertebra (the remaining half being wedge-shaped) has been known to cause congenital lateral curvature (scoliosis) ; and so has the interpolation of a wedge-shaped half of a lumbar vertebra.

The mamillary and accessory processes of the **lumbar vertebræ** may be large and occasionally are connected by a bridge of bone which encloses a small foramen. The first transverse process may be separate, as a lumbar rib ; the fourth may spring from the side of the body, without connexion with the arch ; and the fifth may have a foramen in it. The posterior part of the arch of the fifth, comprising the spine, the laminæ, and inferior articular processes, is occasionally separate from the rest of the bone (union during life being effected by hyaline cartilage) ; the same condition has been seen in the fourth. The fifth may be fused with the sacrum partly or wholly, and may have pronounced sacral characters on one or both sides (Pl. XVII, p. 272; Figs. 1232, 1233).

The **sacrum** may have six vertebræ, owing to inclusion usually of the first coccygeal but sometimes of the fifth lumbar. More seldom there are only four vertebræ. Sometimes the first sacral is not united to the second, or only partially, and may resemble a lumbar vertebra on the un-united side. The posterior wall of the **sacral canal** may be defective in its whole length. A foramen may be present in the lateral part of the first sacral vertebra between the pedicle and the costal element. The degree of curvature varies greatly in different specimens.

The **coccyx** varies in its number of segments and the extent to which they are fused together. A curved process jutting from the front of the first piece has been recorded. The second piece may have rudimentary transverse processes and pedicles.

The standard work on vertebral variations is by Le Double (1912).

SERIAL HOMOLOGIES OF VERTEBRÆ

The **body** is the only part present in every vertebra from the first cervical to the last coccygeal. The homology of the bodies is manifest throughout the series, except that the *median part* (centrum) of the body of the atlas is detached from its own vertebra and fused with

the second, forming the odontoid process; the *lateral parts, i.e.*, the parts which in other vertebræ are ossified from the vertebral arch, form the anterior, larger parts of the lateral masses. The anterior arch of the atlas does not correspond to the front of the body of a vertebra, but is ossified from a persistent 'hypochordal bow', which disappears in other vertebræ (p. 150).

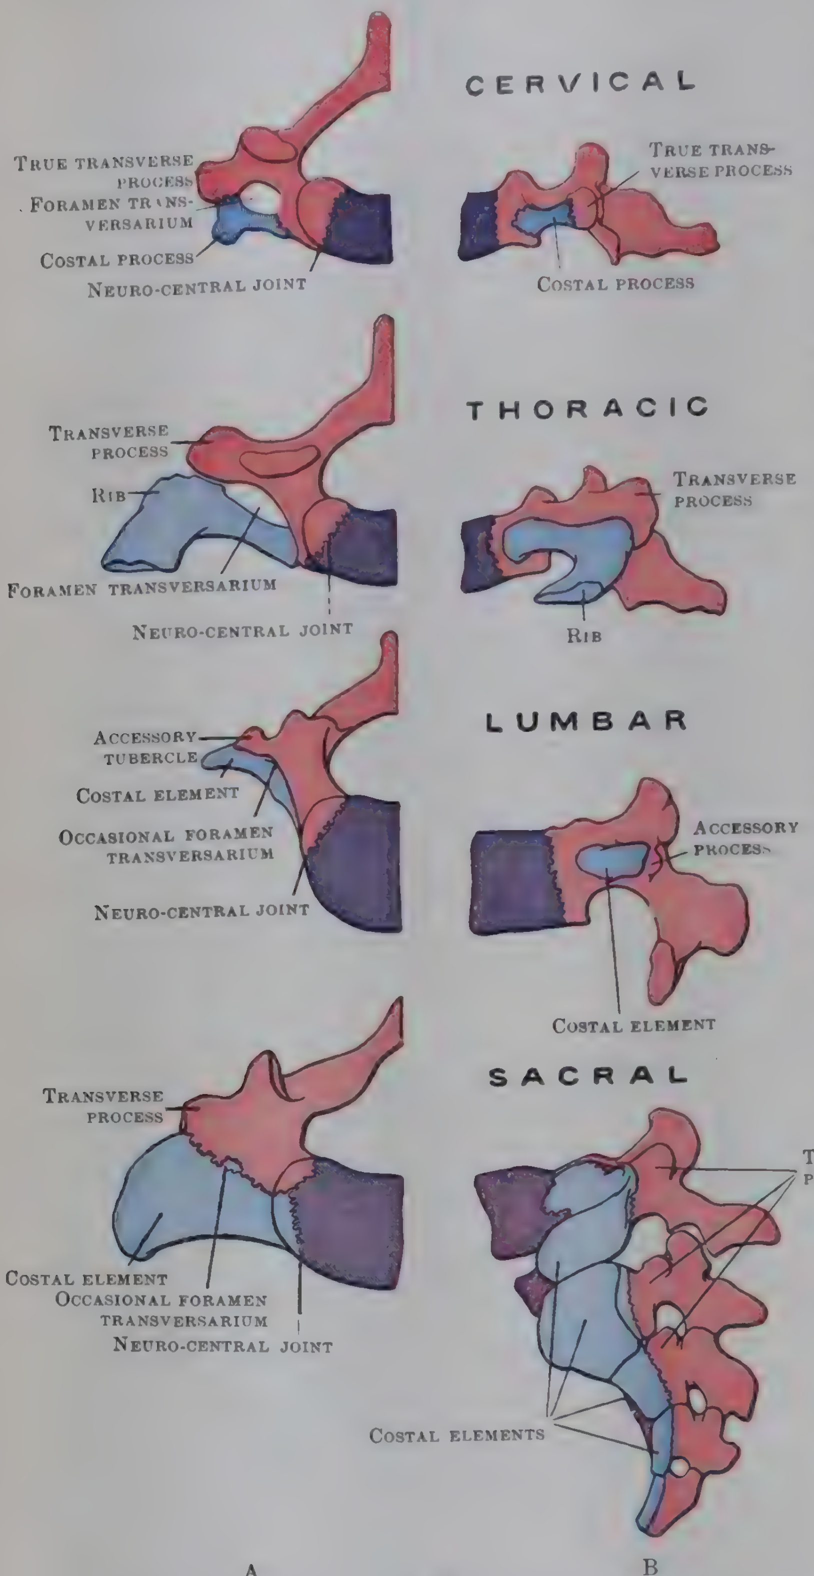

FIG. 144.—DIAGRAM TO ILLUSTRATE HOMOLOGOUS PARTS OF VERTEBRÆ.
Body, *purple*; arch and processes, *red*; costal element, *blue*.
A, from above. B, from the side.

The **vertebral arches** are incomplete below the third and fourth sacral, and wholly absent from the third and fourth coccygeal segments. Their homology is equally obvious, but the **pedicle** of the atlas is obscured in the posterior part of the lateral mass. The roots of the coccygeal cornua are pedicles. The **laminæ**, including the posterior arch of the atlas, are usually complete down to the third sacral; those of the fourth sacral may or may not be complete; those of the fifth are usually unossified; and they are quite unrepresented in the coccyx.

The **spine** of the atlas is represented by the tubercle on the posterior arch. Spines are absent below the third sacral vertebra.

The **articular processes** of the atlas and the superior articular processes of the second cervical vertebra are absent; the articular surfaces of the lateral masses of the atlas and the upper articular surfaces of the second vertebra are homologous with the very small articular areas on the lateral parts of the bodies of the other cervical vertebræ. The superior articular processes of the first sacral vertebra function as ordinary articular processes; the other sacral articular processes are fused together to form the row of articular tubercles on the back of the sacrum, except the inferior articular processes of the fifth piece, which form the sacral cornua. The upper parts of the coccygeal cornua are homologous with superior articular processes; they are absent from the other coccygeal segments.

The **transverse processes** are present in the whole series down to and including the first coccygeal vertebra; but their homologies are less obvious. The transverse processes of the **thoracic** vertebræ are taken as the type and standard. In a **cervical** vertebra the true transverse process is represented by the posterior root; the remainder of the process is the homologue of a rib; the foramen transversarium represents the interval between a transverse process and the neck of a rib. In a **lumbar** vertebra the process called the transverse process is the homologue of a rib; the true transverse process is represented by the mamillary process and the posterior part of the root of the transverse process including the accessory process. No interval is left between the costal and true transverse elements, except in the rare instance where there is a foramen in the fifth lumbar transverse process. In the **sacrum** the lateral mass is made of the true transverse processes posteriorly and the costal elements

anteriorly, the ends of the true transverse processes being the row of transverse tubercles on the back. Each transverse tubercle represents part of the ends of two true transverse processes, for the end of each process expands, growing upwards and downwards, and unites with similar expansions of the process above and below to form the tubercles lateral to the posterior sacral foramina.

STERNUM

The **sternum** or breast-bone [στέρνον (sternon) = the breast] is an elongated flat, dagger-shaped bone, six to eight inches long. It lies in the anterior wall of the thorax in the median plane, extending from the root of the neck to the pit of the stomach. It can be felt through the skin from end to end and has upper and lower ends, anterior and posterior surfaces, and right and left borders. The two clavicles articulate with its upper end, and the cartilages of the upper seven pairs of ribs articulate with it at intervals along its borders. It has three main parts, named, from above downwards, the *manubrium*, the *body*, and the *xiphoid process*. In youth, the body is in four pieces—united by cartilage.

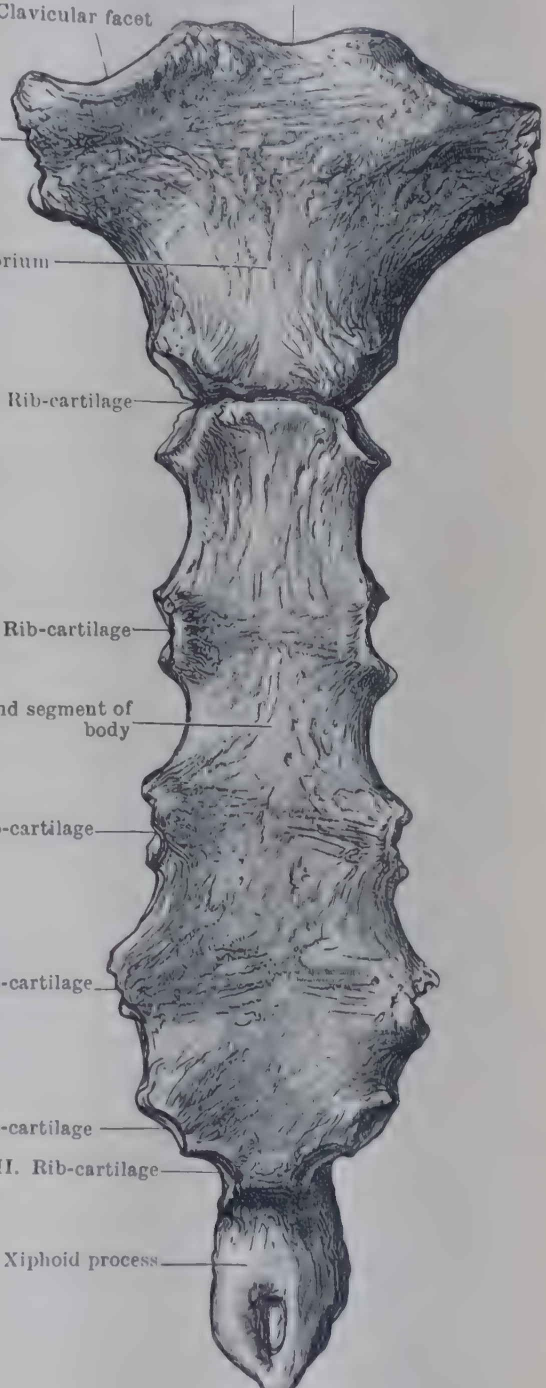

FIG. 145.—STERNUM (anterior view).

The **manubrium** [= a handle] is the widest piece of the sternum, and, unless the skeleton is that of an old person, it is a separate bone; for the manubrium and the body are united by cartilage and do not fuse together till an advanced age. It is triangular in outline, each side measuring about two inches; but the lower angle is cut off—giving it a short lower border. The *posterior surface* is slightly concave from side to side and is not so rough as the *anterior surface*. The *upper border* is the upper end of the sternum and is more than twice the width of the lower border. The middle part of the upper border is concave from side to side and can be felt in the root of the neck as the floor of the **suprasternal notch**; on each side of the suprasternal notch there is a larger notch for articulation with the medial end of the clavicle or collar-bone. On the *right* and *left margins*, immediately below the **clavicular notch**, there is a rough mark or a pit on which the cartilage of the first rib is implanted.

The lower border of the manubrium and the upper end of the body of the sternum, together, can be felt and often seen as a transverse ridge on the front of the chest about two inches below the upper end of the sternum, for the two bones are slightly thickened at their junction, and join at a very obtuse angle called the **sternal angle**. The ridge can be felt in stout people as well as in thin, and is the most serviceable of the landmarks on the front of the chest. The cartilage of the second rib joins the side of the sternum at the

junction of the manubrium and body, *i.e.*, at the sternal angle. The second rib is therefore easily identified.

The **body** consists of four segments fused together and is the longest of the three parts of the sternum. As a rule it is more than twice as long as the manubrium in men and rather less in women; it is about an inch wide at its *upper end*, increases slightly down to the fourth segment and then dwindles in breadth, and the *lower end*, at its junction with the xiphoid process, is the narrowest part. The *posterior surface* is slightly concave from above downwards and usually is smoother than the *anterior surface*. Each *margin* bears four pits for articulation with costal cartilages. The upper three pairs of pits are at the ends of indistinct **transverse lines** that indicate the junction of segments of the body. The fourth pair is on the sides of the fourth segment. In addition there are, on each side, an articular pit or notch between the body and the manubrium, and one between the body and the xiphoid process—the latter notch being on the front of their junction rather than at its side. The second rib-cartilage articulates with the notch between manubrium and body; the third, fourth, fifth, and sixth with the pits or notches on the body; and the seventh with that between the body and the xiphoid process.

The **xiphoid process** is the smallest piece of the sternum; it lies in the anterior wall of the abdomen in front of the liver and can be felt in the floor of the depression known as the *epigastric fossa* or "pit of the stomach". Its junction with the body—the *xiphi-sternal joint*—can be felt as a short transverse ridge in the upper margin of that fossa; the ridge marks the lower limit of the thorax in the median line in front, and is the landmark, in the median line, for the diaphragm, the upper surface of the liver, and the lower border of the heart.

The xiphoid process is usually flat and pointed [ξίφος (xiphos) = a sword; εἶδος (eidos) = shape], but it may be almost any shape; it may have a hole in its middle or it may be bifid. It is made of cartilage with a core of bone; the core enlarges with age at the expense of the cartilage till the process is quite ossified; it is more yielding therefore in youth than in old age. At first it is united to the body by cartilage but fuses with it after middle age.

The sternum slopes from above downwards and forwards—the manubrium slanting more than the body. The **upper end** is on a level with the *lower* border of the body of the **second** thoracic vertebra (Fig. 150); the **sternal angle** with the *upper* border of the body of the **fifth** and with the interval between the third and fourth thoracic spines; the **xiphi-sternal joint** with the **ninth** thoracic vertebra and the tip of the eighth thoracic spine.

The **manubrium** is thicker at its upper and lower parts than in the middle. The clavicular notches look upwards and sidewards, and its thickest and strongest part is below and medial to them, where it receives shocks transmitted through the clavicle. The slightly raised area on the *anterior surface*, below the medial part of the clavicular notch, gives origin to the sternal head of the sterno-mastoid; part of the pectoralis major arises from the large, concave area that accounts for most of each half of the front of the manubrium. On the *posterior surface* of the manubrium, part of the sterno-hyoid arises medial to the clavicular notch, and part of the sterno-thyroid about half-way down. The capsule of the sterno-clavicular joint is attached to the margins of the **clavicular notch**; the articular disc of that joint to the junction of the manubrium and first costal cartilage; the interclavicular ligament, slightly, to the floor of the **suprasternal notch**.

The chief structures *behind the manubrium* are: (1) the edges of the pleuræ and lungs, (2) the remains of the thymus, (3) the left innominate vein, (4) the arch of the aorta and its three branches, and (5) the trachea, which ends opposite the sternal angle.

The **body** is thinner along its middle than along the margins. Its *anterior surface* gives origin to part of the pectoralis major; the lower part of its *posterior surface* gives origin to part of the sterno-costalis and the sterno-pericardial ligaments are attached to its upper and lower ends.

The chief structures *behind the body* are—the edges of the pleuræ and lungs, the pericardium and heart; and the ascending aorta and right pulmonary artery behind the first segment.

The **xiphoid process** is thicker in the middle than at the sides. It is thinner than the body, but their posterior surfaces are flush—hence the depression called the epigastric fossa. It varies in length, so that its lower end, though palpable, is of no use as a landmark.

The linea alba (p. 456) is attached to its *lower end*. Fibres of the rectus abdominis and of the external and internal oblique aponeuroses are inserted into its *anterior surface*; of the internal oblique and transversus aponeuroses into its *margin*; part of the sterno-costalis and a slip of the diaphragm arise from its *posterior surface*, to which the fascia transversalis and the falciform ligament of the liver also are attached.

The sterno-chondral ligaments are attached to the front and back of the sternum at the notches for the rib-cartilages, and the intra-articular ligaments, when present, to their floors.

Ossification. — The following table gives the approximate dates of the appearance of centres and of fusion of segments, but there is a certain amount of variation, and centres for adjoining segments may appear almost simultaneously :—

	Manubrium.	Body, 1st Seg.	2nd Seg.	3rd Seg.	4th Seg.	Xiph. proc.
Centres (one or two) appear	5th month of intra-uterine life	6th m.	7th m.	8th m.	9th m.	3rd year
Parts unite	Old age	21st yr.	Puberty	Child	Middle age	

The fourth segment does not always have a separate centre. Epiphyses have been found at the clavicular notches in an adult.

Structure and Variations.—The sternum is composed of highly vascular spongy bone enclosed in thin compact bone. The *vascular foramina* are best marked on the back of the manubrium. Occasionally there is a hole in the lower part of the body, and more rarely the sternum is fissured longitudinally to a greater or lesser degree, the gap being wider above; the cleft is sometimes associated with *ectopia cordis*—a condition incompatible with life. Deformities, such as a bending back of the lower part of the sternum, arise from disease and in certain occupations. The two halves of the sternum are often asymmetrical, the clavicular notch being higher and the costal notches more crowded together on one side, with the junction of manubrium and body oblique; occupational use of the right upper limb may account for the asymmetry in some cases. Occasionally the manubrium includes the first segment of the body and carries three pairs of ribs, as in the gibbon; the *sternal angle* is then between the third pair of costal cartilages, and is felt about 3 inches below the suprasternal notch. The eighth costal cartilage in about ten per cent. of bodies reaches the sternum, more often on the right side than on the left; and in rare cases the seventh cartilage fails to reach the sternum. Small ossicles called *suprasternal bones* are sometimes found in the ligaments of the sterno-clavicular joint. (See Cobb, 1937.)

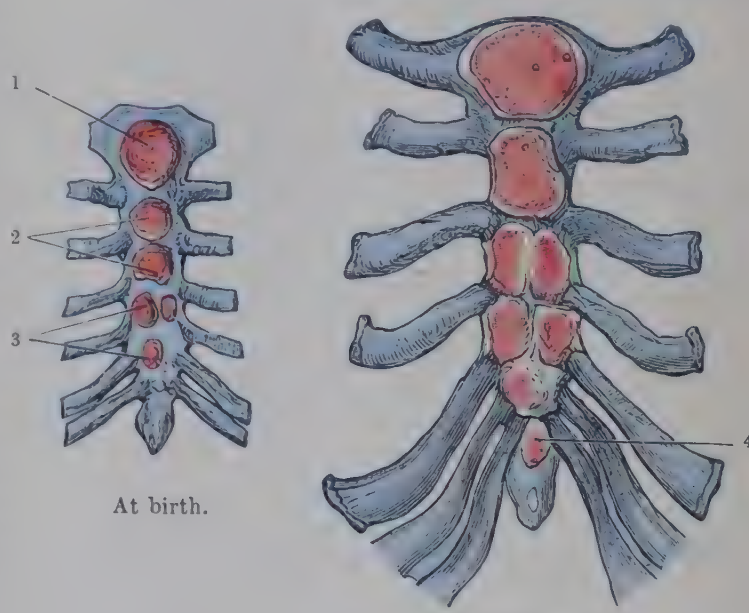

FIG. 146.—OSSIFICATION OF STERNUM.

1. Appears at 5th intra-uterine Month. 2. At 6th and 7th M. 3. At 8th and 9th M. 4. At 3rd Year.

In women the manubrium is at a rather lower level and is narrower and longer than in men, but the body of the sternum is wider and shorter (Paterson, 1904).

RIBS (COSTÆ)

There are twelve **ribs** on each side in both sexes. They are thin, narrow, curved strips of bone, and, though elongated, they are classed among the "flat" bones. They are attached posteriorly to the thoracic vertebræ and curve round the sides of the chest, slanting downwards and forwards; anteriorly they end by joining a **costal cartilage**. The ribs lie at the back, at the sides, and at the front of the thorax; and they provide protection for the sides and back of the upper part of the abdomen also. The upper seven ribs increase in length from above downwards and are called *true* ribs because their cartilages are attached to the side of

the sternum. The lower five are called *false* ribs; they diminish in length from above downwards and their cartilages fail, by increasing distances, to reach the sternum; but the ends of the eighth, ninth, and tenth each join the one above, edge to edge. The cartilages of the eleventh and twelfth are free, and are called *floating ribs.*

A rib has anterior and posterior ends, external and internal surfaces, and superior and inferior borders. The *posterior end* is called the **head**, and is articular; the *anterior end* is hollowed out to form a pit into which the costal cartilage fits. The *upper border* is smooth and rounded; the *lower* is thin and sharp. The *outer surface* is convex; the *inner* is concave lengthwise.

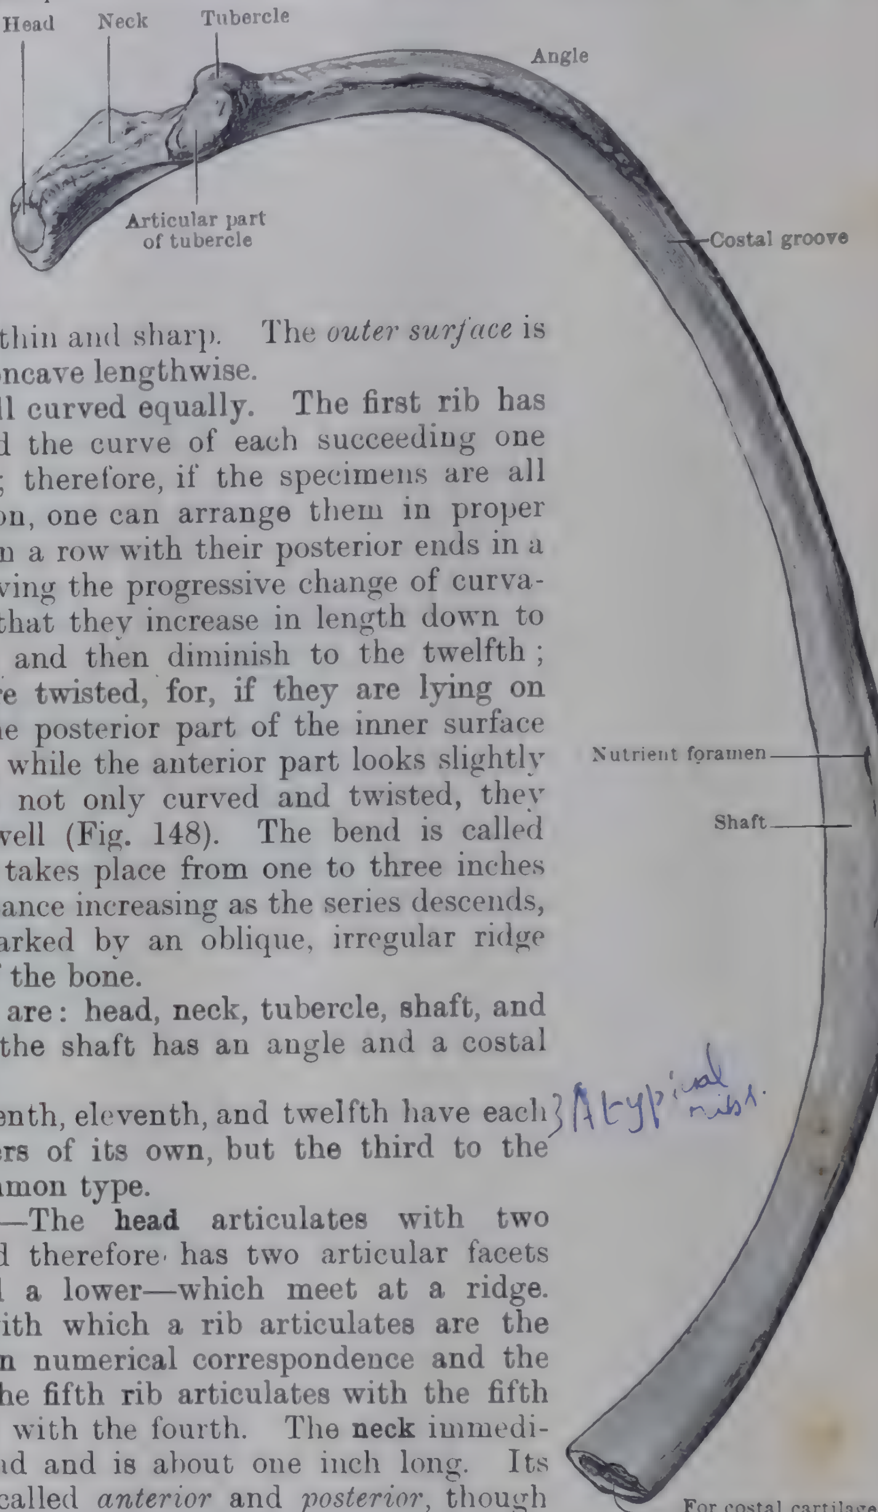

FIG. 147.—FIFTH RIGHT RIB FROM BELOW.

The ribs are not all curved equally. The first rib has the sharpest curve, and the curve of each succeeding one is wider or more open; therefore, if the specimens are all from the same skeleton, one can arrange them in proper order by laying them in a row with their posterior ends in a straight line and observing the progressive change of curvature. It will be seen that they increase in length down to the seventh or eighth and then diminish to the twelfth; and also that they are twisted, for, if they are lying on their lower borders, the posterior part of the inner surface looks largely upwards, while the anterior part looks slightly downwards. Ribs are not only curved and twisted, they are slightly bent as well (Fig. 148). The bend is called the *angle* of a rib; it takes place from one to three inches from the head, the distance increasing as the series descends, and its position is marked by an oblique, irregular ridge on the outer surface of the bone.

The **parts** of a rib are: **head, neck, tubercle, shaft,** and **costal cartilage**; and the shaft has an angle and a costal groove.

The first, second, tenth, eleventh, and twelfth have each some special characters of its own, but the third to the ninth belong to a common type. 3 Atypical ribs.

3rd – 9th – Typical ribs

A Typical Rib.—The **head** articulates with two thoracic vertebræ and therefore has two articular facets on it—an upper and a lower—which meet at a ridge. The two vertebræ with which a rib articulates are the one with which it is in numerical correspondence and the one above that, *e.g.*, the fifth rib articulates with the fifth thoracic vertebra and with the fourth. The **neck** immediately succeeds the head and is about one inch long. Its surfaces are usually called *anterior* and *posterior*, though they are continuous respectively with the inner and outer surfaces of the shaft. The **tubercle** is situated on the outer surface where the neck and shaft join; it articulates with the front of the tip of the transverse process of the vertebra with which the rib corresponds numerically. The **shaft** is all the rest of the bone. The ridge on the outer surface that marks the position of the **angle** is placed near the posterior end. In the first rib the angle is at the junction of neck and shaft and the ridge coincides with the tubercle; in the second rib the ridge is close to the tubercle; as the ribs are followed down, the ridge gradually recedes from the tubercle, down to the eighth or ninth; and below that the ridge becomes indistinct. The curve of a rib is sharpest at the

angle and a curved bone is most likely to be broken where the curve is sharpest; the rib is therefore thickest there. The **costal groove** is the long, shallow groove on the inner surface of the shaft immediately above the lower border.

The articular surface of the **head** of a rib is surrounded by a joint-capsule; the thick, anterior part of the capsular ligament—radiate ligament—is attached to the front of the head. Of the two facets the lower is the larger; the blunt ridge between them gives attachment to the intra-articular ligament which lies within the joint and binds the rib to the intervertebral disc.

The **neck** lies in front of the transverse process. The posterior surface is rough and is bound to the transverse process by the inferior costo-transverse ligament; the upper border is rough and raised as the **crest**, from which the superior costo-transverse ligament stretches up to the transverse process next above. The lower part of the anterior surface is smooth and covered with pleura. It is separated from the upper part by a faint ridge that gives attachment to the posterior intercostal membrane. The **tubercle** bulges backwards and downwards and has a *facet* on its lower and medial part for articulation with the transverse process. An articular capsule surrounds the facet, and the lateral costo-transverse ligament connects the rough part of the tubercle with the tip of the transverse process.

The *upper border* of the **shaft** gives insertion in all its length to an external intercostal muscle, and, internal to that, a posterior intercostal membrane is attached between the neck and the angle, while an internal intercostal muscle is inserted into the rest of the length of the border. The **costal groove** is broad and well-marked posteriorly, but indistinct in the anterior part of the rib; the intercostal vessels and nerve run along the groove. The groove has an upper and a lower lip, the lower lip being the sharp *lower border* of the bone; the external intercostal muscle arises from the whole length of its lower lip; the posterior intercostal membrane is attached to the floor of the groove between the tubercle and the angle; an internal intercostal muscle arises from the upper lip from the angle forwards. The rest of the *inner surface* of the rib is smooth and is covered with pleura.

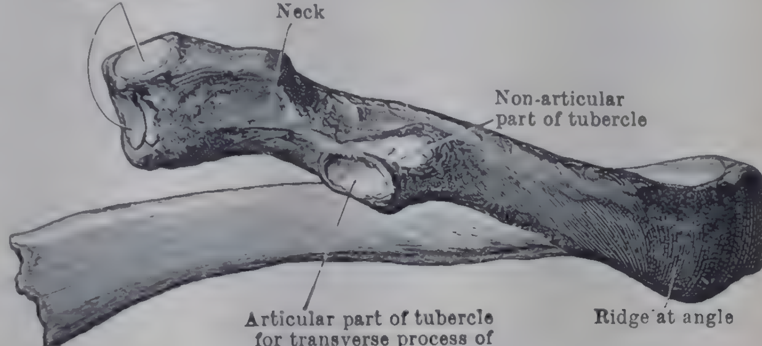

Fig. 148.—Fifth Right Rib from behind.

Many muscles are attached to the *outer surface* of the ribs. The *angle* is very obtuse, and is open upwards; the ridge that marks it is for the attachment of the ilio-costo-cervicalis—*i.e.*, the lateral division of the large composite mass of muscle, called sacro-spinalis, that lies alongside the spines of the vertebræ. On the longer ribs there is often a slight bend called the *anterior angle*, marked by an indistinct ridge on the outer surface two inches or more from the anterior end; the ridge is for the origin of slips of the serratus anterior and obliquus externus abdominis.

In each of the upper ten ribs the anterior end is the widest part of the rib.

The **first rib** is the shortest rib, except the twelfth; it is the most sharply curved, and it is broad in comparison with its length. It lies at the boundary between neck and thorax, largely under cover of the clavicle; its posterior end is above the level of the clavicle, and its anterior end is immediately below the clavicle (Fig. 150). Unlike the other ribs, it lies nearly all in one oblique plane, and its **surfaces** are *upper* and *lower*, its **borders** *inner* and *outer*. The inner border is concave; the outer border is convex. The surfaces are not always easily distinguished at first glance, but if the rib is laid on the table and its head touches the table, then its lower surface is looking downwards; if it is turned upside down the head stands away from the table.

The **head** is small and articulates with one vertebra, the first thoracic. It has therefore only one facet. The **neck** is relatively long, and is compressed from above downwards; the top of the pleura and lung lie immediately in front of it. The **tubercle** is on the outer border and is relatively large.

The outer part of the *lower surface* of the **shaft** is roughened by the attachment of the internal intercostal muscle. The inner part is covered with pleura and is crossed obliquely by the first intercostal nerve which may groove it. The subclavian artery and vein lie across the *upper surface*, producing broad, shallow grooves. The groove for the artery is about the middle of the shaft; the groove for the vein is nearer the anterior end. The scalenus anterior muscle is inserted into the **scalene tubercle** and a small rough triangular area that separates the two grooves; the tubercle is a small projection on the *inner border* of the rib. The surface behind the groove for the artery between that groove and the

tubercle of the rib—gives insertion to the scalenus medius muscle, while the first digitation of the serratus anterior arises from it near the outer border immediately behind the groove for the artery. The greater part of the anterior primary ramus of the first thoracic nerve, on its way to join the brachial plexus, runs upwards and laterally in front of the neck and then lies in the posterior part of the groove for the artery, between the artery and the scalenus medius. On many specimens the grooves and tubercles are faintly marked; while in others there is a special groove for the lodgment of the first thoracic nerve, or the lowest trunk of the brachial plexus, immediately behind the groove for the artery. The subclavius muscle and the costo-clavicular ligament are attached to the upper surface of the rib at its junction with the cartilage.

The external and internal intercostal muscles of the first space arise from the *outer border.* A fibrous sheet, called the suprapleural membrane, stretches fanwise from the transverse process of the seventh cervical vertebra to be attached to the *inner border.*

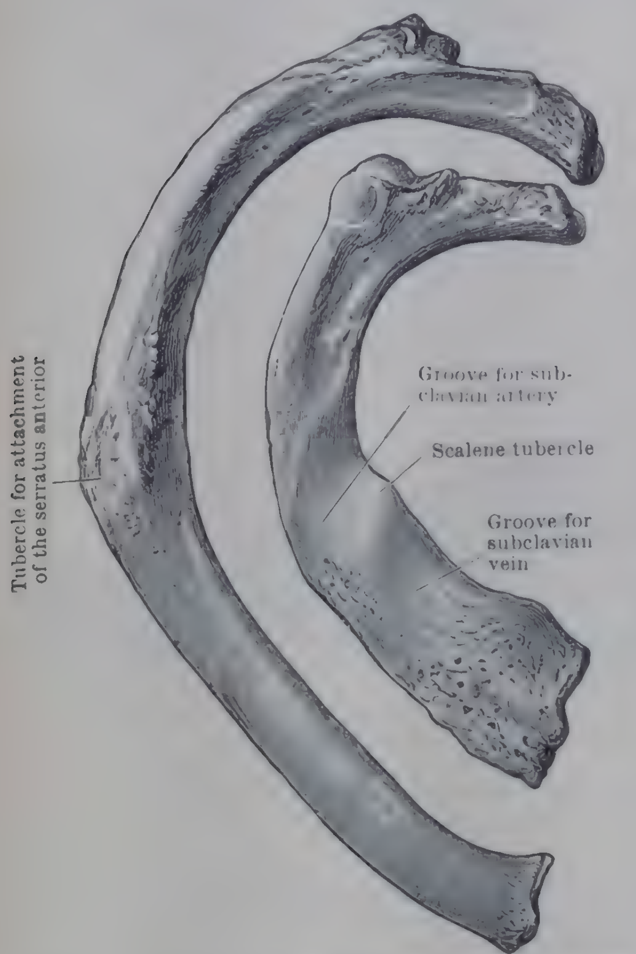

Fig. 149.—First and Second Right Ribs as seen from above.

The **second rib** is about twice as long as the first, and the sharpness of its curve distinguishes it from one of the lower ribs of similar length; it is not twisted; its surfaces are, in direction, intermediate between those of a first rib and those of a typical rib, and its costal groove is poorly marked. But the *special character* of the second rib is that on its outer surface, about its middle, there is a broad rough **tubercle** for the origin of part of the **serratus anterior** muscle. No other rib has a similar tubercle.

The **tenth, eleventh,** and **twelfth** ribs have each only one facet on the head, for each articulates with only one vertebra and that is the thoracic vertebra of corresponding number. The tenth, however, may be a typical rib. The eleventh differs from the tenth mainly in that its tubercle is small and has no articular facet, and the angle is ill-defined; but the tubercle and angle of the tenth also may be ill-defined, so that it is sometimes difficult to say whether a given rib is tenth or eleventh if the other ribs of the same skeleton are not at hand.

The **twelfth rib** is small and slender. It may be as short as the first, or even shorter. *Tubercle, angle,* and *costal groove* are absent or are poorly marked. The **body** tapers off at the free end, while other ribs are nearly always slightly swollen at their anterior ends.

Costal Cartilages

The **costal cartilages** are bars of hyaline cartilage fitted into the pits at the anterior ends of the ribs and held in place because the perichondrium of each is continuous with the periosteum of its rib. They greatly increase the resilience of the framework of the thorax and the perichondrium is so strong that there is little or no displacement of the fragments when a costal cartilage is fractured. The **upper seven** pairs join the sternum and can be felt at its sides; they increase in length from above downwards, from one inch to four or five inches. The *first* cartilage is fitted on to a rough mark on the margin of the manubrium and is held in place by the continuity of its perichondrium with the periosteum

of the sternum; the *other six* are joined to the sternum by synovial joints. The first and second slope downwards slightly from the bony rib to the sternum; the third is horizontal; the fourth incli s upwards; the fifth, sixth, and seventh continue the direction of the rib for about an inch, and then turn upwards, with increasing degrees of obliquity, to reach the sternum. The cartilages of the **lower five** ribs diminish in length from above downwards; they can be felt in the costal margin between the thorax and abdomen. The eighth, ninth, and tenth continue in the direction of their ribs for about an inch and then turn upwards; they fail, by increasing distances, to reach the sternum, and each tapers off to a point. They are each united edge to edge with the one above, forming synovial joints at the points of contact, except the tenth, which is separated from the ninth by the fibrous tissue that unites them. The eleventh and twelfth are mere pointed cartilaginous tips on the ends of the ribs.

THORAX

The **thorax** lodges the lungs, the heart and many other structures. It gives them protection and its skeleton provides attachment for many muscles besides those that belong to the thorax itself; but the chief use of the thorax in mammals is to act as a bellows by which air, for oxygenating the blood, can be drawn into the lungs. Its framework is a bony and cartilaginous cage the bars of which are arranged so that they not only resist atmospheric pressure as the bellows is opened, but also, by their mobility, share in the expanding movement.

The skeleton or cage is made of the thoracic vertebræ and intervertebral discs, the sternum, the ribs, and their cartilages. It is barrel-shaped, but is narrower above than below. It is also longer behind than in front, and is compressed from before backwards, so that it is wider from side to side, the greatest width being at the level of the eighth or the ninth rib. The antero-posterior diameter of its interior is greatly diminished by the bodies of the vertebræ. It communicates with the front of the neck by an inlet, and with the abdomen by an outlet.

The **inlet** is small and is kidney-shaped in outline; it slopes from above downwards and forwards; it measures about 2 inches or 50 mm. from before backwards and 100 mm. across. It is bounded by the first thoracic vertebra behind, the manubrium in front and the first pair of ribs and their cartilages at the sides. It is occupied by the apices of the lungs and pleuræ, the windpipe, the gullet, and numerous vessels and nerves that pass between neck and thorax (Fig. 597, p. 707).

The **outlet** is large and is uneven in outline. It is bounded by the xiphi-sternal joint, the lower six pairs of costal cartilages, the shafts of the twelfth pair of ribs, and the last thoracic vertebra. It is closed by the diaphragm, which forms a highly vaulted and movable floor for the thorax and roof for the abdomen, separating the two cavities (Fig. 385). The *infrasternal angle* is situated at the anterior part of the inferior aperture; its sides are the seventh pair of costal cartilages; its apex is the xiphi-sternal joint; and the xiphoid process juts down into the angle.

The **posterior wall** of the thorax is made up of the thoracic vertebræ and intervertebral discs and the posterior part of the ribs. The ribs have a backward sweep as far as their angles which makes their angles nearly flush with the tips of the spines of the vertebræ, so that Man, unlike most animals, can lie on his back with stability and ease. The forward projection of the vertebral bodies and the backward curve of the ribs create a large hollow, on each side, in the posterior part of the interior of the thorax for the lodgment of the thickest part of the lung.

In the **sides** of the thorax there are the shafts of the ribs which are not all the same distance apart, nor are they parallel. The upper intercostal spaces are wider than the lower; and the ribs slope downwards and forwards with an obliquity which increases from the first down to the ninth or tenth, and the intercostal spaces are wider therefore in front than behind. The obliquity is more marked in women than in men, and in the old than in the young. The sides slope

outwards down to the level of the eighth or ninth rib, and usually slope inwards slightly below that.

The **anterior wall** is made of the manubrium and body of the sternum, the anterior ends of the upper ten pairs of ribs and their cartilages. It is shorter than the posterior wall or the sides, especially in the median plane, for the upper border of the manubrium is opposite the lower border of the second thoracic vertebra and the xiphi-sternal joint is opposite the ninth.

In the fœtus the thorax is compressed from side to side. At birth its form alters with the expansion of the lungs, but full transverse expansion takes place only after the child begins to

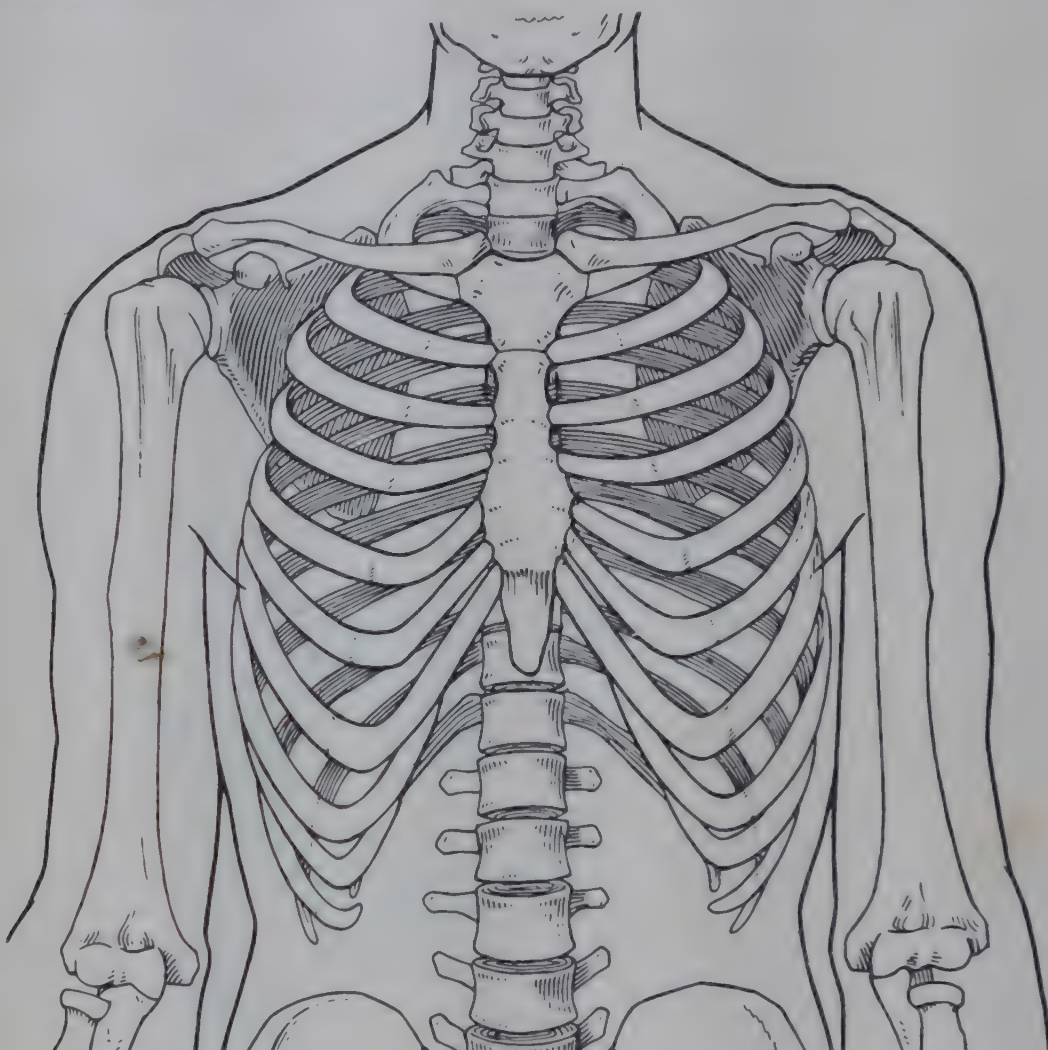

FIG. 150.—FRONT OF PORTION OF SKELETON SHOWING THORAX.

walk and to use its upper limbs more exclusively for prehensile purposes. *In a woman* the thorax is shorter and rounder than in a man, and the upper ribs are more movable.

Surface Relations.—The thorax is well covered externally with muscles that belong to the upper limb, the abdomen, the back, and the neck. There are only three parts that have no muscular covering. These are (1) a finger's-breadth down the middle of the sternum, (2) the median line of the back, (3) a portion of the seventh rib just medial to the lower part of shoulder-blade, especially when the shoulder is drawn forwards.

The **first rib** provides the bony resistance felt in the neck above the middle of the clavicle; its cartilage is immediately below the sternal end of the clavicle.

The **second rib** is the most easily identified of all on the front of the chest. Its cartilage joins the sternum at the **sternal angle**, which is always easily felt; both angle and second cartilage are often easily seen as well as felt. When ribs have to be counted, or when a particular rib has to be found in the living person, the best method is to find the second and count downwards from it. There are

rough and ready, though uncertain, guides to some of the other ribs and cartilages. The *nipple* is usually opposite the **fourth intercostal space** between the anterior ends of the bony parts of the fourth and fifth ribs. The cartilage felt on the costal margin next the sternum is nearly always the **seventh.** The cartilage felt where the groove marking the lateral margin of the rectus abdominis reaches the costal margin is usually the **ninth.** The **tenth** cartilage is the lowest one felt when the costal margin is examined from the front, and it is at the level of the body of the *third lumbar vertebra.* A line drawn from the medial end of the clavicle to the point a thumb's-breadth behind the lowest point of the tenth cartilage will

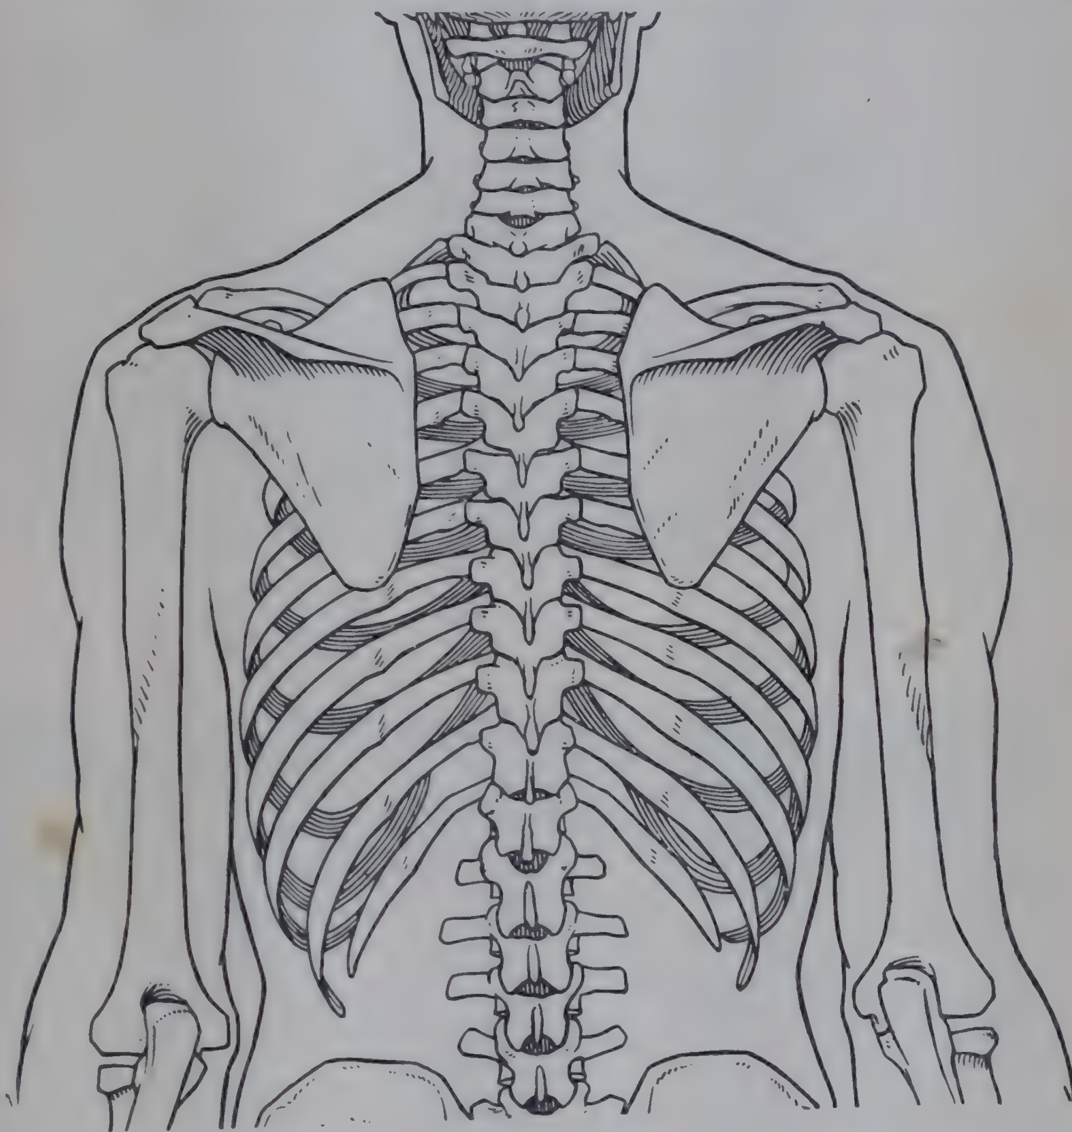

FIG. 151.—BACK OF PORTION OF SKELETON SHOWING THORAX.

pass through or near the junction of ribs and cartilages from the second to the tenth. If the *posterior axillary line* is followed downwards, the lowest rib it crosses is the **eleventh.** The **twelfth** rib may be felt, but sometimes it is so short that it is hidden by the sacro-spinalis. **On the back** the point where the *spine of the scapula* meets the medial border overlies the **fourth** rib; and the *inferior angle* of the scapula overlies either the **seventh** intercostal space or the eighth rib.

Ossification, Structure, and Variations of Ribs

Ossification.—A rib is ossified from one primary centre and one or two or three secondary centres. The **primary centre** appears near the angle (first in the sixth rib) in the sixth week of intra-uterine life, and ossification spreads rapidly through the rib. **Secondary centres** appear at *puberty* and the epiphyses fuse with the rest of the bone at 25. The **first rib** has *one* epiphysis for the **head** and *one* for the **tubercle.** The **second to the sixth,** inclusive, have *one* epiphysis for the **head,** *one* for the *articular* part of the **tubercle,** and *one* for the *non-articular* part. The **seventh to the tenth,** inclusive, have *one* for the **head** and *one* for the **tubercle.** The **eleventh and twelfth** have *one* for the **head.**

Structure and Variations.—A rib is composed of highly vascular spongy bone enclosed in a flattened tube of compact bone. The compact bone is thicker in the two surfaces than at the borders. The inner table is much thicker than the outer, and both tables are thickest at the angle. The *vascular foramina* are best marked at the back of the neck; the *nutrient canal* is in the costal groove and is directed towards the vertebral end.

The most important variation is a **cervical rib**. It may unite with the sternum or with the first costal cartilage, or with the vertebral end of the first rib, making a bicipital rib. Part of the cervical rib may be represented by fibrous tissue, and in some cases the only part present is the sternal end. Occasionally increase of number is due to a lumbar rib. Diminution in number is rare, but sometimes the twelfth rib is absent, or the first rib is rudimentary and may fuse with the second, making a bicipital rib. Sometimes two ribs are partly fused together. Occasionally the posterior parts of two ribs are united by a projection from each articulating with an intervening nodule of bone. The anterior end of a rib is sometimes very wide and may have a hole or a cleft in it. *Costal cartilages* also may be broad and perforated. The seventh cartilage sometimes throws out a projection which articulates with a similar projection from the sixth; the sixth may unite similarly with the fifth. The seventh sometimes fails to reach the sternum, but a commoner anomaly is that the eighth articulates with the sternum, more often on the right than on the left side. In old age the cartilages may undergo partial ossification; this condition may be regarded as normal in the first costal cartilage in elderly people. Costal cartilages are seldom exactly alike on the two sides.

Development of Vertebræ, Ribs, and Sternum

Vertebræ.—In the Section on Embryology it is explained that the *paraxial mesoderm* is divided by transverse clefts into a number of segments called *mesodermal somites*, and that the cells of the ventro-medial or *scleratogenous* parts of the somites proliferate and form a continuous mesodermal sheath around the notochord and neural tube [σκληρός (sclēros) = hard; γεννάω (gennaō) = produce]. The sheath is called the **membranous vertebral column**: in it the vertebræ are formed, and pass through a pro-cartilage stage and a cartilage stage before ossification. A *pro-cartilage vertebra* has only a body enclosed in a horseshoe-shaped vertebral bow. The **body** surrounds the notochord, and its position is such that it corresponds to the contiguous halves of two adjacent somites, its middle being opposite an *intersegmental septum*, *i.e.*, the interval

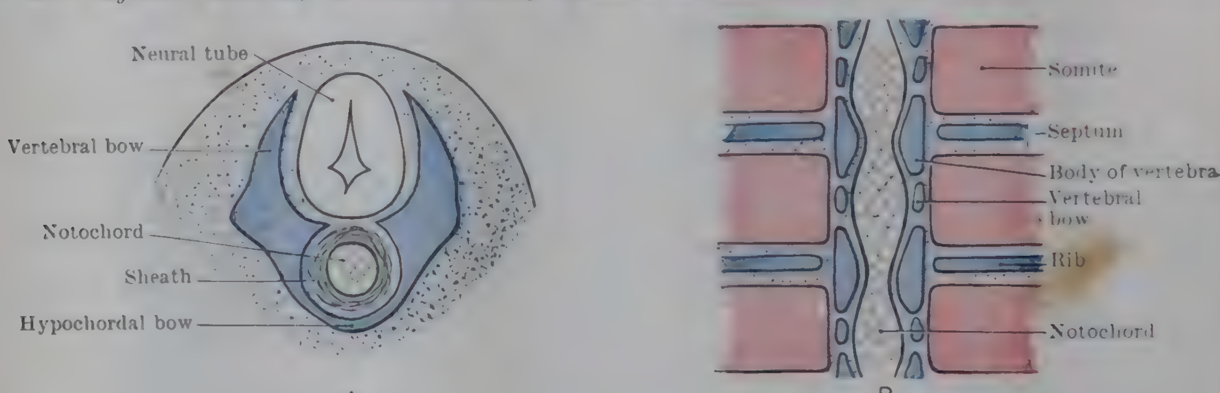

Fig. 152.—Development of the Membranous Basis of a Vertebra. (After Keith, 1948.)
A, in transverse section. B, in longitudinal section, showing the relation of the vertebræ to the primitive segments.

between two somites (see Wyburn, 1944). The middle part of the **vertebral bow** is sometimes called the *hypochordal bow* [ὑπό (hypo) = below]; it is ventral to the headward part of the vertebral body to which it belongs; the two limbs of the bow slant backwards to enclose the neural tube dorsal to the tailward part of the vertebral body; in time they meet each other dorsal to the neural tube and thus form a *vertebral ring*.

About the fourth *week* of intra-uterine life, the scleratogenous tissue between two bodies, opposite the middle of a somite, begins to undergo fibrous and chondrifying changes and becomes an *intervertebral disc*. About that time *chondrification* begins also in the **vertebral body** and in the **limbs of the bow**; the body and the bow rapidly unite, and chondrification of the bow is completed dorsally during the fourth *month* of intra-uterine life. The body forms the median part (*centrum*) of a body of a vertebra. The limbs of the bow form the postero-lateral parts of a body and the vertebral arch and its processes; the transverse processes and the spine grow out from it into the intersegmental septum that lies between the two somites to which the vertebra corresponds. The scleratogenous tissue between the arches of two vertebræ becomes the ligamenta flava and the capsules that unite articular processes. *Ossification* begins at the seventh week of intra-uterine life in the arches and at the tenth week in the bodies.

The ventral or hypochordal part of the vertebral bow disappears, except in the **atlas** vertebra, where it chondrifies and ossifies to form the anterior arch. The atlas is therefore a complete vertebral ring; its centrum becomes the odontoid process, and its lateral masses correspond to the parts of the body of a typical vertebra that are formed from the vertebral bow. The ligaments that connect the odontoid process with the margins of the foramen magnum represent the disc between the atlas and the last occipital segment.

PLATE V

Fig. 2.—Lateral Radiograph of the same Skull of a Full-Time Fœtus.
Compare with Fig. 175, p. 209.

PLATE VI

PLATE VI.—LATERAL RADIOGRAPH OF THE SAME MALE SKULL AS IN PLATE VIII.

Compare with Fig. 155, p. 162; Fig. 164, p. 193; with Plate VII (radiograph of one-half of the same skull in which confusion due to doubling of outlines is absent) and with radiographs of the living head (Plates LXXIV, p. 945, LXXV, p. 969, and LXXX

The rudimentary condition of a **coccygeal** vertebra is due to the failure of the limbs of the vertebral bow to develop. The incomplete condition of the laminæ of the last two **sacral** vertebræ is due to imperfect chondrification and ossification of vertebral bows. Imperfections in the formation of vertebral bows in regions farther up in the vertebral column give rise to the condition known as *spina bifida*, commonest in the lumbar region because fusion spreads downwards from the cervical region.

The part of the *notochord* enclosed in the bodies of the vertebræ is first constricted, and finally disappears after ossification begins. The part enclosed in the discs persists in them as their pulpy centres. For the evolutionary history of the notochord and the vertebral column, consult Gadow (1933).

Ribs.—The ribs are developed in the intersegmental septa and pass through pro-cartilage and cartilage stages before ossification. Each articulates at first with only one vertebra—*i.e.*, the vertebra opposite the septum in which the rib is developed. Later, the vertebral ends of the ribs, except the first, tenth, eleventh, and twelfth, are shifted headwards, so that each articulates not only with its own vertebra but also with the disc and the vertebra above.

Sternum.—The sternum is formed from mesodermal tissue in front of the pericardium. The **manubrium** probably arises in association with the ventral part of the shoulder-girdle, and the **body** and **xiphoid process** from a pair of *sternal bars* that grow from the mesodermal rudiment of the manubrium and fuse together in the median plane. After chondrification the sternum becomes connected with the costal cartilages by synovial joints. For the morphology of the sternum, consult Paterson (1904).

SKULL

The **skull** is the skeleton of the head and face. It is made of 22 bones, including the mandible, which is the skeleton of the lower part of the face and is a movable bone. The other 21 bones are so firmly knit together that they are taken apart with difficulty; they are built together in such a way that they enclose one large cavity and three smaller ones. The large cavity is the *cranial cavity*, and contains the brain and its membranes; the smaller cavities are the *cavity of the nose*, and the two *orbits*, which hold the eyeballs. There are lesser cavities contained within certain of the skull-bones; these are the *middle ear*, the *internal ear*, and the *air-sinuses*. The skull-bones consist of two plates or **tables** of compact substance that enclose a layer of spongy substance between them—in this case called **diploë**. In some of them the diploë is absorbed, leaving cavities or air-sinuses between the tables of compact bone; the sinuses communicate with the cavity of the nose and have a mucous lining continuous with that of the nose.

The *hyoid bone*, which lies in the neck below the mandible, is described along with the skull-bones, but is not part of the skull. The *auditory ossicles*, which lie in the middle ear, are described in the Section on the Sensory Organs.

Some of the united bones of the skull are paired and some are unpaired. The *paired* bones are bracketed (2), the *unpaired* (1), in the following list.

Frontal (1)	Nasal (2)	The first six in the list—eight bones in all—are those that share in the formation of the walls of the cranial cavity.
Ethmoid (1)	Lacrimal (2)	
Sphenoid (1)	Inferior nasal conchæ (2)	
Occipital (1)	Vomer (1)	
Parietal (2)	Maxillæ (2)	
Temporal (2)	Zygomatic (2)	
	Palatine (2)	

In a young person, these bones are separable. The joints by which they are held together are either *sutures* (p. 334), in which the articulating parts are connected by a ribbon of fibrous tissue, or *primary cartilaginous joints* (p. 334), in which they are connected by hyaline cartilage. With advancing years the joints disappear and neighbouring bones fuse together gradually.

There is some confusion in regard to the meaning of the terms *skull, cranium,* and *calvaria.* In ordinary English, 'skull' denotes the skeleton of the head with or without the mandible, and the word 'cranium' may be used in the same general sense. Its use in technical works is better restricted, however, to mean 'skull without mandible', although κρανιον (kranion) originally had the still more restricted meaning of the part of the head covered with hair. Even the word 'calvaria' has been employed in the general sense of *brain-pan* or *skull* but it usually means the top part of the skull or skull cap [*calvus* = bald, *calva* = the scalp].

In catalogues of craniological collections the following meanings are attached to the terms :—*Skull* = entire skeleton of head and face including mandible ; *Cranium* = skull without mandible ; *Calvaria* = skull after bones of the face have been removed or destroyed. In this text the word 'skull', being the more generalized term, is frequently employed instead of 'cranium' as a matter of convenience and common usage.

It is much more important that the student should acquire a knowledge of the skull as a whole than of the separate bones. The detailed description of the separate bones is put at the end of the Section for reference, and the skull as a whole is dealt with earlier. It is advisable to identify at the outset the following parts, for they will be referred to as landmarks.

(1) The **orbits** are the pair of large pyramidal cavities in the front of the skull (Fig. 154). They are so named because the eyes rotate in them. [*Orbita* = a wheel rut, a circuit.]

(2) The **anterior bony aperture of the nose** is the large, egg-shaped hole between and below the two orbits ; through it one can see into the cavities of the nose.

(3) The **external auditory meatus** or ear-hole (Fig. 155) is the small, round or oval hole or passage seen in the lower part of the side of the skull about midway between the front and the back. [*Meatus* = a passage.]

A standard position is used to facilitate description or measurement of the skull. When it is in its **proper position** the lower margin of the orbit and the upper margin of the orifice of the meatus are in the same horizontal plane. This plane is known as the " Frankfurt plane " (Fig. 176).

(4) The **zygomatic arch** is the bridge of bone on the side of the skull that spans the interval between the lower part of the orbit and the front of the meatus [ζύγωμα (zygōma) = a bar, from ζυγόν = anything that connects two bodies].

(5) The **foramen magnum** is the large, round hole on the lower surface of the skull a little behind its centre (Fig. 156).

(6) The **posterior bony apertures of the nose** are a pair of large openings about two inches in front of the foramen magnum ; they are oval and oblique, and are close together ; through them one can see into the cavities of the nose from behind.

(7) The **bony palate** is the platform of bone that forms the median part of the front of the lower surface of the skull ; its posterior edge is the *lower* margin of the posterior apertures of the nose (when the skull is held right way up).

(8) Examine the interior of the skull (Fig. 157). The cranial cavity has a very uneven floor, and is divisible into three main regions which are at different levels. Those regions are called the **anterior, middle**, and **posterior cranial fossæ** ; each of them has a median part and a right and a left lateral part.

SKULL AS A WHOLE

The skull as a whole is slightly flattened from side to side. Looked at from above, it is smooth, but from below it is very uneven. It is never quite bilaterally symmetrical, but usually is nearly so.

The **exterior of the skull** is examined from five points of view : from the front, the back, above, below, and from the side. Each of those aspects is called a 'norma' [= a square]. They are named norma frontalis, occipitalis, verticalis, basalis, and lateralis. There are no boundary lines between the aspects, for they overlap one another to a large extent, but the area visible is fixed by proper orientation of the skull with the coronal, or sagittal plane or the Frankfurt plane (Fig. 176) set at right angles to the line of vision.

Norma Verticalis

The **top of the skull** has convex contours, so that any impact received at a particular point is distributed over a considerable area, and the danger of fracture is thereby lessened. The horizontal outline varies considerably in different

specimens, but in most European skulls the outline is ovoid, the wider part being nearer the back than the front (Fig. 153).

The top of the skull shows portions of four bones—the **frontal** bone is the large

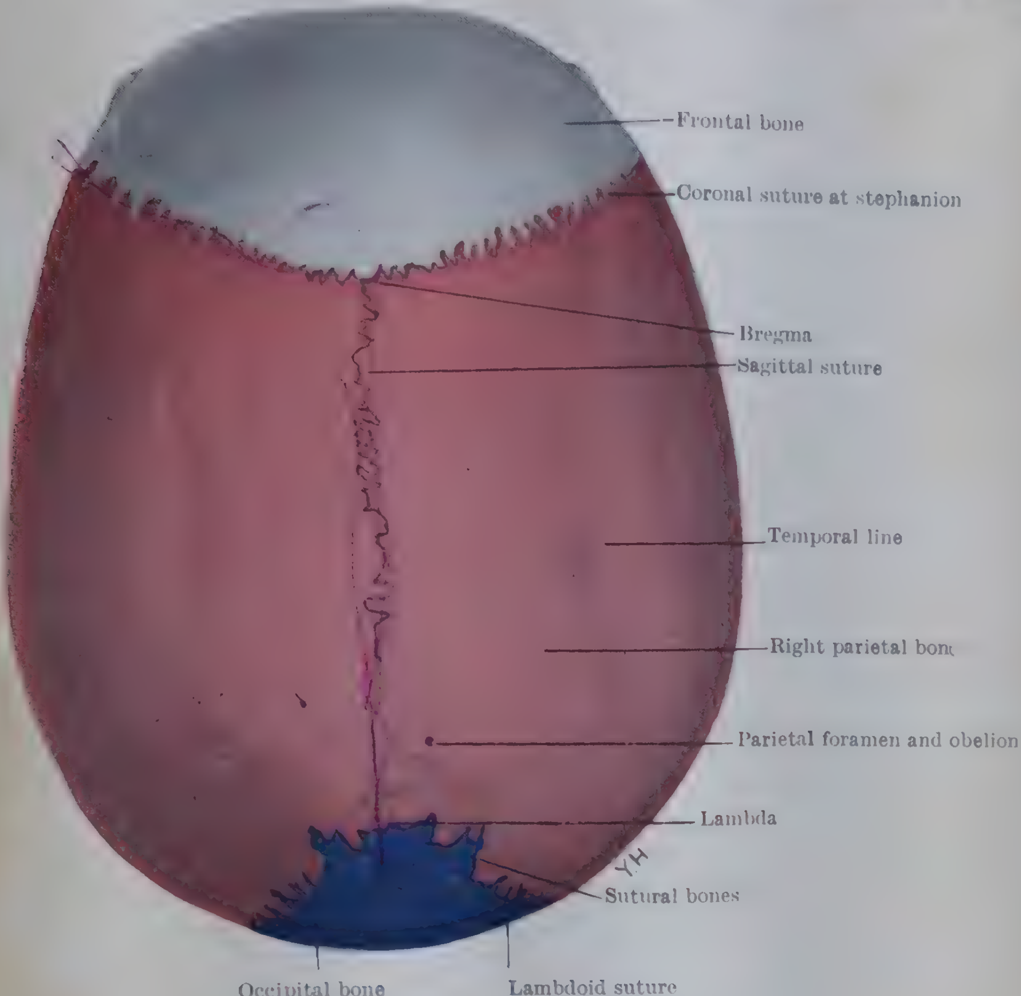

FIG. 153.—TOP OF THE SKULL (Norma Verticalis).

shell-like bone, seen in Fig. 155, forming the forehead and the anterior part of the top of the skull [*frons* = the brow]. The **occipital** bone forms the back of the skull and only a small part of it is seen from above [*occiput* (*ob caput*) = the back of the head up to the crown ; *sinciput* (*semi caput*) = the front part of the head from the crown to the forehead]. Between the frontal and occipital bones lie the right and left **parietal** bones which form a large part of the top and side of the skull [*paries* = a wall]. They are convex, with a rather square outline, and meet in the median plane above.

The bones are united by serrated *sutures*—the jagged, saw-like edges of the bones interlocking with one another [*sutura* = a seam]. If the skull is that of a young adult the sutures are seen distinctly as irregular lines between the bones. If the skull is that of an old person they are more or less obliterated and the bones are fused, but the positions of the sutures are usually indicated by narrow, irregular linear depressions. In many skulls small circumscribed pieces of bone are seen in the sutures in certain places, and are called **sutural bones** (Fig. 153).

The suture that unites the frontal bone to the two parietal bones and arches across the skull from side to side, is the **coronal suture** [*corona* = a curved line, circle, crown]. The suture that unites the occipital bone to the two parietal bones is called the **lambdoid suture**, because it is shaped like the Greek capital letter *Lambda* [Λ = L]. The suture between the two parietal bones is called the **sagittal suture**; that name is given because in an infant's skull the sagittal suture, the lambdoid suture, and an unossified region, called the anterior fontanelle, together resemble a heraldic arrow [*sagitta* = an arrow].

The point where the sagittal suture meets the coronal suture is called the **bregma** [βρέγμα = the front part of the head]. At birth the parts of the frontal

and parietal bones around the bregma are not fully ossified, and leave a large, lozenge-shaped membranous area which is yielding to the touch and is called the *anterior fontanelle*, because it rises and falls with every beat of the heart; in a healthy child the bones approach each other and close the fontanelle by the end of the second year. The coronal suture slopes downwards and forwards from the top of the skull; the bregma is therefore the farthest back point on the suture; it is immediately in front of the mid point of a line drawn from one external auditory meatus to the other in the vertical transverse plane, and is occasionally felt as a depression in the living head. The *post-coronal depression* is the name given to a slight flattening or even hollowing seen in some skulls on the surface of each parietal bone behind and parallel to the coronal suture. Occasionally there is a broad, low ridge along the line of the sagittal suture.

The **lambda** is the point at which the sagittal and lambdoid sutures meet.

The **vertex**, or highest point of a skull held in proper position, is on the sagittal suture near its middle, but varies slightly in different skulls. The **parietal foramen** is a small hole present in many skulls in the parietal bone near the sagittal suture about 35 mm. from the lambda. It is usually only big enough to admit a pin; a small artery and vein pass through it; the vein connects the veins of the scalp with the superior sagittal venous sinus which lies along the middle line on the inside of the skull-cap, and infection can travel along the vein from the scalp and so reach the sinus. The sagittal suture is less serrated between the two parietal foramina than it is elsewhere.

The *sagittal fontanelle* is an unossified space in the region of the parietal foramina; it is usually closed at birth. If it is not closed at birth, the parietal foramen in the adult skull will probably be large enough to admit a match. The point on the sagittal suture between the two parietal foramina is called the **obelion** [ὀβελός (obelos) = ÷ (a mark used by literary commentators)].

The **parietal eminence** is the most convex part of the parietal bone, and is the region where the top of the skull and the side and the back merge into one another. Its position varies with the shape of the skull, but none the less it is used as a landmark, for it is fairly easily identified in the living head. It is best felt with the palm of the hand and overlies the most convex part of the surface of the brain.

The frontal eminences anteriorly and the temporal lines at the sides are visible, but will be dealt with later. In some specimens the zygomatic arches can be seen when the skull is looked at from above.

Norma Frontalis

The **front of the skull** (Fig. 154) is uneven in contour and outline. Almost more than any other aspect of the skull it varies with age, race, and sex, besides displaying individual variations in the details of its configuration.

The front of the skull is made up of: (1) the frontal region or forehead; (2) the two orbits; (3) the bony external nose, between and in front of the orbits; (4) the anterior bony aperture of the nose; (5) the two maxillæ, forming the upper jaw; (6) the zygomatic bone or cheek-bone, below the lateral part of the orbit; and (7) the mandible, when it is in place.

Frontal Region.—The forehead is formed by the frontal bone and is convex. Superiorly it merges into the top of the skull; inferiorly it is limited by the orbits, where wide thin shelves of bone project backwards to form most of the roofs of the two orbits, and by the root of the nose. The **nasion** is the point in the median plane at the root of the nose where the two nasal bones articulate with the frontal bone: it is opposite the anterior extremity of the brain. The **glabella** is the small region immediately above the nasion, between the two eyebrows [*glabellus* = without hair]. The **superciliary arch** is the smooth elevation that arches upwards and in a lateral direction from the glabella a little above the margin of the orbit. Behind it, in the interior of the frontal bone, there is usually a large air-space, called the **frontal sinus** (Figs. 163, 166), from which a short channel leads down into the cavity of the nose. The **frontal eminence** is the most convex part of

each half of the frontal bone; it is situated about two finger-breadths above the lateral end of the superciliary arch.

The **supra-orbital margin** or upper margin of the orbital opening is a curved

border. At the highest point of the curve, about two finger-breadths from the median plane, there is usually a small **supra-orbital notch**; the notch can be felt in the living head by the thumb-nail pressed on the margin *from below*. Laterally, the

supra-orbital margin ends in a prominent projection which is named the **zygomatic process** of the frontal bone because it curves downwards and articulates with the frontal process of the zygomatic bone. The zygomatic process is easily felt at the lateral end of the eyebrow hairs and is one of the most serviceable landmarks in the head. The ridge that curves upwards and backwards from it is the anterior part of the **temporal line**, and can be both felt and seen in thin people between the brow and the temple.

The two halves of the **frontal bone** are separable at birth and are not fused together completely till some period between the sixth and the tenth year. The suture between the halves is called the *frontal suture.* Remains of the suture can often be seen in the adult skull at and above the glabella, and in some skulls, especially in the more civilized races, the whole suture persists till late in life (p. 215); it is sometimes called the *metopic suture* [μετόπη (metopē) = the interstice between two beam ends (in Doric architecture)]. The point in the middle of the forehead, on the shortest diameter between the two temporal lines, is usually a little above the glabella and is called the **ophryon** [ὀφρύς (ophrys) = the brow].

The **superciliary arch** is more prominent in men than in boys and women; the lower part of the forehead therefore protrudes more in a man, and the forehead is less vertical. Though the arch overlies the frontal sinus it is not produced by the sinus, for in a skull in which the sinus is small or absent the arch may be prominent. The upper part (corrugator supercilii) of the orbicularis oculi arises from the medial end of the arch. The **frontal eminence** is the region where the views of the skull from the front, from above, and from the side overlap; it is more conspicuous in boys and women than in men, as their foreheads are more vertical; it overlies the part of the brain called the middle frontal gyrus. Like the parietal eminence it is best felt with the palm of the hand.

The **supra-orbital margin** is the lower limit of the forehead. Its lateral two-thirds is thin and sharp and bends down to the zygomatic process. The medial third is rounded; it bends down into the medial margin of the orbit to articulate with the frontal process of the maxilla, and its end is sometimes called the *maxillary process.* The **supra-orbital notch** is situated at the junction of the medial third and lateral two-thirds of the margin; the supra-orbital vessels and nerves lie in it as they pass out of the orbit and turn upwards into the scalp. In the bottom of the notch there is a minute foramen through which the frontal diploic vein passes to join the supra-orbital vein. In some skulls there are two shallow notches instead of one; in others the notch is converted into a **supra-orbital foramen** by a bridge of bone.

External Nose.—The bony part of the external nose is formed by the two *nasal bones* lying side by side in the bridge of the nose, and, on each side of these, by the *frontal process of the maxilla*, which lies behind the nasal bone in the side of the nose, extends up to reach the frontal bone, and forms also the medial margin of the orbital opening.

Anterior Bony Aperture of Nose.—This opening is bounded above by the lower margins of the two nasal bones, and at the sides and below by the sharp, anterior margins of the frontal processes and bodies of the two maxillæ. It is the anterior opening into the **cavity of the nose**, and one can look through it into the cavity and out through the posterior apertures. The cavity is divided by a thin, median partition or **septum** into a right and a left half. Each half is called a cavity of the nose or nasal cavity, and the term may mean, according to the context, either the whole cavity or one of the halves. Most of the anterior part of the septum is a plate of cartilage; the septum is therefore always incomplete in a macerated and dried skull, and considerable parts of the bony septum may have been broken away. If the bony septum has not been broken the principal part seen through the anterior aperture is the *perpendicular plate of the ethmoid* bone, which forms the upper part of the septum; it is usually slightly bent to one or other side.

The side-wall of the nasal cavity is very uneven, because the three rough curled plates of bone called the *conchæ* project from the side-wall and hang down into the cavity like curtains. The portions of the cavity which lie below the conchæ and lateral to them are called the *meatuses* of the nose—superior, middle, and inferior. The superior concha is too far back to be seen through the anterior aperture, but the inferior and middle conchæ and meatuses can be seen if the conchæ have not been broken away. The middle concha is on a level with the medial wall of the orbit, and is rather less liable to be broken off. The inferior concha is situated about half an inch above the floor of the nose, and even should it have been broken away the ridge on the side-wall of the cavity to which it was attached can be seen.

Maxillary Region.—The lower parts of the two maxillæ meet in the mid-line and a sharp, median spur of bone, called the **anterior nasal spine**, projects forwards from them at the lower margin of the anterior aperture of the nose; it is embedded in the lower, mobile part of the septum of the nose immediately above the upper lip. In a much-handled skull it is usually broken off.

A thick curved ridge projects downwards on each side to form, with its neighbour, the horseshoe-shaped **alveolar process** which carries the upper teeth. These are embedded in a row of sockets on the inferior surface [*alveolus* = a small cavity]. If the walls of the sockets for the teeth have not been absorbed, smooth vertical ridges, produced by the roots or fangs of the teeth, are seen above the alveolar margin. The largest of those ridges corresponds to the root of the canine tooth and is called the **canine eminence**. (The *canine* tooth is the third tooth, counting from the middle in front; and the first two teeth are *incisors*.) The **canine fossa** is the wide, shallow depression above and lateral to the canine eminence, reaching up almost to the lower margin of the orbit. The *infra-orbital foramen* is the opening immediately above the canine fossa, about 5 mm. below the lower margin of the orbit; in the living person it is about a finger's-breadth lateral to the side of the nose, and it may be felt indistinctly if pressure is made there with the finger-tip. It transmits the infra-orbital vessels and nerve.

Between the medial ends of the two supra-orbital margins there is a horseshoe-shaped suture which unites the frontal bone to the upper ends of the two nasal bones and frontal processes of the maxillæ. The middle of the suture is the **nasion**, from which a suture runs down the middle of the bridge of the nose between the two nasal bones; the lower end of the suture is called the **rhinion** [ῥίς (rhis) = the nose]. On each side of the bony external nose there is a linear suture between the nasal bone and the frontal process of the maxilla. On the nasal bone, at a varying point, there is often a minute foramen through which a vein passes from the skin to the interior of the nose. Occasionally that vein continues upwards to join the commencement of the superior sagittal sinus in the cranial cavity, and then infection can pass along the vein to the sinus. At the lower end of the nasal bone there is very often a narrow notch that marks the point where the external nasal nerve escapes from the interior of the nose. Some fibres of the procerus muscle are attached to the nasal bone. The levator labii superioris alæque nasi arises from the upper part of the frontal process of the maxilla; the compressor naris arises from the bone near the lower boundary of the anterior aperture of the nose.

The pliable, lower part of the external nose has a framework of cartilage united to the sharp margins of the anterior bony aperture by fibrous tissue. The **anterior bony aperture** is oblique, and is ovoid in outline with the narrow end above and in front. It measures about 30-35 mm. in height, and about 25 mm. across its widest part; it is shorter, wider, and more vertical in flat-nosed races. Parts of the septum and side-walls of the **nasal cavity** can be seen through it, and also the floor and part of the roof when the skull is tilted.

If the bony **septum** is complete, its anterior edge forms an angle into which the septal cartilage fits (Fig. 163). The upper limb of the angle is the perpendicular plate of the ethmoid. The lower limb is formed *posteriorly* by the lower and anterior part of the vomer and *anteriorly* by the prominent, anterior part of the *nasal crest* of the maxillæ (*i.e.*, a rough ridge that stands up from the junction of the palatine processes of the two maxillæ and is continuous with the anterior nasal spine). On the **side-wall** note again the inferior and middle conchæ. The inferior concha reaches the anterior aperture. The middle concha is shorter than the inferior and does not reach so far forwards; the interval between it and the septum is very narrow, and also the part of the middle meatus that lies lateral to it is very narrow, because a part of the labyrinth of the ethmoid, called the *bulla ethmoidalis*, bulges into the meatus; the lower part of the middle meatus is roomier, and in its side-wall the opening of the maxillary sinus can be found. Identify the floor of the fossa for the lacrimal sac in the orbit and then in the side-wall of the nasal cavity immediately in front of the middle meatus. The part of the **roof** visible is the anterior sloping part, formed by the nasal bone and the nasal part of the frontal bone and its nasal spine —a projection which is hidden from the exterior by the nasal bone. The whole **floor** can be seen. Though the upper part of the nasal cavity is very narrow, the floor is half an inch in width; it is made of the palatine process of the maxilla and the horizontal part of the palatine bone, which, at the same time, constitute the bony palate and are seen better on the lower surface of the skull.

The **anterior nasal spine** consists of a spicule from each maxilla; its apex is called the **akanthion** [ἄκανθα (akantha) = a thorn]. Running downwards from it there is the *intermaxillary suture*, the lower end of which, in the front of the alveolar margin, is called the **prosthion** [πρόσθιος = foremost]. On each side of the suture, immediately below the anterior aperture of the nose there is a shallow **subnasal fossa**. The **canine fossa** is below the infra-orbital foramen on the anterior wall of the maxillary sinus; the levator anguli oris arises from its floor. The levator labii superioris arises from the infra-orbital margin above the infra-orbital foramen; the incisive slips of the orbicularis oris arise from the floor of the subnasal fossa and the canine eminence.

Lateral to the canine fossa, the suture between the maxilla and the zygomatic bone can be seen. It begins at the middle of the lower margin of the orbit and ends at the lower border of

the zygomatic arch in line with the lateral margin of the orbit. The **zygomatico-facial foramen** is a small hole on the zygomatic bone about 5 mm. below the lateral part of the lower margin of the orbit; it is only big enough to admit a pin; it transmits the zygomatico-facial branch of the zygomatic nerve and a small branch of the lacrimal artery; sometimes it is represented by two openings instead of one. Below the foramen, a smooth low eminence gives origin to the zygomaticus major; the eminence is conspicuous in some thin people.

The **zygomatic bone** (Figs. 154, 155, 206) makes the hard, prominent part of the cheek; it forms the anterior part of the zygomatic arch and has a considerable share in forming the lower and lateral parts of the rim of the orbit. The part of the zygomatic bone that projects backwards to articulate with the zygoma of the temporal bone is called its **temporal process.** The part that projects upwards along the side of the orbit to articulate with the frontal bone is called its **frontal process**; posteriorly, it articulates with the greater wing of the sphenoid.

Orbit (Figs. 154, 165).—The orbit is a cavity of a shape not unlike a four-sided pyramid laid on one side. The sides are called the *roof*, the *floor*, the *medial wall* and the *lateral wall*. The *base* of the pyramid is the opening on to the face, and the boundaries of the base are the **margins of the orbit.** At the *apex* there is a large aperture; it is the medial and lower part of a cleft called the **superior orbital fissure** (Fig. 154); the rest of the fissure extends forwards, upwards, and in a lateral direction *between the roof and the lateral wall* of the orbit, becoming narrower as it does so. The fissure leads back into the middle cranial fossa, and its size varies in different skulls.

Between the roof and the medial wall there are three foramina—the optic and two ethmoidal. The **optic foramen** is the round aperture immediately above and medial to the apex of the orbit; it leads back into the middle cranial fossa. The **anterior** and **posterior ethmoidal foramina** are farther forward; they are about half an inch apart and the anterior is the larger. They lead into canals that open into the median part of the anterior cranial fossa, but their openings there are rather hidden under lips of bone.

The **fossa for the lacrimal gland** [*lacrima* = a tear] is a broad, smooth depression, of varying depth, in the anterior and lateral part of the roof of the orbit, under shelter of the zygomatic process of the frontal bone. The **fossa for the lacrimal sac** (Fig. 155) is on the medial wall close to the orbital margin. If the lacrimal bone is broken away, only part of the fossa will be seen, for it is a fairly broad, vertical groove, partly on the anterior part of the lacrimal bone and partly on the frontal process of the maxilla. The **lacrimal bone** is the thin, uneven scale of bone, about the size of a finger nail, placed behind the frontal process of the maxilla and in front of the orbital plate of the ethmoid. The fossa becomes continuous with the **naso-lacrimal canal**, the upper opening of which is seen at the *junction of the medial wall and floor* of the orbit; the canal is a short tunnel that leads down into the inferior meatus of the nose under cover of the anterior part of the inferior concha—a fact which one can demonstrate by pushing a match down through the canal from the orbit (Fig. 166). The lacrimal sac is a wide tube, blind at its upper end, and its lower end is continuous with the naso-lacrimal duct, which goes down through the canal into the nose. The lacrimal gland produces the lacrimal fluid; most of the fluid evaporates, and the remainder passes into the sac and thence into the nose—any excess of fluid overflowing the eyelids as tears. The gland is at the upper, lateral part of the orbit, and the sac is at the lower, medial part; that arrangement ensures that the front of the eye shall be well washed.

Between the floor and the lateral wall of the orbit there is a long cleft, called the **inferior orbital fissure,** which opens into a space behind the maxilla called the infratemporal fossa. The **infra-orbital groove** is in the floor of the orbit. It begins about the middle of the inferior orbital fissure and runs nearly straight forwards in the roof of the maxillary sinus which occupies the interior of the maxilla. The anterior part of it has a thin roof of bone and is called the **infra-orbital canal**; and the canal opens on the face as the infra-orbital foramen. In one or both orbits the groove may be roofed over in all its length; one can then find it by passing a pointer back through the infra-orbital foramen.

The chief **relations** of the orbit are :—*Superiorly*—The frontal sinus to a varying extent ; the anteror cranial fossa, containing the frontal lobe of the brain. *Inferiorly*—The maxillary sinus in the body of the maxilla (Fig. 165). *Medially*—Near the apex, the sphenoidal sinus in the body of the sphenoid (Fig. 164) ; farther forward, the ethmoidal sinuses, which separate the orbit from the cavity of the nose (Fig. 166) ; within the orbital margin, the floor of the fossa for the lacrimal sac intervenes between the orbit and the nasal cavity, and is so thin that an operator can reach the lacrimal sac by passing from the nose through the floor of the fossa, if he wants to avoid a scar at the medial corner of the eye. *Laterally*—The posterior part of the orbit is related to the middle cranial fossa, which lodges the temporal lobe of the brain ; the anterior part is related to the anterior part of the temporal fossa (p. 161).

The two **orbits** are placed so that their medial walls are almost parallel, while their lateral walls are nearly at right angles to each other ; the axis of each orbit is directed therefore in a forward and lateral direction ; none the less, the axes of the two eyeballs are antero-posterior and parallel. Each orbit is about 50 mm. long.

The **orbital opening** or base of the orbit is more or less four-square, measuring about 40 mm. each way ; it is directed forwards and slightly in a lateral direction, and it is tilted so that the upper and lower margins slope slightly downwards from medial to lateral side. The *lower margin* of the opening is formed by the maxilla and the zygomatic bone. *The lateral margin* is formed by the frontal process of the zygomatic bone and the zygomatic process of the frontal bone ; the suture between the processes, near the upper angle of the opening, can usually be felt in the living person ; within the middle of the margin, about 10 mm. below the suture, there is a slight eminence (felt by the finger-tip rather than seen) for the attachment of the lateral palpebral ligament and the check and suspensory ligaments of the eye. The *upper margin* is the supra-orbital margin of the frontal bone ; its lateral two-thirds is sharp, and the medial third is smooth and rounded ; the supra-orbital notch or foramen is at their junction ; the supratrochlear nerve and vessels, passing out of the orbit on to the forehead, cross the margin about 5 mm. medial to the supra-orbital notch and may produce a shallow groove. The *medial* margin is formed by the maxillary process of the frontal bone and the frontal process of the maxilla ; the medial palpebral ligament and the orbicularis oculi are attached to the margin immediately in front of the groove for the lacrimal sac.

The orbit being pyramidal, its walls are more or less triangular in outline. The lateral wall is strong and fairly thick. The other walls are made of thin bone—especially the medial wall, where the bone is almost like paper.

The *roof* is concave ; it is formed by the orbital plate of the frontal bone, supplemented posteriorly by the lesser wing of the sphenoid. The frontal sinus extends for a variable distance backwards *in* the roof of the orbit between the two tables of the orbital plate. At the lateral angle of the roof there is the wide **fossa for the lacrimal gland** (*i.e.*, the greater part of the gland ; the smaller part protrudes beyond the fossa into the upper eyelid). At the medial angle the trochlea is attached ; the attachment may be marked by a very small pit or by a spicule of bone, or by both (the **trochlear fossa** and **spine**) ; the trochlea is a small fibro-cartilaginous ring through which the tendon of the superior oblique muscle of the eyeball passes.

The greater part of the *lateral wall* is formed by the greater wing of the sphenoid, but the anterior part is formed by the frontal process of the zygomatic bone. On the anterior part there is a small aperture, called the **zygomatic foramen**, through which the zygomatic nerve leaves the orbit, accompanied by a small branch of the lacrimal artery ; sometimes there are two apertures instead of one. A great part of the lateral wall is separated posteriorly from the roof by the **superior orbital fissure**, which is bounded medially by the body of the sphenoid, above by the lesser wing, below and laterally by the greater wing. The two heads of the lateral rectus muscle of the eyeball lie across the wide, lower and medial part of the fissure. Some of the structures transmitted by the fissure pass between the two heads ; the others pass above both heads. They are :—

(*a*) *Between the Heads.*—The ophthalmic vein or veins, passing backwards to join the cavernous sinus [ὀφθαλμός (ophthalmos) = *oculus* = the eye] ; the abducent nerve, the naso-ciliary nerve, and the two divisions of the oculomotor nerve—all passing forwards.

(*b*) *Above the Heads.*—The trochlear nerve, the frontal nerve, and the lacrimal nerve, all passing forwards, in that order from medial to lateral side ; a small branch of the lacrimal artery passing backwards to the dura mater ; occasionally a small branch of the middle meningeal artery passing into the orbit ; and sympathetic twigs from the carotid plexus. [Μῆνιγξ (mēninx) = any membrane, but especially a membrane around the brain.]

The *floor* is formed chiefly by the orbital surface of the body of the maxilla, which is, at the same time, the roof of the maxillary sinus. But the antero-lateral corner of the floor is formed by the zygomatic bone ; and the posterior corner is formed by the orbital process of the palatine bone—that is, the anterior of the two projections on the upper end of its perpendicular plate.

A great part of the floor is separated from the lateral wall posteriorly by the **inferior orbital fissure.** The fissure is bounded *above* by the greater wing of the sphenoid, *below* by the orbital surface of the maxilla and the orbital process of the palatine bone ; its *anterior* end is closed either by

the zygomatic bone or by an articulation between the greater wing and the maxilla. The posterior end of the inferior orbital fissure meets the medial end of the superior orbital fissure at the apex of the orbit. The greater part of the inferior fissure leads into the infratemporal fossa behind the maxilla; but its posterior part leads down into the pterygo-palatine fossa, which also is behind the maxilla and is below the most posterior part of the orbit. The inferior orbital fissure *transmits*: the maxillary nerve, as it changes its name to infra-orbital nerve; the infra-orbital vessels; the zygomatic nerve; small twigs from the spheno-palatine ganglion to the lacrimal gland and the periosteum of the orbit; a vein which connects the ophthalmic veins with the pterygoid venous plexus in the infratemporal fossa.

The **infra-orbital groove** and **canal** run forwards in the floor of the orbit and the roof of the maxillary sinus. The infra-orbital nerve, accompanied by the infra-orbital vessels, traverses the groove and canal, sends down branches through the facial wall of the sinus to the incisor and canine teeth, and enters the face through the infra-orbital foramen.

The upper end of the **naso-lacrimal canal** separates the anterior part of the floor from the medial wall; and at the medial corner of the floor, immediately lateral to the canal, there is a shallow depression for the origin of the inferior oblique muscle of the eyeball.

The *medial wall* of the orbit is formed, from behind forwards, by: the anterior part of the side of the body of the sphenoid; the orbital plate of the ethmoid; the lacrimal bone; and the posterior part of the frontal process of the maxilla. The optic foramen and the ethmoidal foramina lie between the medial wall and the roof. The **optic foramen** is bounded by the body of the sphenoid and the roots of the lesser wing; it transmits the optic nerve and the ophthalmic artery; note that the ophthalmic vein and artery pass through different apertures. The **anterior** and **posterior ethmoidal foramina** are the orbital ends of the anterior and posterior ethmoidal canals, which transmit vessels and nerves of the same name.

The **fossa for the lacrimal sac** grooves the anterior part of the lacrimal bone and the posterior part of the frontal process of the maxilla; its margins are called the **lacrimal crests**; the anterior crest is part of the medial margin of the orbit; the posterior crest gives attachment to the pars lacrimalis of the orbicularis oculi muscle. The upper end of the suture between the two bones is called the **dacryon** [*δάκρυον* (dakryon) = *lacrima* = a tear].

Norma Occipitalis

The **back of the skull** is markedly convex and has the outline of a wide arch; the arch is widest usually at the level of the parietal eminences. The bones seen are portions of the two parietal bones, a portion of the occipital, which lies between the two parietal bones and is continued into the base of the skull below (Fig. 155), and the mastoid portion of the temporal bone and its mastoid process, which are visible at the lower corner on each side. The parts already seen on the top of the skull but seen again in the back are the parietal eminences, the posterior part of the sagittal suture, the parietal foramina, the lambda, and the lambdoid suture, which is now seen in the whole of its extent.

From the lower end of the lambdoid suture, on each side, the *occipito-mastoid suture* descends between the occipital bone and the mastoid temporal. The **mastoid foramen** is the aperture seen in the suture or on the mastoid temporal near the suture, and it varies in size from a pin-point to a match; it passes through the skull-wall and opens internally in the posterior cranial fossa into the groove for the sigmoid venous sinus; it transmits a small branch of the occipital artery and an emissary vein that connects the sinus with the veins on the outside of the head; it is at the level of the external auditory meatus and about three finger-breadths behind it.

The **external occipital protuberance** is the projection—usually well marked—in the median plane, at the lower part of the back of the skull, about midway between the lambda and the foramen magnum. It is easily felt in the living person immediately above the nape of the neck, and it is a useful landmark. If two protuberances are felt there, one below the other, the lower one is the normal protuberance. The central point of the protuberance is called the **inion**. The **superior nuchal line** is the blunt, curved ridge that arches laterally from the protuberance. The protuberance and the right and left superior nuchal lines mark the boundary between the back of the head and the back of the neck [*ἰνίον* (inion) = back of head or nape of neck; *nucha* = nape of neck]. The part of the skull seen in perspective below the protuberance and the superior nuchal lines belongs to the lower surface of the skull.

In some skulls a curved ridge is seen immediately above the superior nuchal

line; it is called the *highest nuchal line*, and gives attachment to the epicranial aponeurosis, a tendinous sheet in the scalp.

In most skulls the most bulging part of the back of the head is not at the protuberance but is a little above it. The degree of bulging of the occipital bone above the nuchal lines varies with the size and shape of the occipital lobes of the brain, and is frequently unequal on the two sides.

The **lambda** is situated between two and three inches above the protuberance. In many heads it can be felt by the finger-tip as an apparent depression, owing to the prominence of the apical part of the occipital bone; it overlies the interval between the two halves of the brain a little behind the parieto-occipital sulcus in the brain.

Norma Lateralis

The **side of the skull** is divisible into two parts: a smaller part below and in front belongs to the face and is very uneven; a larger ovoid part above and behind belongs to the brain-case. Each **parietal bone** occupies a wide area between the frontal and occipital bones; below it and extending into the base of the skull is the **temporal bone.** The part, shaped like a large scale, which lies below the parietal bone is the *squama* or **squamous temporal** (*squama* = a scale); the prominent, narrow process which arches forward from it is the zygomatic process or **zygoma** which reaches the zygomatic bone to form the zygomatic arch. The **mastoid temporal** lies behind and is so named because of the rounded **mastoid process** which projects down from it [μαστός (mastos) = the breast]. In front of the mastoid process lies the round or oval opening of the bony external auditory meatus, the tunnel leading into the middle ear in a dried skull. Most of the **sphenoid bone** lies in the base of the skull but a portion of its greater wing can be seen wedged between the frontal bone and the squamous temporal and reaching a corner of the parietal bone.

Many of the parts seen already when the posterior and the upper and the anterior aspects of the skull were examined, are seen again in the lateral aspect. Identify again the superior nuchal line, the lambdoid suture, the occipito-mastoid suture, the mastoid foramen, the parietal eminence, the coronal suture, the frontal eminence, the superciliary arch, the bony external nose, the maxilla, the zygomatic bone, the margins of the orbit, and the zygomatic process of the frontal bone. The following parts are now to be looked for.

The **temporal line** is a long, curved ridge that begins at the zygomatic process of the frontal bone. From there it curves upwards and slightly medially and then arches backwards across the frontal bone along the lateral margin of the forehead; then backwards over the parietal bone, passing through the parietal eminence or immediately below it; having passed the parietal eminence it bends downwards and slightly forwards, and it ends by joining a blunt, prominent ridge called the **supramastoid crest**; that crest is situated on the squamous temporal near its junction with the mastoid temporal. The anterior part of the temporal line is easily felt in the living head above the zygomatic process of the frontal bone between the forehead and the temple. Its middle part is usually represented by two lines—an upper and a lower—about half an inch apart; the bone between those lines is often more polished than that above and below, and if the lines are indistinct they can often be identified as the margins of a smooth strip along the upper part of the side of the skull. The posterior part of the line is frequently very indistinct. [*Tempora* = the temples, from *tempus* = time: grey hairs appear first in the temples.]

The **temporal fossa** is the wide space outlined by the temporal line and the zygomatic arch. Parts of four bones are seen in the **floor** of the fossa: (1) the lower part of the *parietal* bone; (2) the *squamous* part of the *temporal* bone below the parietal bone and united to it by a curved suture called the *squamous suture*; (3) a small part of the *frontal* bone in the upper and anterior part of the fossa; (4) a part of the *greater wing of the sphenoid* below the frontal and in front of the squamous temporal. In the anterior part of the fossa the

four bones are so close together that a small circle, the size of a sixpence or a shilling, would include portions of them all; the region enclosed by such a circle is called the **pterion**, because one of the pairs of Hermes' wings was attached to the corresponding part of his head-piece. [πτέρυξ (pteryx) = a wing].

In a man's skull, the centre of the pterion is 3 cm. behind the lower end of the zygomatic process of the frontal bone and about 1 cm. higher *i.e.*, about 4 cm. above the zygomatic arch. It is a region made much use of as a guiding point when the

position of deeper structures and their relations to the surface of the head are being explained. In many skulls sutural bones are present in the region of the pterion.

The part of the greater wing of the sphenoid which is seen in the temporal fossa is its *temporal surface*. The surface is limited below by a horizontal, antero-posterior ridge called the **infratemporal crest**. The crest may be smooth and blunt or rough and prominent; it separates the temporal surface of the greater wing from the infratemporal surface, which is seen on the lower surface of the skull.

The **zygomatic arch** is formed by the zygomatic bone and its temporal process and the zygoma of the temporal bone; it can be felt from end to end, and

in thin people it stands out prominently between the temple and the side of the face. About an inch in front of the auditory meatus the arch divides into two parts, the **anterior** and **posterior roots** of the zygoma, which diverge from each other. The posterior root extends backwards, the anterior root turns medially towards the side of the skull.

The **anterior root** is easily found if one traces the lower border of the arch backwards; it is broad and its two surfaces look upwards and downwards; its lower surface is convex and is continuous, at the side of the skull, with a smooth, convex elevation, called the **articular eminence**, which is seen on the lower surface of the skull in the front of a smooth concavity called the **articular fossa** (Fig. 156). The lateral end of the lower surface of the root is called the **tubercle of the root of the zygoma** and is made use of as a landmark; it is felt immediately in front of the head of the mandible when the mouth is shut, immediately above it when the mouth is opened.

The **posterior root** is continuous with the upper border of the zygomatic arch. It joins the side of the skull and is continued backwards as a ridge immediately above the external auditory meatus, where it can be felt through the skin of the ear; it ends by joining the supramastoid crest immediately behind the level of the meatus. The posterior root and the upper border of the arch are opposite the lower border of the brain.

From the lower surface of the posterior root a smooth triangular prominence, called the **post-glenoid tubercle**, juts downwards immediately in front of the auditory meatus and extends medially for some distance, forming the posterior boundary of the lateral part of the articular fossa.

The **temporal line** gives attachment to the epicranial aponeurosis, to the temporal fascia, and to the uppermost fibres of the temporalis muscle; where the line is divided, the fascia is attached to the upper line and to the space between the lines, but the muscle fibres reach only the lower line. The point where the lower temporal line crosses the coronal suture is called the **stephanion** [*στέφανος* (stephanos) = a circle or crown].

The **temporal fossa** contains the temporalis muscle, the middle and deep temporal vessels, the deep temporal nerves, the zygomatico-temporal branch of the zygomatic nerve, and a quantity of fat—all under cover of the temporal fascia; and the chief structures on the surface of the fascia are the superficial temporal vessels, the auriculo-temporal nerve, and the temporal branches of the facial nerve.

The depth and width of the fossa depend, in a measure, on the size of the temporal muscle, which is proportional to the size and weight of the mandible. The anterior and lower part of the fossa is much the deepest part and has an *anterior wall*, which separates it from the orbit; the anterior wall is formed by the zygomatic process of the frontal, the frontal process of the zygomatic, and sometimes by the greater wing of the sphenoid where it articulates with that process of the zygomatic bone. On the part of the wall formed by the zygomatic bone there is a small aperture, called the **zygomatico-temporal foramen**, which transmits the zygomatico-temporal nerve, accompanied by a small branch of the lacrimal artery. The posterior border of the frontal process of the zygomatic bone gives attachment to the temporal fascia, and it shows a slight fullness or tubercle called the *marginal tubercle*; the point where the posterior border of the frontal process joins the upper border of the zygomatic arch is the **jugal point**.

The *floor* of the fossa gives origin to the temporalis muscle. It is limited below by the infratemporal crest of the sphenoid, by the roots of the zygoma, and by a short, horizontal ridge on the squamous temporal between the anterior root and the infratemporal crest; that ridge separates the temporal surface of the squamous temporal from a small triangular area—its infratemporal surface—which forms part of the roof of the infratemporal fossa. The part of the floor formed by the greater wing sometimes shows grooves for the deep temporal arteries; and the part of the floor above the auditory meatus shows a long and narrow vertical groove for the middle temporal artery.

The **pterion** (p. 162) is opposite the point where the anterior branch of the middle meningeal artery is deeply embedded in a groove on the inner side of the skull-wall and is most liable to injury, and it is opposite the point on the brain where the stem of the lateral sulcus breaks up into its three rami.

The suture between the two constituent bones of the **zygomatic arch** runs obliquely from above downwards and backwards.

The *upper* border of the zygomatic arch—thin, sharp, and nearly horizontal—is formed chiefly by the zygoma, and gives attachment to the temporal fascia. The *lower* border, formed chiefly by the zygomatic bone, is thicker and rougher and extends much farther forwards, but not so far back; it slopes downwards as it is traced forwards, for the arch is much deeper in front than behind; the lower border gives origin to the masseter muscle, which arises also from the *deep* surface of the arch, while the *superficial* surface is subcutaneous. The **tubercle of the root of the zygoma** gives attachment to the temporo-mandibular ligament. The anterior root is not only

continuous with the articular eminence but also forms part of it. The **posterior root** and the **supramastoid crest** give attachment to the temporal fascia.

A small portion of the squamous temporal lies below and behind the supramastoid crest. The anterior part of that portion sends downwards a pointed extension, called the **post-auditory process** (Fig. 185), which forms the upper part of the posterior wall of the external auditory meatus.

The *post-glenoid tubercle* corresponds to a prominent process developed in some mammals to prevent backward displacement of the mandible.

The **suprameatal triangle** is a small (and often inconspicuous) depression below the posterior root of the zygoma, immediately behind the upper margin of the external auditory meatus. Although small, it is very important, for the tympanic antrum lies about half an inch directly medial to it. The tympanic antrum is a cavity in the temporal bone, and it often has to be opened into when diseased; the road to it is through the suprameatal triangle, the position of which, therefore, has to be accurately known. If the depression of the triangle is fairly well marked, one may be able to feel it in the living head by pulling the ear vigorously forwards and downwards, and pressing with the finger-tip immediately above and behind the meatus.

The entire **external auditory meatus**, leading from the exterior to the drum of the ear, is about 25 mm. long, but only the medial, bony part of it is left in a dried skull; the lateral part is made of cartilage and has been removed during maceration. The bony part is a tunnel about 15 mm. long. Its *inferior wall* and the greater part of the *anterior* and *posterior walls* are formed by the lateral half of the *tympanic plate*, a small plate of bone which is curled to form these boundaries (see p. 176). The *upper wall* and small adjoining parts of the anterior and posterior walls are formed by the squamous temporal. The *medial end* of the meatus is closed up during life with a tense, vibratile membrane, the **tympanic membrane**, which separates the meatus from the tympanic cavity or **middle ear** and forms the greater part of the lateral wall of the middle ear. The tympanic cavity or middle ear or drum of the ear [τύμπανον (tympanon) = a kettledrum] is a cavity in the temporal bone, and is narrow from side to side. The membrane is the drum-head, and it, along with the contents of the middle ear, has been removed during maceration, and therefore, when one looks into the meatus, the bony surface seen at the far end is the medial wall of the middle ear (Figs. 158, 160).

The **styloid process**—a slender process about an inch long—projects downwards, forwards, and slightly medially from behind the lower edge of the tympanic plate [στῦλος (stylos) = a pillar, a stake, a pen]. It is situated deeply in the interval between the mastoid process and the mandible. It is dealt with more fully when the lower surface of the skull is examined.

The **mastoid part** of the temporal bone lies behind the external meatus, wedged in between the parietal bone, the occipital bone, and the squamous temporal; it is united with the parietal and occipital by sutures, but is continuous with the squamous temporal; the line of fusion is a little below and behind the supramastoid crest (Fig. 185), but the crest approximately indicates the position of the junction of the two parts. The lower part of the mastoid temporal juts downwards as a thick, prominent process—the *mastoid process*, which is easily felt behind the ear in the living head.

There may be no triangular depression to mark the **suprameatal triangle** in the skull the student is using, and even a well-marked triangle measures only a few millimetres. The triangle is above and behind the opening of the meatus, close to the meatus, at the meeting of tangents drawn to the upper and posterior margins of the meatus. The *suprameatal spine*, described as a spicule of bone on the antero-inferior side of the triangle, is seldom present.

The **external auditory meatus** is barely wide enough to admit an ordinary pencil. It passes in a medial direction and slightly forwards; its opening into the middle ear is very oblique, so that the tympanic membrane, which closes the opening, looks downwards and forwards as well as in a lateral direction. The outer orifice also is oblique—the upper margin overhanging the lower—and it is at a slightly higher level than the outer orifice of the cartilaginous part. The parts of the outer orifice formed by the lateral margin of the tympanic plate are rough for the attachment of the cartilage of the auricle; the auricularis posterior muscle arises from the bone behind the meatus.

In the child the meatus is very short, for the tympanic plate, which forms so much of the meatus, is at birth not a curved *plate* but an incomplete, slender *ring*; in a child, therefore, the tympanic membrane is quite near the surface of the head. In an infant's skull there is a

foramen in the floor of the meatus; for, as the ring becomes a plate, ossification is incomplete in its lower part till the fifth year. Occasionally the foramen persists in the adult.

The meatus as a whole is described in the Section on the Sensory Organs; the student is liable to get misleading ideas about the meatus if he studies the osseous portion apart from the cartilaginous portion.

The **medial wall of the tympanic cavity**, seen when one looks into the meatus, is uneven, and has about its middle a white bulging called the **promontory**. If the meatus is fairly wide, and the skull is tilted this way and that, a little hole may be seen above the posterior part of the promontory; it is called the **fenestra vestibuli**, because it leads into the *vestibule* of the internal ear. During life the footpiece of the auditory ossicle called the *stapes* or stirrup fits into it. [*Fenestra* = a window.]

The **tympano-mastoid fissure**, which transmits the auricular branch of the vagus nerve, is a narrow slit between the posterior part of the lateral margin of the tympanic plate and the front of the mastoid temporal. In many skulls the tympanic plate is so closely applied to the mastoid that the fissure is represented by a minute foramen just large enough to emit the nerve.

The mastoid portion of the temporal bone or **mastoid temporal** is more or less triangular in outline, the apical part being the mastoid process. Anteriorly it fuses with the squamous temporal a little behind and below the *supramastoid crest*, and, below that, it is closely related to the tympanic plate. Posteriorly it articulates with the occipital bone. Its upper border or base articulates with the postero-inferior angle of the parietal bone. The point, at the lateral angle of the occipital bone, where the lambdoid, parieto-mastoid, and occipito-mastoid sutures meet together, is called the **asterion** [ἀστήρ (astēr) = a star]; the superior nuchal line of the occipital bone, when well marked, reaches the asterion. In skulls in which the supramastoid crest is not a mere curved ridge but is a broad, blunt, prominent elevation, there is a depression behind the crest in the angle between the squamous temporal and the base of the mastoid temporal. Note that, in the living head, the depression is immediately behind the top of the root of the auricle—a full inch away from the meatus—and is not to be mistaken for the suprameatal triangle; it is directly opposite the sigmoid venous sinus immediately below its commencement.

The **mastoid process** juts down from the mastoid temporal and is felt as a prominence behind the lower part of the auricle. It is opposite the foramen magnum, and a line drawn from one mastoid process to the other passes immediately below the foramen. It is absent at birth; it is small in a child, for it does not begin to appear till the second year and is not fully developed till after puberty; it is variable in size in the adult, and is usually larger in men than in women.

In the adult, the mastoid temporal (including the mastoid process) is permeated with small air-spaces called the **mastoid air-cells**. The cells are diverticula from the tympanic antrum that replace the marrow and diploë in the mastoid temporal, and they may extend into adjoining parts of the petrous and squamous. They begin to develop at or shortly before birth. They increase in number and size slowly, and do not extend into the mastoid process till shortly before puberty; but at puberty they begin to enlarge rapidly and reach their full size in a year or two. They remain in communication with the tympanic antrum, and, like it, they are lined with a thin muco-endosteum which is continuous with the mucous lining of the tympanum and is covered with simple, flat epithelium. Occasionally in the adult the cells are few in number or are absent, the bone being diploëtic or even quite dense; on the other hand, the cells may extend to the mastoid process during childhood.

The sterno-mastoid muscle is inserted into a strip that extends from the tip of the mastoid process to the asterion and then includes the lateral third of the superior nuchal line; the splenius capitis into a strip immediately below that for the sterno-mastoid; the longissimus capitis into the back of the root of the mastoid process; and the posterior belly of the digastric arises from the floor of the well-marked groove, called the **mastoid notch**, at the medial side of the root of the mastoid process.

The **infratemporal fossa** (Fig. 156) is the open space behind the maxilla; it communicates with the temporal fossa through a wide opening under cover of the zygomatic arch. Its *anterior wall*—full and rounded—is the posterior surface of the maxilla. The lowest part of that surface, behind the last molar tooth, is the **tuberosity of the maxilla**. (The *molar* teeth or grinders are the hindermost three teeth in a full set of eight a side.) Above the posterior surface of the maxilla, between it and the greater wing of the sphenoid, there is the horizontal cleft, called the **inferior orbital fissure**, by which the infratemporal fossa communicates with the orbit, where the fissure has been seen already (pp. 158 and 159).

The greater part of the *roof* of the fossa is a large, fairly flat surface of bone already pointed out as the *infratemporal surface* of the greater wing of the sphenoid; the lateral margin of the surface is the **infratemporal crest**, which also has been referred to already (p. 162).

The *medial wall* of the fossa is the *lateral pterygoid plate*. This plate is thin and wide, and is set nearly perpendicularly behind the maxilla. Between its upper part and the upper part of the maxilla there is a narrow V-shaped

cleft, called the **pterygo-maxillary fissure**, whose upper end joins the inferior orbital fissure at almost a right angle. The maxillary artery passes out of the infratemporal fossa through the pterygo-maxillary fissure into the *pterygo-palatine fossa.*

The **pterygo-palatine fossa** is the small, confined space one sees immediately beyond the pterygo-maxillary fissure. If a pin or a match is passed through the upper part of the fissure into the fossa, and onwards through the fossa, it appears in the nasal cavity. The hole in the medial wall of the fossa through which the pin enters the nose is the **spheno-palatine foramen.**

The **infratemporal fossa** is a roomy space that contains the two pterygoid muscles, the spheno-mandibular ligament, the pterygoid venous plexus, the maxillary artery (first and second parts) and its branches, the mandibular nerve and its branches, and the chorda tympani nerve —all embedded in a quantity of fat and lying under cover of the tendon of the temporalis, the coronoid process, and the ramus of the mandible and the masseter muscle. The coronoid process and the ramus constitute a *lateral wall* of the fossa; the temporalis tendon is inserted into the process; the masseter lies on the lateral surface of the process and the ramus, being inserted into the lateral surface of the ramus. [Μασητήρ (masētēr) = a chewer.]

The *anterior wall* of the fossa (*i.e.*, the posterior surface of the maxilla, ending inferiorly in the maxillary tuberosity) presents, about its middle, two or three small holes which are the upper ends of the **dental canals** through which vessels and nerves descend to the molar and premolar teeth of the upper jaw.

The *roof* of the fossa is chiefly the infratemporal surface of the greater wing of the sphenoid, and partly also the infratemporal surface of the squamous temporal, *i.e.* a small triangular area that lies in front of the medial part of the articular eminence. In the infratemporal surface of the sphenoid, close to its posterior border, there are two holes, called the **foramen ovale** and **foramen spinosum**, which will be considered with the lower surface of the skull (p. 171).

The *medial wall* is the lateral pterygoid plate and a narrow strip of bone which belongs to the tubercle of the palatine bone and is wedged in between the lower part of the plate and the maxilla; very often, however, the strip is so closely united to the bones between which it lies that it cannot be distinguished, and the lower part of the plate appears to be fused with the maxilla.

The **pterygo-palatine fossa** is a small space situated *below* the apex of the orbit, bounded *anteriorly* by the maxilla, *posteriorly* by the common root of the pterygoid process and greater wing of the sphenoid bone, and *medially* by the perpendicular plate of the palatine bone, which separates it from the cavity of the nose. The fossa is filled with fat, in which there lie the third part of the maxillary artery and its branches, corresponding veins, the maxillary nerve, and the spheno-palatine ganglion and its branches.

The fossa communicates with the infratemporal fossa by the **pterygo-maxillary fissure**, through which the maxillary artery enters it and the maxillary nerve leaves it. It is on a level with the zygomatic arch immediately below the jugal point, about two inches distant from the side of the head. In intractable neuralgia of the branches of the maxillary nerve a needle conveying analgesic fluid may be passed through the contents of the infratemporal fossa into the pterygo-palatine fossa to reach the maxillary nerve.

The following apertures (several of which will be referred to more fully later), open into or out of the pterygo-palatine fossa: (1) the pterygo-maxillary fissure; (2) the inferior orbital fissure, through the posterior end of which the fossa communicates with the apical part of the orbit; (3) the greater palatine canal, which descends to the posterior corner of the bony palate; (4) the foramen rotundum, which opens out of the middle cranial fossa; (5) the pterygoid canal, which passes backwards through the root of the pterygoid process; (6) the palatino-vaginal canal, which passes backwards and medially in the roof of the nose; (7) the spheno-palatine foramen.

The **spheno-palatine foramen** is in the medial wall of the fossa and is bounded by the spheno-palatine notch and the lower surface of the body of the sphenoid. It opens into the superior meatus of the cavity of the nose immediately above the posterior end of the middle concha, but during life it is closed up by the mucous membrane. It transmits the spheno-palatine vessels and the long and short spheno-palatine nerves from the spheno-palatine ganglion. The foramen can be identified in the dried skull if a match is pushed onwards through the pterygo-palatine fossa into the nose, where one can see it by looking through the posterior aperture of that side; the foramen is large and round, but by frequent examination the thin bone around it may have been broken down, so that it may be a large opening with jagged margins.

Norma Basalis

When the skull is turned upside down for the examination of the **lower surface** of its base, many of the parts already seen from the other aspects are seen again. These and the main features of the region should be identified (Fig. 156).

The **medial pterygoid plate** is the most posterior bone in the side-wall of the nasal cavity; inferiorly a portion of it stands also in the side-wall of the nasal part of the pharynx (naso-pharynx), *i.e.*, the uppermost division of the interior of the pharynx; its medial surface is therefore clothed with mucous membrane. The posterior border is thin and sharp, and rather more than half-way up a sharp spur of bone sometimes juts backwards from it; above that spur, the border divides into two ridges which bound the **scaphoid fossa**, the medial margin of which is looked on as the upper part of the border. The end of the pharyngo-tympanic tube, as it opens on the side-wall of the naso-pharynx, is closely related to the medial margin of the scaphoid fossa and is supported inferiorly by the spur of bone. The lower or palatine end of the posterior border is continued into the hooklet or **hamulus**, the concavity of which is directed backwards and upwards towards the base of the skull; the *lower* surface of the root of the hamulus is crossed by a groove. The anterior part of the tensor palati muscle arises from the floor of the scaphoid fossa, descends along the lateral surface of the medial pterygoid plate, and the slender tendon of the muscle turns at a right angle in a medial direction and forwards, in the groove on the lower surface of the hamulus, and spreads out as it enters the soft palate. The posterior border of the medial plate, in its whole length, gives attachment to the pharyngo-basilar fascia; its lower half or third, together with the hamulus, gives origin to the upper part of the superior **constrictor of the pharynx**; **the tip of the hamulus** gives attachment to a fibrous band, the pterygo-mandibular ligament, which extends to the posterior end of the mylo-hyoid ridge of the mandible and gives origin to most of the remaining fibres of the superior constrictor.

The **lateral pterygoid plate** is wider than the medial plate, and its lower part is slightly bent in a lateral direction. Its posterior border is sharp and very uneven; its surfaces give origin to the pterygoid muscles. The lateral pterygoid muscle has two heads—an upper and a lower. The lower head arises from the lateral surface of the lateral pterygoid plate; the upper head arises from the infratemporal surface and infratemporal crest of the sphenoid. The two heads pass backwards, join together, and are inserted chiefly into the front of the neck of the mandible (the mandible should now be placed in position). The medial pterygoid muscle also has two heads—a superficial and a deep. The superficial head is very small and arises from the tuberosity of the maxilla and the strip of the tubercle of the palatine bone that appears between the maxilla and the lateral pterygoid plate. The deep head forms nearly the whole muscle; it arises from the medial surface of the lateral pterygoid plate and the surface of the tubercle that appears in the pterygoid fossa. The two heads join and pass downwards and backwards to be inserted into the medial surface of the mandible above and in front of the angle.

The **infratemporal surface** of the greater wing of the sphenoid is limited in front by the inferior orbital fissure, laterally by the infratemporal crest, while posteriorly it extends backwards and ends as the spine of the sphenoid at the medial side of the articular fossa of the temporal bone. The **spine of the sphenoid** is grooved on its medial side by the chorda tympani nerve, and it gives attachment to (1) the posterior part of the tensor palati muscle, (2) the spheno-mandibular ligament, which stretches to the margin of the mandibular foramen, and (3) the pterygo-spinous ligament—a weak fibrous band that stretches to the posterior border of the lateral pterygoid plate, but may, however, be transformed into a bar of bone.

The **foramen spinosum** is antero-medial to the spine of the sphenoid. It transmits the middle meningeal vessels and sympathetic plexus, a nerve-filament called the nervus spinosus, and lymph-vessels from the meninges.

The **foramen ovale** is antero-medial to the foramen spinosum. The only large structure that it transmits is the mandibular nerve, including the motor root of the trigeminal nerve; but there pass through it also the accessory meningeal artery, small veins which connect the cavernous venous sinus with the pterygoid venous plexus, lymph-vessels from the meninges, and, sometimes, the lesser superficial petrosal nerve. The foramina ovale and spinosum began as notches on the posterior edge of the greater wing, and were gradually enclosed in bone.

Very frequently there is a small aperture, called the **sphenoidal emissary foramen** (*Vesalii*), situated antero-medial to the foramen ovale and close to the scaphoid fossa. It opens directly into the middle cranial fossa and transmits a small emissary vein that connects the cavernous sinus with the pterygoid plexus. In the same neighbourhood there are one or more minute foramina that transmit either emissary or diploic veins. And occasionally there is a very small unnamed hole behind the foramen ovale for the transmission of the lesser superficial petrosal nerve.

Posterior Region of Lower Surface of Skull

There are only three bones in the posterior part of the base of the skull—the occipital bone, and the right and left temporal bones. The **occipital** bone occupies a large part of the region in the middle and posteriorly; the **temporal** bone is wedged in at the side between the occipital bone and the greater wing of the sphenoid.

The **occipital bone** is divided into four parts which surround the foramen magnum—the *basilar part* (*basi-occiput*) in front, a *condylar part* at each side, and a large, expanded *squamous part* behind. The four parts are separable at birth, but usually are fused together by the sixth year.

The **foramen magnum** is the large opening in which the medulla oblongata, or lowest division of the brain, becomes continuous with the spinal cord. It is on a level with the mastoid process at the side of the head, and is opposite a point on the back of the neck midway between the external occipital protuberance and the spine of the second cervical vertebra.

The **foramen magnum** is usually ovoid in outline with the narrower part in front, and its antero-posterior diameter varies from 30 to 40 mm. It *contains* the upper end of the spinal cord with its membranes and blood-vessels, the spinal roots of the accessory nerves, the vertebral arteries surrounded by plexuses of sympathetic nerves derived from the inferior cervical ganglia, lymph-vessels from the meninges of the brain; the lowest part of the cerebellum lies in it; and the membrana tectoria and upper band of the cruciate ligament pass upwards through it to be attached to the upper surface of the basi-occiput in front of the foramen magnum. The posterior atlanto-occipital membrane is attached to the posterior margin of the foramen magnum; the anterior atlanto-occipital membrane and the apical ligament of the odontoid process to the anterior margin; the alar ligament to the low tubercle on the medial surface of the occipital condyle on the side of the foramen magnum. The vertebral artery enters the foramen immediately behind the condyle, and sometimes grooves the margin of the foramen. The posterior margin of the foramen is in the same horizontal plane as the bony palate; and its middle point is called the **opisthion** [ὀπίσθιος (opisthios) = posterior]. The anterior margin is usually a little higher, for the foramen is slightly oblique in white races; the middle point of the margin is called the **basion**.

The **basilar part** of the occipital bone, or **basi-occiput**, is a wide bar of bone, thin at the margin of the foramen magnum, but thick at its anterior end, where it joins the body of the sphenoid. In youth it is united to the sphenoid by a plate of cartilage. It is fused with the sphenoid after the twenty-fifth year, but the position of their fusion may be indicated by an interrupted transverse depression. The **pharyngeal tubercle** is a small elevation which lies at the centre of the basi-occiput. It is about half an inch in front of the foramen magnum and on a line passing through the upper part of the neck of the mandible on each side. The surface of bone in front of the tubercle is clothed with the muco-periosteum of the roof of the pharynx.

The hole with jagged edges, seen alongside the anterior part of the basi-occiput, is the **foramen lacerum**; it leads directly up into the middle cranial fossa but is filled in the living state by cartilage and the structures which pierce it. Look for the pterygoid tubercle and the pterygoid canal on its anterior margin, as seen from below. The *pterygoid tubercle* is a small rounded elevation at the extreme upper end of the medial pterygoid plate. The posterior end of the **pterygoid canal is** on the anterior margin of the foramen—immediately above the tubercle and rather hidden by it—and is only large enough to admit a thick pin; in some skulls it is so hidden that it cannot be seen, but a hook or a bent pin enables one to find it. The canal runs forwards through the root of the pterygoid process, and its anterior end opens into the pterygo-palatine fossa. (See also pp. 183 and 186.)

The **pharyngeal tubercle**, in an articulated skeleton, lies directly above the tubercle on the anterior arch of the atlas. The pharyngeal tubercle gives insertion to the uppermost bundle of fibres of the superior constrictor of the pharynx and attachment to a median, fibrous longitudinal band, called the *pharyngeal raphe*, that lies in the posterior wall of the pharynx. The rectus capitis anterior is inserted into an impression on the basi-occiput in front of the occipital condyle, and the longus capitis into an impression lateral to the pharyngeal tubercle and in front of it; the back of the uppermost part of the pharynx is therefore recessed in between the right and left longus capitis muscles, and the prevertebral fascia is attached to a line which curves forwards from behind the pharyngeal tubercle to the front and lateral margins of the impression for the longus capitis.

The basi-occiput, the body of the sphenoid and the ethmoid form what is called the **basi-cranial axis**; a line drawn between the tips of the pterygoid tubercles marks the spheno-occipital junction. Posteriorly, the basicranial axis is wedge-shaped and solid; anteriorly it is thick but is hollow—owing to the sphenoidal and ethmoidal sinuses.

The **condylar parts** of the occipital bone lie at the sides of the anterior half of the foramen magnum, and are so named because they bear the occipital condyles.

The **occipital condyles** are the large, smooth, oblong protuberances that lie at the margins of the foramen magnum. They articulate with the lateral masses of the atlas vertebra, and through them the weight of the head is transmitted to

the vertebral column. The nodding movements of the head take place at the joints between the condyles and the atlas. The condyle and the joint are at the level of the mastoid process and are almost directly opposite it. The articular surface of each condyle is often notched at the sides, and in some skulls the notches meet and divide the articular surface into two parts.

The **condylar fossa** is the depression behind the condyle. In many skulls there is a canal that begins in the fossa and passes obliquely forwards and upwards into the cranial cavity; it is named the *posterior condylar canal*. The bony wall of the fossa is thin and may have an artificial perforation in it that can be mistaken for the canal, but the artificial opening leads directly up into the cranial cavity—not obliquely.

The **occipital condyles** lie alongside the anterior part of the foramen magnum. They are placed obliquely, their anterior ends being nearer each other than the posterior ends. The articular surface of each is convex from before backwards and slopes downwards from lateral to medial side. The articular capsule is attached to the margins of the articular surface, and the alar ligament is attached to the medial surface of the condyle.

The **condylar fossa** accommodates the upper part of the back of the lateral mass of the atlas when the head is bent backwards.

The **posterior condylar canal**, when present, passes above the posterior part of the condyle and opens, in the posterior cranial fossa, into (or near) the groove on the upper surface of the jugular process that lodges the lower end of the sigmoid venous sinus. The canal transmits a vein that connects the sinus with the suboccipital venous plexus.

The external opening of the **anterior condylar canal** is above the lateral margin of the anterior part of the condyle; it is usually largely hidden by the condyle, and the skull has therefore to be tilted before the opening is seen. The beginner should not mistake the jugular foramen for it because the foramen chances to catch his eye first. The jugular foramen is a large irregular opening nearly half an inch away from the condyle, and through it one can see into the cranial cavity. The anterior condylar canal is only wide enough to admit a match; it is medial to the jugular foramen and quite close to the condyle; internally, it opens into the cranial cavity a little above the margin of the foramen magnum (p. 187).

The **jugular process** is the part of the occipital bone—about half an inch square—that lies lateral to the posterior half of the condyle. Its anterior border is the posterior margin of the jugular foramen; this border is concave from side to side and the concavity is called the **jugular notch.**

The **anterior condylar canal** passes in a medial direction and backwards above the anterior part of the condyle. The important structure that passes through it is the hypoglossal nerve; but it transmits also a meningeal branch of the ascending pharyngeal artery, veins which connect the meningeal veins and the veins of the medulla oblongata with the pharyngeal venous plexus, and lymph-vessels from the meninges.

The **jugular process** is the homologue of the transverse process of a vertebra. It blends medially and posteriorly with the rest of the occipital bone; its anterior margin is free and bounds the **jugular notch**; its lateral margin is united to the petrous temporal by a plate of cartilage which may ossify after the twenty-fifth year; its lower surface is rough and gives insertion to the rectus capitis lateralis, and the prevertebral fascia is attached to the anterior margin in front of the rectus; its upper surface, in the floor of the posterior cranial fossa, has a broad shallow groove which lodges the lower part of the sigmoid venous sinus.

In some skulls a curved process, called the *intrajugular process*, projects from the floor of the jugular notch and partially or completely divides the jugular foramen. Occasionally a projection, called the *paramastoid process*, juts downwards from the lateral part of the jugular process, and it may be long enough to articulate with the transverse process of the atlas.

The **squamous part** is by far the largest division of the occipital bone It lies partly in the base and partly in the back of the skull. The *external occipital protuberance* and the *superior nuchal lines*, already examined (p. 160), are the boundary between the base and the back. The part in the base may be comparatively flat or may be full and rounded—the contour varying with the size and shape of the cerebellum, which lies on the upper surface of this part of the bone.

The **external occipital crest** is a median ridge that extends from the protuberance to the posterior margin of the foramen magnum; in some skulls it is very poorly marked.

The **inferior nuchal lines** are a pair of faint curved ridges, situated about

midway between the foramen magnum and the superior nuchal lines. Each begins about the middle of the external occipital crest and arches in a lateral direction and forwards and downwards towards the side of the occipital bone.

The upper end or border of the ligamentum nuchæ is attached to the **external occipital crest** and **external occipital protuberance**; the protuberance and the medial part of the **superior nuchal line** give attachment to the epicranial aponeurosis and origin to the uppermost fibres of the trapezius; the lateral part of the line gives origin to the occipital belly of the occipito-frontalis and insertion to part of the sterno-mastoid and of the splenius capitis. The semispinalis capitis is inserted into the medial half of the area between the **superior** and **inferior nuchal lines**; the obliquus capitis superior into the lateral half; the rectus capitis posterior minor into the medial part of the area below or in front of the inferior nuchal line; the rectus posterior major into the lateral part. Though the oblique muscle and the two recti are small, their insertions are wide and in many skulls are mapped out by ridges. Place the atlas and the skull together properly and note the position and the direction taken by the obliquus superior as it passes from the transverse process of the atlas to its insertion into the occipital bone.

All the divisions of the **temporal bone** appear in the lower surface of the skull:—the lower end of the *mastoid temporal*; the *tympanic plate*; the lower surface of the *petrous temporal* medial to the tympanic plate; the *styloid process* emerging from behind the lower part of the tympanic plate; and the portion of the *squamous temporal* that bears the articular eminence and articular fossa is in front of the tympanic plate.

The petrous part of the temporal bone is more easily identified in the interior of the skull (p. 179). In the base of the skull it can be seen extending medially from the region of the mastoid process and external auditory meatus to lie between the occipital bone behind and medially and the sphenoid bone in front. Its apex lies behind the root of the pterygoid process (see Fig. 156). Certain parts that belong to the temporal bone (or are placed close alongside it) are easily identified. (1) The **articular eminence** medial to the posterior part of the zygomatic arch and continuous with its anterior root; (2) the **articular fossa** behind the articular eminence; the head of the mandible is in relation with the fossa when the mouth is shut, and is pulled forwards and downwards into relation with the eminence as the mouth is opened; (3) the **spine of the sphenoid** medial to the eminence or medial to the fossa; (4) the **post-glenoid tubercle** in the posterior boundary of the fossa immediately in front of the opening of the external auditory meatus; (5) the **tympanic plate** behind and below the fossa; (6) the **mastoid process** behind and below the external auditory meatus; (7) the **mastoid notch** at the medial side of the root of the mastoid process; (8) the **foramen lacerum** alongside the anterior part of the basi-occiput, between it and the petrous temporal.

The floor of the **mastoid notch** gives origin to the posterior belly of the digastric muscle. Close to the medial side of the notch and parallel with it, the occipital artery runs backwards and in a lateral direction in contact with the mastoid temporal or with the suture between it and the occipital bone, and usually produces a groove on the bone. The entire absence of a groove indicates that the artery was lower than usual.

The **styloid process** lies deeply in the interval between the mastoid process and the mandible and intervenes between the parotid gland and the internal jugular vein. It projects downwards, forwards, and medially from the petrous temporal, behind the lower part of the tympanic plate, which partly ensheaths its basal portion. Two ligaments and three muscles are attached to it. The stylo-hyoid ligament stretches from its tip to the hyoid bone; the stylo-mandibular ligament (which is a thickened part of the fascia that covers the antero-medial surface of the parotid gland) extends from the front of it to the posterior border of the mandible. The stylo-glossus arises from the front of it near the tip; the stylo-hyoid from the postero-lateral surface of the middle third; the stylo-pharyngeus from the medial side near the root. The styloid process is ossified in cartilage from two centres—an upper and a lower. The lower part of the process does not fuse with the upper till after puberty and may remain a separate bone throughout life.

The following parts are now to be looked for:—

The **stylo-mastoid foramen** is the aperture immediately behind the root of the styloid process, between it and the mastoid process, in front of the mastoid notch. It is the lower end of a canal, in the substance of the temporal bone, through which the facial nerve travels on its way from the brain to the exterior of the skull; besides the facial nerve, it transmits the stylo-mastoid branches of the posterior auricular vessels, which pass upwards through it into the temporal bone.

The **jugular foramen** is a large opening with uneven margins situated a little to the medial side of the root of the styloid process, and it leads into the posterior cranial fossa. It is bounded anteriorly by the petrous temporal and posteriorly by the jugular process of the occipital bone.

The largest structure in the jugular foramen is the internal jugular vein, which begins in it as a continuation of the sigmoid venous sinus. The vein is dilated at its commencement and the dilatation is called the *superior bulb* of the internal jugular vein. To accommodate the bulb there is a concavity, called the **jugular fossa**, on the petrous temporal where it forms the antero-lateral wall of the jugular foramen.

The jugular foramen is opposite the external auditory meatus and is almost at the level of its lower margin. A part of the bone that bounds the jugular fossa forms also the floor of the tympanic cavity or middle ear. That relationship can be verified if one looks at the medial wall of the tympanic cavity through the external meatus and gauges the position of the floor of the cavity. In middle-ear disease, infection may damage the bone and attack the internal jugular vein.

The **jugular foramen** leads upwards and backwards into the cranial cavity, and the structures it transmits will be enumerated more intelligibly when it is examined from inside the skull (p. 189). Sometimes spicules of bone project across the foramen from its margins, and they may divide it into compartments.

The right internal jugular vein is usually larger than the left, and the right jugular foramen and fossa are therefore larger than the left. When the fossa is large there may be very little bony substance between it and the tympanic cavity and antrum, which lie above it.

On the lateral wall of the foramen, in the floor of the jugular fossa, there is a small 'pin-point' aperture: it is the medial end of a narrow, horizontal canal, called the **mastoid canaliculus**, which passes through the temporal bone and opens laterally in the tympano-mastoid fissure. The canal is traversed by a slender nerve-filament called the auricular branch of the vagus. The canal is not present at birth, but is formed as the growing tympanic plate and mastoid temporal enclose the nerve—which is outside the skull in an infant.

The **carotid canal** is a tunnel in the petrous temporal through which the internal carotid artery travels to reach the cranial cavity. The lower end of the canal is immediately in front of the jugular foramen and fossa in the lower surface of the petrous temporal; it is a circular or an oval opening, wide enough to admit a thin pencil. From this opening the canal leads upwards for a short distance; it then bends to become horizontal and runs in a medial direction and forwards to open into the side of the foramen lacerum. Since the lower end of the canal is anterior to the jugular foramen, the internal carotid artery, as it enters the bone, is in front of the internal jugular vein.

The lower end of the canal is opposite the anterior margin of the orifice of the external auditory meatus, and the ascending part of the canal lies below and in front of the middle ear and the internal ear; the thudding sound that one hears in the head during moments of excitement or after a spurt of violent exertion is due to the beating of the carotid artery against the bone which separates it from the internal ear.

The anterior margin of the jugular foramen and fossa is separated from the lower opening of the carotid canal by a ridge of bone on which there may be more than one small hole for small vessels that enter the bone. But one of these foramina is the lower end of the **tympanic canaliculus**, through which a small nerve, called the tympanic branch of the glosso-pharyngeal nerve, passes up to enter the tympanic cavity and form the tympanic plexus on its medial wall.

The **carotid canal** transmits the internal carotid artery, the internal carotid plexus of sympathetic nerves derived from the superior cervical ganglion, small veins that connect the cavernous venous sinus with the pharyngeal venous plexus, and lymph-vessels from the meninges. On the postero-lateral wall of the canal, immediately above its lower aperture, there are the openings of two very narrow tunnels; they are the **carotico-tympanic canaliculi**, which transmit the tympanic branches of the carotid artery and of the carotid sympathetic plexus.

The **quadrate area** of the petrous temporal is the rough, nearly four-square area medial to and in front of the lower opening of the carotid canal, between that opening and the foramen lacerum. The *antero-lateral border* of the area lies against the posterior border of the greater wing of the sphenoid, *i.e.*, the border immediately behind the foramen ovale and foramen spinosum; the two borders may touch each other or there may be a narrow fissure between them.

The *cartilaginous part* of the *pharyngo-tympanic tube* lies along the fissure, or the line of contact, in a shallow groove shared by both the bones. The postero-lateral end of the groove is at the medial side of the spine of the sphenoid, and it is continuous there with two canals in the interior of the temporal bone. These canals are one above the other and are separated by a thin, bony septum. The lower and wider is the **canal of the pharyngo-tympanic tube**—*i.e.*, the osseous part of the tube—and it passes obliquely into the middle ear or tympanic cavity. If a pin or a hook is run along the groove to its postero-lateral end and pushed onwards, it will pass, usually without difficulty, into the canal; and, if one looks through the external auditory meatus, the point will be seen in the tympanic cavity. The upper canal is the **canal for the tensor tympani.** That tiny muscle springs chiefly from the cartilage of the tube, runs in the canal above the bony part of the tube, enters the tympanic cavity and is inserted into one of the auditory ossicles, namely, the *malleus*.

Squamo-tympanic fissure is the name given to the narrow slit between the articular fossa of the squamous temporal and the upper edge of the tympanic plate. The lateral end of the slit is directly in front of the opening of the external auditory meatus; the medial end is directly behind the spine of the sphenoid. See also pp. 221, 223.

The **foramen lacerum** can be seen between the petrous temporal and the basi-occiput, and the posterior end of the **pterygoid canal** is situated on the anterior margin of the foramen above and lateral to the **pterygoid tubercle**; they will be dealt with more fully when the floor of the cranial cavity is examined (p. 185).

The **quadrate area** gives origin to the levator palati muscle. Cartilage, or dense fibrous tissue, unites the *postero-medial border* of the area to the basi-occiput, and its *antero-medial border* to the posterior border of the greater wing of the sphenoid; the cartilaginous part of the pharyngo-tympanic tube lies along its line of union with the greater wing. The levator palati at its origin is therefore postero-medial to the tube. The tensor palati is a thin muscle with a triangular outline; the apex of the triangle is the tendon as it turns round the lower surface of the pterygoid hamulus, and the base is the origin of the muscle from the skull. It arises from the spine of the sphenoid and from the floor of the scaphoid fossa, and, between those points, from the cartilage of the tube; the upper part of the muscle therefore lies on the antero-lateral side of the tube and separates it from the mandibular nerve descending from the foramen ovale and the middle meningeal artery ascending to the foramen spinosum.

The **bony part of the pharyngo-tympanic tube** is about 10 mm. long. It is in the temporal bone, between the tympanic plate and the petrous temporal; and a thin bony septum separates it from the canal for the tensor tympani, which is above it. One end opens into the anterior part of the tympanic cavity; from there the tube passes medially, forwards and slightly downwards, and opens on the lateral end of the groove for the cartilaginous part, at the medial side of the spine of the sphenoid, where the opening is easily found. Push a pin through the opening and along the tube to the tympanic cavity, and note that the tube has the ascending part of the carotid canal on its postero-medial side, and the mandibular joint on the antero-lateral side.

The **tympanic plate** has three surfaces. The medial part of the **posterior surface** is fused with the petrous temporal and helps to form the anterior wall of the first part of the carotid canal; the lateral part is fused with the mastoid temporal and the post-auditory process of the squamous temporal, but is partly separated from the mastoid by the tympano-mastoid fissure. The **upper surface** is curved, for it belongs to the curled, lateral part of the plate; it forms the lower wall of the **external auditory meatus**, nearly the whole of its anterior wall, and the greater part of its posterior wall; the rough, curved *lateral margin* of the plate gives attachment to the cartilage of the auricle. The **anterior surface** is free and concave and is related to the upper part of the parotid gland, which separates it from the back of the head and neck of the mandible. Its *lower border* is uneven and sharp, and gives attachment to the fascia that covers the postero-medial surface of the parotid gland; its *upper border* forms the floor of the pharyngo-tympanic tube and the posterior boundary of the squamo-tympanic fissure, and it gives attachment to the fascia that covers the antero-medial surface of the parotid gland.

The *lateral part* of the **squamo-tympanic fissure** may be obliterated by fusion of the tympanic plate with the back of the post-glenoid tubercle. The *middle part* leads up into the tympanic cavity; the anterior process of the malleus is stuck into it; and the tympanic branch of the middle meningeal artery passes upwards through it. In many skulls a thin strip of bone is seen between the lips of the medial part of the fissure; that strip is the lower edge of the tegmen tympani (a part of the surface of the petrous temporal seen in the middle cranial fossa, p. 184); to reach the fissure the tegmen is continued downwards as the antero-lateral wall of the bony part of the pharyngo-tympanic tube, and it divides the fissure into two slits—a **petro-squamous fissure**, in front of the edge of the tegmen, and a **petro-tympanic fissure**, which is more important; it is between the edge of the tegmen and the tympanic plate and is below the tube. The chorda tympani nerve, having traversed the tympanic cavity from behind forwards, enters a small hole in the anterior wall of the cavity, runs obliquely downwards and forwards in the

antero-lateral wall of the pharyngo-tympanic tube, and issues from the skull through the petro-tympanic fissure; it then runs in a medial direction and forwards and downwards, grooving the medial side of the spine of the sphenoid; and it ends by joining the lingual nerve nearly an inch below the foramen ovale.

The **articular fossa** and the **articular eminence** are for articulation with the head of the mandible, and their margins give attachment to the articular capsule, the thickened lateral part of which, called the temporo-mandibular ligament, is attached to the **tubercle of the root of the zygoma**; but the fossa and the eminence are separated from actual contact with the head of the mandible by an articular disc of fibro-cartilage which is attached by its circumference to the capsule and divides the cavity of the joint into an upper and a lower part. The bone of the deepest part of the fossa is so thin that it is translucent.

CRANIAL CAVITY

The **cranial cavity** is the large cavity that lodges the brain. The bones which share in its formation are the frontal, the ethmoid, the sphenoid, the occipital, the two parietal, and the two temporal bones. The cavity is lined with the outermost of the three membranes or meninges of the brain, namely, the **dura mater**; the dura mater consists of two closely adherent fibrous layers, the *outer* of which clothes the bone, serving the purpose of periosteum, and is called the *endocranium.* The periosteum on the outside of the skull is called the *pericranium.* The pericranium and the endocranium are both continuous with the fibrous ribbons, called *sutural ligaments*, that lie between the articulating edges of the bones; and they are continuous also with each other round the lips of the various foramina and fissures that lead from the cranial cavity to the exterior.

Section of Skull.—The cranial cavity can be exposed for examination either by a median section which splits the skull into a right and a left half, or by a horizontal section which removes the skull-cap. The second method is the more common; the saw-cut is usually made to pass through the *frontal* bone immediately above the superciliary arches, through the two inferior angles of the *parietal* bone and the upper part of the *squamous temporal* on each side, and through the *occipital* bone immediately above the external occipital protuberance. The two parts are then examined separately: the skull-cap shows the roof of the cranial cavity; the lower part of the skull shows its floor; the front, the sides, and the back are included partly with the roof and partly with the floor.

The advantage of the median section is that it not only exposes the cranial cavity but also lays open the nasal cavity and the sphenoidal sinus. If the skull which the student has procured for himself has had the skull-cap removed, the lower part of the skull should be divided into a right and a left half. If he has an uncut specimen of skull he should remove the skull-cap by the saw-cuts indicated above, and then split the lower part of the skull into halves.

In making the sagittal section he should use a very fine saw and should make the cut a little to one or other side of the median plane in order to avoid injury to the septum of the nose, but, at the same time, he must be careful not to injure the conchæ, which project from the side-wall of the nasal cavity. The first cut should be made through the bony palate and the alveolar process of the maxilla; if they are not cut first they will break when the thicker parts of the skull are divided. The two halves can be tied together or hinged together with improvised pins and hooks when the student wants to examine both halves at once.

Thickness of Skull.—In cutting the skull the student will note that the inner table is thinner than the outer table, and that the whole thickness of the walls of the cranial cavity varies in different areas. The thicker and thinner areas are not all constant in position in different skulls, but the areas well covered with muscles are thinner than those that are more exposed, *e.g.*, the floor of the temporal fossa and the floor of the posterior cranial fossa on each side of the median plane.

The bone of the skull as a whole is thicker in some races than in others (the more primitive races usually having the advantage of thicker skull-bones); but in all races the skull-bones are thinner in women and children than in men. The skull of a child is very thin, but is more yielding and elastic than that of an adult and is less liable to fracture. There are, however, great differences in thickness in the skulls of adults of the same race and sex and in different parts of the same skull. Measurements of 448 male white American crania by Wingate Todd (1924) yielded thicknesses of between 5 mm. and 7 mm. at the posterior border of the foramen magnum and at the vertex. At the position of greatest breadth the thickness was between slightly under 3 mm. and 6 mm. Variations occur ranging from less than one-eighth of an inch to almost half an inch. There is no known relation between the thickness of the skull-bones and the quality of the intelligence, but a thick skull obviously protects the brain more efficiently from injury by violence. It is not possible to gauge the thickness of the skull

with any certainty during life, except during the course of an operation; and in the early steps of an operation on the skull it is safer to assume that the skull is thin.

Roof of Cranial Cavity

The **skull-cap** is the **roof** of the cranial cavity or **vault** of the skull. If the horizontal saw-cut has been made as indicated, the skull-cap includes part of the *frontal* bone in front, part of the *occipital* bone behind, nearly the whole of both *parietal* bones in the middle, and a very small part of the *squamous* portion of the *temporal* bone on each side at the lower border of the parietal bone.

The internal or **cerebral surface** of the vault is highly concave in every direction. The dura mater is only loosely attached to the skull-vault, except at the sutures, where, in a young adult skull, it is continuous with the sutural ligaments.

The **sutures** between the bones may be indistinct, for if their obliteration has begun it will be more advanced on the inner surface than on the outer; and if the skull is that of an old person the sutures may have disappeared. The sutures are:—The **sagittal suture**, uniting the two parietal bones; the **coronal suture**, uniting them to the frontal bone; the **lambdoid suture**, uniting them to the occipital bone; and the **squamous suture**, on each side, uniting the parietal bone to the squamous temporal. The squamous suture is at a lower level on the inside of the skull than on the outside, because the squamous temporal overlaps the parietal bone on the outside.

The following additional parts are to be noted in the vault:—

The **frontal crest** (Fig. 157) is a median ridge on the anterior wall of the cranial cavity—on the lower part of the cerebral surface of the frontal bone—and it may extend far enough up to be seen on the skull-cap.

The **sagittal groove** is a shallow, median furrow on the cerebral surface of the vault, extending from above the root of the nose to the occipital protuberance. It begins on the frontal crest, passes upwards and backwards on the frontal bone, backwards along the sagittal suture, and downwards on to the occipital bone, widening progressively during its course. The superior sagittal venous sinus lies along it in the upper border of the falx cerebri, which is attached to its lips. (The falx cerebri is a fold of the inner layer of the dura mater projected downwards from the cranial vault as a tense, median partition to keep the two halves of the cerebrum apart.)

The **granular pits** are small irregular depressions that are placed here and there alongside the sagittal groove. They are more numerous and larger in the skull of an old person than in a young skull, and the bone in their floors may be thin enough to be translucent. They lodge arachnoid granulations, which are small bud-like growths that protrude from the arachnoid mater. (The arachnoid mater is the middle and the thinnest of the three membranes that enclose the brain) [ἀράχνιον (arachnion) = a spider's web].

The **parietal foramen** when present, is in the parietal bone, close to the sagittal groove, about an inch or an inch and a half above the lambdoid suture.

The **vascular grooves** (Fig. 164) are narrow and branching for meningeal vessels. They extend from the cut edges of the vault towards the top; the largest of them are on the parietal bone and are for the branches and tributaries of the middle meningeal vessels; their direction is upwards and backwards (Fig. 181). Small vascular foramina are numerous, especially in and near the grooves. The **impressions for cerebral gyri** are the shallow, ill-defined depressions found all over the vault. They correspond to the gyri or convolutions on the surface of the brain.

Floor of Cranial Cavity

The **upper surface of the base of the skull** is the floor of the cranial cavity. Grooves for meningeal vessels are seen on it; and the impressions for gyri are better marked than on the vault. The dura mater is more firmly attached to the bone of the floor than to that of the vault.

The floor is divided into three main districts, one behind the other and at different levels, corresponding to the anterior, middle and posterior **cranial fossæ**, of which the anterior is at the highest level and the posterior at the lowest.

The bones seen in the floor of the cavity include the sphenoid bone and the petrous part of the temporal bone which are best seen from this aspect. Identify the temporal bone (blue in Fig. 157) and its petrous part, so named from its hardness [πέτρος (petros) = a stone]; it is the conspicuous pyramidal elevation lying obliquely about midway between the front and back of the cavity on each side and contains the middle and internal parts of the ear. The sphenoid bone is uncoloured in Fig. 157 and is wedged among the other bones of the skull [σφήν (sphen) = a wedge]. Its body is the middle portion; the lesser wings extend to the side in front, and the greater wings spread out from the sides of the body at a lower level to help in the formation of the floor and side-wall of the middle fossa.

Anterior Cranial Fossa

The **anterior cranial fossa** contains the lower part of the frontal lobes of the brain. It is bounded in front and at the sides by the frontal bone. Its floor is divided into:—(1) a median part, which is above the nasal cavity and is formed by the ethmoid bone and the body of the sphenoid; and (2) a right and a left lateral part, each of which is above the orbit and is made up of the orbital plate of the frontal bone and the lesser wing of the sphenoid (Figs. 157, 163).

In the **median division** the chief parts to be looked for are:—

The **crista galli** is the upstanding, median process seen in front.

The **foramen cæcum** is the small pit in front of the crista galli [*cæcum* = blind]. The foramen, however, is not always blind: at its bottom there may be a small aperture which transmits a vein.

The **frontal crest** is the median ridge seen above the foramen cæcum in the anterior boundary of the fossa; it extends upwards on to the vault and fades away there.

The **cribriform plates** of the ethmoid are a pair of narrow, horizontal plates of bone placed along the sides of the root of the crista galli; they are named "cribriform" because they are full of little holes [*cribrum* = a sieve]; they separate the cranial cavity from the nasal cavities (Figs. 164, 165).

Behind the cribriform plates there is a broad, fairly flat area of bone which is the anterior part of the upper surface of the body of the sphenoid. It is named the **jugum sphenoidale** [from a resemblance to *jugum* = yoke] and is limited behind by the **limbus sphenoidalis**. The limbus is the anterior lip [*limbus* = edge] of a shallow transverse furrow, called the *optic groove*, that leads laterally on each side into the *optic foramen*. The optic groove and foramen are, however, included in the middle cranial fossa (p. 181).

By far the greater part of the **lateral division** is formed by the orbital plate of the frontal bone; only a small part posteriorly is formed by the lesser wing. The **orbital plate** separates the cranial cavity not only from the orbit but also from the ethmoidal air-sinuses; for the medial part of the plate overlies the labyrinth of the ethmoid—roofing in the sinuses (Fig. 179). The *frontal sinus* extends backwards for a variable distance between the two tables of bone of which the plate is composed; and the upper table therefore separates the cranial cavity from part of the frontal sinus.

In the skull of an old person the suture between the orbital plate and the **lesser wing** may be obliterated, but if it is visible the outline of the wing can be made out—fairly broad at its medial end and tapering to a point at the lateral end. The posterior border of the lesser wing is the free, sharp margin of the floor of the lateral part of the fossa, and it ends *medially* in a prominent process, called the **anterior clinoid process**, that juts backwards behind the optic foramen.

Each lateral part of the floor of the anterior cranial fossa is convex, rather uneven, and slopes downwards towards the median portion, more so anteriorly than posteriorly, where both parts are smoother and more nearly horizontal. Together with the corresponding half of the median

portion it supports the frontal lobe of the brain; the ridges and **impressions for gyri** on the lateral part correspond to the sulci and gyri on the orbital surface of the brain, and therefore vary in the pattern they make; they are much better marked in some skulls than others.

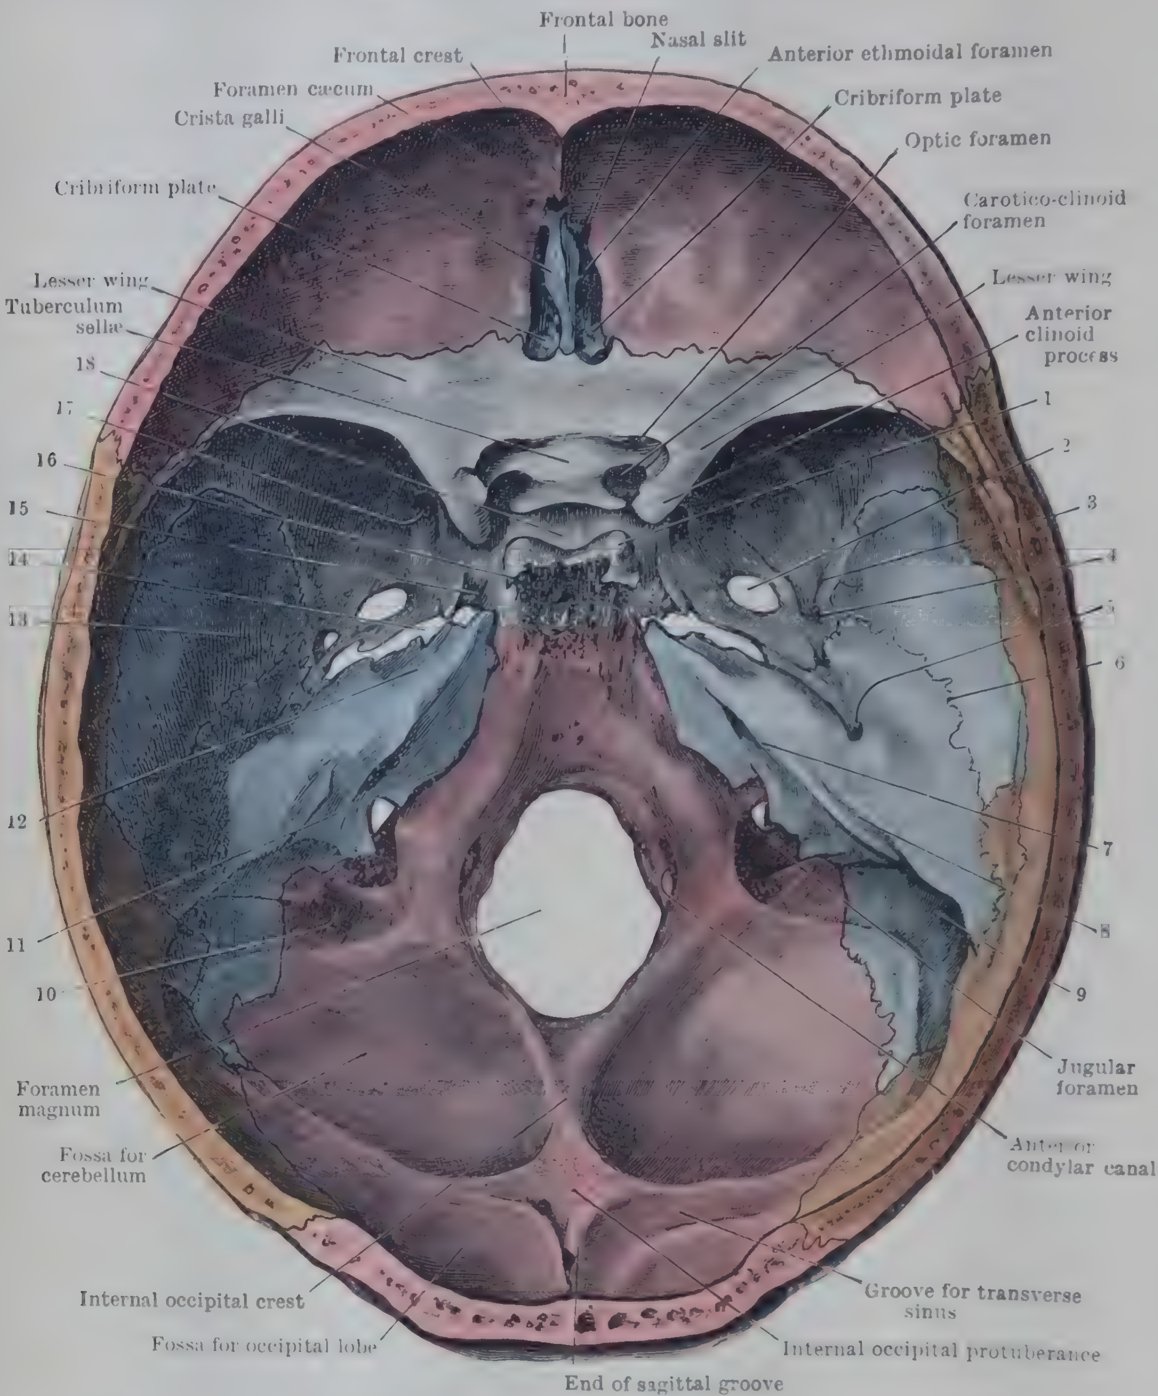

FIG. 157.—FLOOR OF CRANIAL CAVITY.

Red: frontal; occipital. **Blue**: ethmoid; temporal. **Orange**: parietal. **Uncoloured**: sphenoid.

1. Posterior clinoid process.
2. Foramen ovale.
3. Groove for middle meningeal vessels.
4. Foramen spinosum.
5. Hiatus for greater superficial petrosal nerve.
6. Occasional suture between petrous and squamous temporal.
7. Internal auditory meatus.
8. Groove for superior petrosal sinus.
9. Groove for sigmoid sinus.
10. Groove for sigmoid sinus.
11. Groove for the inferior petrosal sinus.
12. Impression for trigeminal ganglion.
13. Squamous temporal.
14. Spheno-petrous fissure.
15. Carotid groove, in front of foramen lacerum.
16. Dorsum sellæ of sphenoid.
17. Leads into foramen rotundum.
18. Hypophysial fossa.

The antero-lateral margin of the orbital surface of the frontal lobe, *i.e.*, the superciliary margin of the brain, fits into the angle between the floor and the antero-lateral wall of the fossa, which corresponds, on the exterior, to a line drawn from the root of the nose upwards and then laterally along the superciliary arch and onwards to the root of the zygomatic process of the frontal bone, and then backwards to the pterion. The gyrus rectus, which is the most medial gyrus of the orbital surface, lies on the cribriform plate and on the jugum sphenoidale behind

that; the olfactory tract and bulb, placed obliquely on the lateral part of the gyrus rectus, lie on the jugum and on the cribriform plate at the edge of the orbital plate. The **cribriform plate** is at a lower level than the rest of the floor, and the holes in it are arranged in two irregular rows; the nerve-filaments—twenty or so—which constitute the olfactory nerve come up from the nose through these foramina and end in the olfactory bulb.

In the lateral part of the fossa, especially in front and at the side, there are narrow, branching *grooves for the anterior meningeal vessels* derived from the middle meningeal and ethmoidal vessels.

The **crista galli** is the upper anterior part of the perpendicular plate of the ethmoid projected upwards into the cranial cavity. It is highest and thickest in front, where it may contain either spongy bone or an air-cavity which opens directly into the nose or into the frontal sinus. From its anterior part two processes or *alæ* project forwards to articulate with the frontal bone and form the side-boundaries of the **foramen cæcum**, which is between the frontal bone and the crista galli.

The anterior end and anterior part of the convex border of the falx cerebri are attached to the sharp, sloping border of the crista galli and to the frontal crest. The anterior part of the superior sagittal sinus lies on the frontal crest in the convex border of the falx, and its commencement may be connected with the veins of the nose by a vein transmitted by the foramen cæcum.

The **nasal slit** is a short and narrow cleft—often difficult to find—situated between the anterior parts of the crista galli and cribriform plate; it leads down into the nasal cavity (Fig. 193).

The **anterior** and **posterior ethmoidal canals** are narrow tunnels that begin at foramina of the same name between the roof and medial wall of the orbit (where they have been seen already). From these foramina they run in a medial direction, between the labyrinth of the ethmoid and the medial part of the orbital plate of the frontal bone, to open into the cranial cavity; their openings are often hidden by overhanging lips of bone. The *posterior* canal transmits the posterior ethmoidal vessels and opens at the junction of the cribriform plate with the front of the sphenoid. The posterior ethmoidal nerve, also contained in the canal, does not reach its cranial end, being distributed to the mucous lining of the ethmoidal and sphenoidal sinuses. The *anterior* canal is larger and opens at the side of the cribriform plate about the middle. It transmits the anterior ethmoidal vessels and the anterior ethmoidal nerve, which is a continuation of the naso-ciliary nerve. The nerve runs forwards on the cribriform plate and descends to the nose through the **nasal slit** or through a foramen a little lateral to the slit, and it is accompanied by small branches of the vessels.

The **lesser wing of the sphenoid** is triangular in outline and compressed from above downwards. It lies in the roof of the orbit and superior orbital fissure and in the floor of the anterior cranial fossa; posteriorly, it overhangs the middle cranial fossa. It arises by two roots separated by the optic foramen: the *anterior root*—broad and flat—is continuous with the jugum sphenoidale; the *posterior root*—much smaller—springs from the side of the body of the sphenoid and stands between the optic foramen and superior orbital fissure. The spheno-parietal venous sinus lies in the dura mater on the lower surface of the posterior margin of the wing. The **anterior clinoid process** is a flattened projection with a rounded free end; it juts backwards from the postero-medial angle of the wing and gives attachment to the anterior end of the free margin of the tentorium cerebelli.

Middle Cranial Fossa

The **middle cranial fossa** is divided into a median part and a right and a left lateral part, and its floor resembles a bird with outspread wings.

Median Part of Middle Cranial Fossa

The median part is elevated above the level of the lateral parts. It is bounded *anteriorly* by the sphenoidal limbus, and *posteriorly* by an upstanding plate of bone called the dorsum sellæ. Its floor is the body of the sphenoid and is separated therefore from the cavity of the nose by the sphenoidal sinus enclosed within the bony shell of the body of the sphenoid (Fig. 164). The parts to be looked for are the optic groove and foramina, the sella turcica, and the carotid grooves.

The **optic groove** is in the most anterior part of the floor, immediately behind the anterior cranial fossa; it may be well-defined or very shallow. On each side the optic groove ends at the **optic foramen**, which opens into the medial side of the back of the orbit, where it has been seen already (pp. 158 and 160).

Sella turcica is the name given to the middle part of the upper surface of the body of the sphenoid, from a resemblance to a Turkish saddle. The pommel is the transverse, oval elevation, called the **tuberculum sellæ**, situated directly behind the optic groove. The seat is the wide, smooth depression behind the tuberculum; it is called the **hypophysial fossa** because the hypophysis cerebri (p. 822) lies in it.

Behind the hypophysial fossa there is an upstanding square plate of bone (broken off in many skulls) called the **dorsum sellæ** or back of the saddle. The upper corners of the dorsum sellæ form the **posterior clinoid processes.** The anterior and posterior clinoid processes get their name from a fancied resemblance to the four posts of a bed [κλίνη (cline) = a bed].

The **carotid groove** is a broad, shallow, ʃ-shaped groove on the upper part of the side of the body of the sphenoid. It begins at the medial side of the foramen lacerum, ascends for a short distance, then runs forwards on the side of the sphenoid body, and finally turns upwards to end medial to the anterior clinoid process. The internal carotid artery lies in it, and its sinuous bends indicate the course of the artery in the cranial cavity.

In many skulls there is a pair of **middle clinoid processes.** Each middle clinoid process, when present, is usually a small tubercle situated a little behind the lateral end of the tuberculum sellæ. In some skulls it is a large process and joins the anterior clinoid process, converting the termination of the carotid groove into a foramen called the **carotico-clinoid foramen** (Fig. 157). Occasionally it joins the posterior clinoid process instead, or it may branch and join both the anterior and the posterior clinoid process.

The **optic foramen** is a short, wide, nearly circular canal that passes in a lateral direction, forwards and slightly downwards from the cranial cavity into the orbit, and transmits the optic nerve and the ophthalmic artery. It is bounded by the body of the sphenoid and the two roots of the lesser wing—the thin bone of the body separating it from the sphenoidal sinus. The **optic groove** connects the two optic foramina. The optic chiasma, which connects the two optic nerves, does not, however, lie in the groove, but is situated a little distance above it.

The **hypophysial fossa** lodges the hypophysis and is roofed over by a fold of dura mater, called the diaphragma sellæ, which has a hole in the middle of it for the stalk that connects the hypophysis with the brain. The **posterior clinoid processes** give attachment to the anterior ends of the circumferential margin of the tentorium cerebelli. Low down on the side of the dorsum sellæ, where its root joins the body of the sphenoid, there is a narrow groove that accommodates the medial margin of the beginning of the inferior petrosal sinus; the groove is only the width of a thick pin, but can usually be seen even when the dorsum sellæ is broken off.

The cavernous venous sinus lies at the side of the body of the sphenoid on the horizontal part of the **carotid groove**; its centre is opposite a point on the upper border of the zygomatic arch directly above the tubercle of the root of the zygoma. The carotid artery, lying in the carotid groove, is embedded in the sinus, together with the carotid plexus, the oculomotor, trochlear, ophthalmic, and abducent nerves. The maxillary nerve runs forwards towards the foramen rotundum immediately below the carotid groove and cavernous sinus. These structures are therefore all related to the body of the sphenoid—the cavernous sinus, the carotid artery, and the maxillary nerve being closely related to it and to the sphenoidal sinus within it. The two cavernous sinuses are connected by intercavernous sinuses that cross the back of the **tuberculum sellæ**, the front of the **dorsum sellæ**, and the floor of the **hypophysial fossa.** The notch between the tuberculum sellæ and the anterior clinoid process is occupied by the carotid artery as it leaves the carotid groove.

Lateral Part of Middle Cranial Fossa

Each lateral division of the middle cranial fossa is a wide, deep hollow limited *anteriorly* by the lesser wing of the sphenoid, and *posteriorly* by the upper border of the petrous temporal; it sinks to the level of the zygomatic arch and lower surface of the body of the sphenoid; and it contains the temporal lobe of the brain. The principal parts on the exterior of the skull to which it is related are the orbit *in front,* the temporal fossa *laterally,* and the infratemporal fossa and the mandibular joint *below.*

The bones in its walls are :—(1) The petrous part of the temporal bone, *i.e.,* the pyramidal mass of bone that forms its posterior wall; (2) the squamous temporal, in front of the petrous, in the side-wall of the fossa and slightly in the floor; (3) the greater wing of the sphenoid, partly in the side-wall in front of the squamous temporal and partly in the anterior wall and in the floor in front of the petrous temporal. Beyond the limits of the fossa the lower part of the parietal bone lies in the side-wall of the cranial cavity above the squamous temporal, and its antero-inferior angle articulates with the top of the greater wing.

The *anterior lip* of the hollow is the posterior margin of the anterior fossa; it overhangs the hollow, and ends laterally, on the side-wall, **opposite the pterion.** The *posterior lip* is the upper margin of the petrous temporal; it is channelled

lengthwise by a groove—sometimes well defined, but sometimes poorly marked and interrupted—which lodges the superior petrosal venous sinus; close to its medial end there is a wide, very shallow notch, called the *trigeminal notch*, on which the trigeminal or fifth cranial nerve lies.

The noteworthy feature in the *anterior boundary* of the fossa is the large, oblique gap between the wings of the sphenoid, called the **superior orbital fissure**, which opens into the orbit, where it has been examined already (pp. 147, 149).

The points to be noted in the *floor* are the foramen rotundum, foramen ovale, foramen lacerum, foramen spinosum, and the grooves for the meningeal vessels.

The **foramen rotundum** is the round hole situated almost directly below the medial end of the superior orbital fissure; it leads horizontally forwards into the upper part of the pterygo-palatine fossa and transmits the maxillary nerve; if a pin is pushed forwards through the foramen, and the skull is looked at from the side, the point of the pin will be seen entering the pterygo-palatine fossa. The foramen is situated in the root of the greater wing close to the body of the sphenoid, and it is separated only by thin bone from the sphenoidal sinus.

The **foramen ovale** is almost half an inch behind the foramen rotundum, near the posterior border of the greater wing, and it transmits the mandibular nerve; it has been seen already in the roof of the infratemporal fossa (pp. 170, 171).

The **foramen spinosum**—behind and lateral to the foramen ovale and quite close to it—also has been seen from the infratemporal fossa; it transmits the middle meningeal vessels.

The **grooves for the middle meningeal vessels** are usually sufficiently distinct to enable one to trace the course of the main trunk of the artery and its branches on the walls of the cranial cavity; their whole course is seen in a skull split into halves without previous removal of the skull-cap (Fig. 164). The **main groove** begins at the foramen spinosum, runs forwards and in a lateral direction on the part of the squamous temporal that bears the articular eminence of the lower surface of the skull. It divides into an anterior and a posterior branch at a point that varies but is usually near the side of the skull opposite a point on the upper margin of the zygomatic arch about midway between the auditory meatus and the margin of the orbit. The **anterior groove** extends from that point to the anterior inferior angle of the parietal bone *opposite the pterion*; in that region the groove is usually very deep and often roofed over and converted into a tunnel for a short distance; becoming a groove again, it extends upwards and backwards, branching over the parietal bone, the chief branch of the groove taking a line towards the point on the top of the skull midway between nasion and inion. The **posterior groove** extends backwards and upwards across the squamous temporal on to the parietal bone, branching as it goes—the chief branch taking a line towards the lambda. The meningeal vessels, since they are so closely related to the bone, are liable to be torn when the skull is injured during life—especially the veins, for they lie between the arteries and the bone. The chief point of danger is at the pterion, where the anterior branch is lodged in a deep groove and may lie in a tunnel. The grooves are in the inner table of the skull-bones, and in an injury to the head the inner table may be cracked and the vessels torn, though the outer table is not broken.

The **foramen lacerum** is a large hole, with ragged margins, already seen on the lower surface of the skull. Seen in the floor of the cranial cavity, it is situated between the petrous temporal and the sphenoid. The carotid canal opens into it laterally, and the carotid artery crosses it to reach the carotid groove on the sphenoid. A spur of bone, called the **lingula**, projects obliquely backwards from the lateral margin of the carotid groove. In some skulls the lingula is a mere spicule of bone; in others it is long enough to reach the petrous temporal and form a complete lateral boundary for the foramen lacerum. In many skulls the roof of the carotid canal is deficient in bone, or has been partly broken away; in that case the jagged margins of the incomplete roof of the canal are continuous with the margins of the foramen lacerum. The posterior end of the **pterygoid canal** is on the anterior margin of the foramen lacerum almost directly below the lingula, but it is found more easily from the lower surface of the skull.

The *posterior wall* of the lateral part of the middle cranial fossa is the anterior face of the petrous temporal, and it is nearly triangular in outline. The parts to be specially looked for in it are the trigeminal impression, the arcuate eminence, the tegmen tympani, and the hiatus for the greater superficial petrosal nerve.

The **trigeminal impression** is a shallow depression—barely wide enough to accommodate a finger-tip—on the anterior surface of the petrous temporal near its apex or medial extremity, below the trigeminal notch. The trigeminal ganglion—the chief ganglion of the trigeminal nerve—lies in it.

The **arcuate eminence** is a smooth, rounded elevation on the anterior surface of the petrous temporal near its upper margin, a little lateral to a point midway between the apex of the petrous temporal and the side of the skull; sometimes it is diffuse and ill-defined. Underneath it, in the substance of the bone, there is one of the curved canals of the internal ear, called the *superior semicircular canal*, the convexity of whose curve produces the elevation.

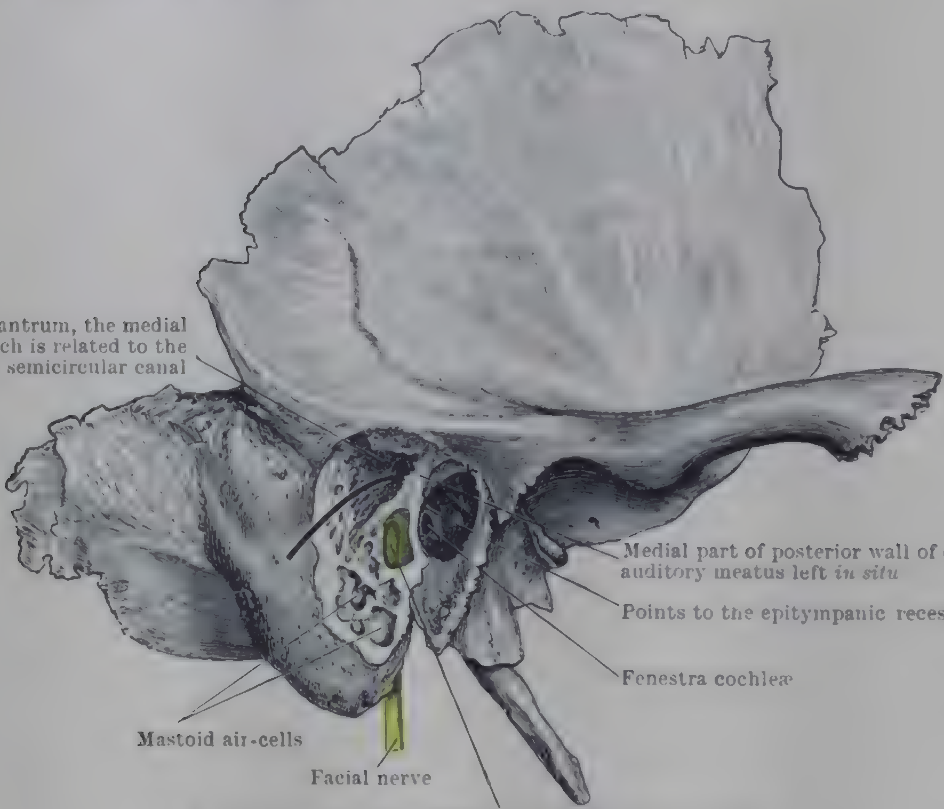

FIG. 158.—RIGHT TEMPORAL BONE PREPARED TO SHOW THE POSITION OF THE TYMPANIC ANTRUM.

The greater part of the posterior wall of the external auditory meatus has been removed, but a bridge of bone has been left at its medial end; under cover of this a bristle (thick black) passes from the tympanic antrum to the tympanic cavity through the posterior canaliculus of the chorda tympani.

The **hiatus for the greater superficial petrosal nerve** is a small slit seen lower down on the anterior surface, and about midway between the apex of the petrous temporal and the side of the skull. It communicates with the facial canal in the interior of the bone, and transmits a slender nerve from which it takes its name. This nerve arises in the substance of the temporal bone from the facial nerve; it emerges from the hiatus and lies in a groove that runs in a medial direction and downwards and forwards to the foramen lacerum.

The **tegmen tympani** is the fairly smooth area of bone that forms the lateral part of the anterior surface of the petrous temporal, and is so named because part of it forms the roof of the middle ear or tympanum (see also pp. 176, 223). It is made of thin bone; disease in the middle ear has therefore only a short way to travel to attack the membranes of the brain and the brain itself. The tegmen tympani is the roof not only of the tympanum but also of the canal for the tensor tympani and the tympanic antrum. The **tympanum** has been seen already at the far end of the external auditory meatus, and its position relative to the cranial cavity can

be gauged from its position as seen through the meatus. The **canal for the tensor tympani** was located when the lower surface of the skull was examined. The **tympanic antrum** is a small but very important cavity (see Fig. 158). It lies in the substance of the temporal bone behind the tympanum and communicates with it by a wide opening; it is about half an inch medial to the suprameatal triangle; it communicates posteriorly with the air-cells which pervade the mastoid portion of the temporal bone to a greater or lesser extent. The antrum is relatively large at birth; the mastoid cells grow as diverticula from the antrum—beginning at or shortly before birth, but not reaching full development till after puberty. If the student has a specimen of his own, he would be well advised to break through the tegmen tympani carefully and snip it away, in order to see the tympanic antrum and note its relation to the middle ear and to the exterior of the skull.

The *anterior lip* of the **lateral part of the middle cranial fossa** has a concave edge which begins medially at the anterior clinoid process and sweeps in a lateral direction and forwards and upwards to end at the side of the skull in the region of the pterion—the groove or tunnel for the anterior branch of the middle meningeal vessels being immediately behind its lateral extremity or even in it. The lip is formed chiefly by the lesser wing of the sphenoid, and is completed laterally by the frontal bone. It fits into the stem of the lateral sulcus of the cerebrum, *i.e.*, the cleft between the frontal and temporal lobes; the lateral end of the stem, where it breaks up into the rami of the sulcus, is therefore opposite the pterion.

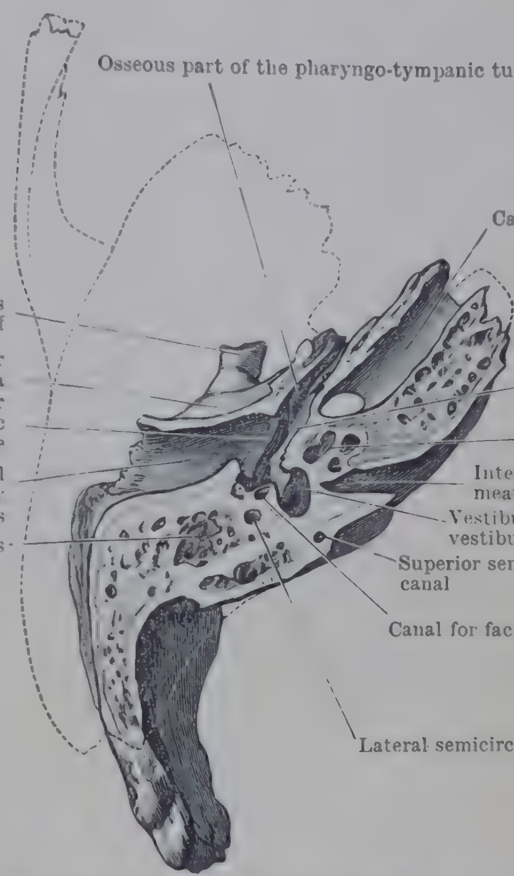

Fig. 159.—Horizontal Section through Left Temporal Bone (Lower Half of Section).

The lower margin of the temporal lobe, *i.e.*, the anterior part of the infero-lateral margin of the cerebrum, fits into the ill-defined groove that marks the junction of the side-wall of the fossa with the floor and posterior boundary; and it corresponds, on the exterior, to a line which begins near the anterior end of the upper border of the zygomatic arch, runs backwards along the upper border of the arch and the posterior root, and is continued backwards a short distance beyond the root to a point that corresponds, in the living head, to the place where the skin of the back of the root of the auricle joins the skin of the head.

The **foramen rotundum** was originally part of the superior orbital fissure, from which it was gradually cut off by the growth of bone. The **sphenoidal emissary foramen**—when present—is a little medial to the foramen ovale.

The **foramen lacerum** is a short, wide canal rather than a foramen; its lower end is on the lower surface of the skull and its upper end is in the floor of the middle cranial fossa. The carotid canal opens into its postero-lateral side near its upper end; and the carotid groove begins on the antero-medial boundary of the upper end. The **lower end** is bounded *postero-laterally* by the petrous temporal, *medially* by the basi-occipital and the body of the sphenoid, and *anteriorly* by the root of the greater wing and pterygoid process of the sphenoid. The **upper end** is bounded *postero-laterally* by the petrous temporal, *medially* and *anteriorly* by the floor of the carotid groove on the body of the sphenoid and the root of the greater wing; and the lingula—if long—completes the *lateral* boundary, which is defective if the lingula is short. The foramen *transmits* a meningeal branch of the ascending pharyngeal artery, some meningeal lymph-vessels, and small veins that connect the cavernous sinus with the pharyngeal venous plexus. It *contains* (1) some cartilage, (2) the internal carotid artery, surrounded by the internal carotid plexus of sympathetic nerves and by a plexus of tiny veins that connect the cavernous sinus and pharyngeal plexus, (3) the deep petrosal nerve, the termination of the greater superficial petrosal nerve, and the beginning of the nerve of the pterygoid canal. The cartilage fills the lower part of the foramen and is pierced by the structures transmitted. The internal carotid artery, after it

emerges from the carotid canal and as it bends up into the cranial cavity to enter the cavernous sinus, lies on the upper surface of the cartilage. While in the foramen the carotid nerve-plexus gives off the deep petrosal nerve. The greater superficial petrosal nerve (a branch of the facial) runs in a groove on the anterior surface of the petrous temporal from its hiatus to the foramen lacerum and joins the deep nerve to form the nerve of the pterygoid canal, which traverses that canal and joins the spheno-palatine ganglion.

The **pterygoid canal** is a narrow, horizontal tunnel, about half an inch long, which traverses the common root of the pterygoid process and greater wing of the sphenoid, and transmits the nerve of the pterygoid canal and an artery of the same name derived from the third part of the maxillary artery. The posterior end of the canal opens on the anterior margin of the foramen lacerum below the lingula and above the pterygoid tubercle. The anterior end opens on the posterior wall of the pterygo-palatine fossa below and medial to the foramen rotundum. The canal is in the floor of the sphenoidal sinus, and may raise a ridge in the floor.

The motor and sensory roots of the trigeminal nerve pass through the **trigeminal notch** and enter the **trigeminal impression** on the roof of the medial end of the carotid canal, where the sensory root joins the trigeminal ganglion; the ganglion also lies partly in the impression and partly overlaps the carotid artery in the foramen lacerum. Three large nerves spring from the ganglion—(1) the ophthalmic, which runs forwards towards the superior orbital fissure but divides into branches before it gets there; (2) the maxillary, which runs forwards to the foramen rotundum; and (3) the mandibular, which descends to the foramen ovale. The motor root runs under cover of the ganglion and is incorporated in the mandibular nerve at the foramen ovale.

The **hiatus for the greater superficial petrosal nerve** transmits that nerve and the petrosal branch of the middle meningeal artery. The nerve runs in a groove medially and forwards, and has to pass under cover of the trigeminal ganglion or the mandibular nerve as it approaches the foramen lacerum.

Below the hiatus there is a small aperture through which the lesser superficial petrosal nerve issues from the substance of the temporal bone; continuous with the aperture there is a narrow groove which runs medially, forwards and downwards (on the roof of the canal for the tensor tympani) to the suture between the petrous temporal and the greater wing of the sphenoid. The aperture and the groove are often very difficult to identify. The nerve lies in the groove and leaves the skull either through that suture or through the foramen ovale or through a minute, unnamed hole which, when present, is behind the foramen ovale.

Occasionally the remains of the original suture between petrous and squamous temporal can be seen in the adult near the side-wall of the skull.

The following parts—which have been briefly defined in this section—are described fully in the Section on The ORGANS OF THE SENSES: The **tympanum**; the **internal ear**, which lies in the substance of the petrous temporal medial to the tympanum; the **canals for the tensor tympani and bony part of pharyngo-tympanic tube**, which open out of the anterior part of the tympanum; the **tympanic antrum**, behind the tympanum; and the **mastoid air-cells**, which communicate with the antrum.

Posterior Cranial Fossa

The **posterior cranial fossa** is in the part of the skull that is placed above the vertebral column and the muscles of the back of the neck. It is the largest and deepest of the cranial fossæ, and lodges the hind-brain, *i.e.*, cerebellum, pons and medulla oblongata.

The **bones** in its walls are: (1) the posterior part of the body of the **sphenoid**, including the *dorsum sellæ*; (2) the posterior surface of the **petrous temporal**; (3) the inner surface of the **mastoid temporal**, in the side-wall behind the petrous temporal; (4) the posterior inferior angle of the **parietal bone**, above the mastoid temporal; (5) the whole of the **occipital bone**, except the part above the external occipital protuberance and superior nuchal lines. The **basilar part** of the occipital bone is in the anterior wall of the fossa, above and in front of the foramen magnum, which occupies the lowest part of the floor. The **condylar part** (including the jugular process) is in the floor, at the side of the foramen magnum. The lower, larger portion of the **squamous part** is in the floor, in the side-wall, and in the posterior wall, being behind the foramen magnum, behind the condylar part and behind the mastoid temporal and inferior angle of the parietal bone. In an adult over 25 years the basilar part is fused with the body of the sphenoid, the line of fusion being barely half an inch below the root of the dorsum sellæ.

The bones in the **rim** of the fossa are: (1) the **dorsum sellæ**, in the middle in front; (2) in the middle posteriorly, a prominent elevation, called the **internal occipital protuberance**, which is nearly opposite the external protuberance; (3) the **upper margin of the petrous temporal**, on each side in front; (4) on each side, posteriorly a broad, shallow, horizontal groove, the **transverse sulcus**, begins at the side of the

internal occipital protuberance and passes forwards to the base or lateral end of the petrous temporal; at that point the groove leaves the rim to become continuous with a deeper groove, called the sigmoid sulcus, which extends sinuously to the jugular foramen. A large venous sinus, called the transverse sinus, lies in the transverse groove, and the sigmoid prolongation of that sinus lies in the sigmoid groove.

A wide fold of the inner layer of the dura mater, shaped like a tent and called the **tentorium cerebelli**, roofs over the posterior cranial fossa and keeps the weight of the hinder part of the cerebrum off the cerebellum. The circumferential or basal margin of the tentorium is attached to the lips of the transverse groove and the lips of the groove for the superior petrosal sinus on the upper margin of the petrous temporal.

The fossa is divisible into a median part and a right and a left lateral part.

Median Part of Posterior Cranial Fossa

The parts to be noted in the median division are the foramen magnum, the anterior condylar canal, the jugular tubercle, the clivus, the groove for the inferior petrosal sinus, and the internal occipital crest.

The **foramen magnum** is in the lowest part of the fossa. The medial surface of the occipital condyle can be seen at the anterior part of the margin on each side, and in many skulls the condyles encroach upon the foramen and reduce the width of its anterior part. (See also p. 172.)

The internal opening of the **anterior condylar canal** is a little above the margin of the foramen magnum where it is formed by the condyle. The opening is rather hidden unless the skull is tilted; and it is often double on one or both sides. The external opening has been seen already on the lower surface of the skull (p. 173).

The **jugular tubercle** is the smooth, rounded elevation situated above and in front of the internal opening of the anterior condylar canal.

The **clivus** is the broad, sloping surface between the anterior margin of the foramen magnum and the root of the dorsum sellæ; it is formed by the upper surfaces of the basilar part of the occipital bone and of the posterior part of the body of the sphenoid; it is related to the pons and medulla oblongata of the brain. [*Clivus*=a slope.]

The **groove for the inferior petrosal sinus** lies along the suture between the basilar part of the occipital bone and the petrous temporal and is shared by both bones.

The **internal occipital crest** is the strong, median ridge between the foramen magnum and the internal occipital protuberance.

The hypoglossal nerve pierces the dura mater as two bundles which unite in the **anterior condylar canal**. When the opening of the canal is double, the two bundles may enter the canal separate or they may both enter through one of the openings, while the other transmits a meningeal artery.

The **jugular tubercle** is at the medial side of the anterior part of the jugular foramen and overlies the anterior condylar canal; immediately behind and lateral to the tubercle there is a short, shallow groove in which the ninth, tenth, and eleventh cranial nerves lie as they pass towards the jugular foramen.

The **clivus** is concave from side to side. Its upper part is related to the pons and the basilar artery, its lower part to the medulla oblongata and the vertebral arteries, and, near the foramen magnum, it is roughened by the attachments of the membrana tectoria and the upper band of the cruciate ligament. Between the two layers of the dura mater that cover the clivus there is a network of venous channels, called the plexus of basilar sinuses, which connect the right inferior petrosal sinus with the left. The abducent nerve, on each side, pierces the inner layer of the dura mater near the lateral margin of the clivus about half an inch below the dorsum sellæ, runs upwards on the clivus between the two layers of the dura mater, and crosses the inferior petrosal sinus to reach the apex of the petrous temporal; at that point, it crosses the petro-sphenoid joint below a slender fibrous band that is sometimes ossified; it then curves round the internal carotid artery to enter the cavernous sinus.

The **groove for the inferior petrosal sinus** begins at the apex of the petrous temporal, *i.e.*, at the medial end of its upper border, where the sinus is connected with the posterior end of the cavernous sinus; it runs obliquely downwards, backwards, and in a lateral direction, along the petro-occipital suture, to the jugular foramen, where the sinus, descending through the antero-medial part of the foramen, joins the commencement of the internal jugular vein.

The **internal occipital crest** gives attachment to a small fold of the inner layer of dura mater, the falx cerebelli, which intervenes between the two hemispheres of the cerebellum. A small venous sinus, called the occipital sinus, lies along the edge of the crest between the two layers of

the falx; sometimes the sinus is paired. The lower part of the crest sometimes divides to enclose a small depression related to the vermis of the cerebellum.

The tentorium cerebelli, the falx cerebri, and the falx cerebelli are attached to the **internal occipital protuberance**; in its immediate neighbourhood the superior sagittal sinus and the straight sinus end, and the transverse sinuses and the occipital sinus begin; the posterior end of the cerebrum is immediately above and lateral to it. The internal occipital protuberance is seldom directly opposite the external protuberance (it is usually a little higher), but there is so little difference in their levels that the external protuberance is usually taken as the surface guide to the position of structures near the internal protuberance. Owing to the two protuberances, that region of the occipital bone is one of the thickest parts of the skull.

Lateral Part of Posterior Cranial Fossa

The chief parts to be noted in this division are the cerebellar fossa, the transverse and sigmoid grooves, the jugular foramen, the posterior condylar canal, the mastoid foramen, and the internal auditory meatus. Points of less importance are the grooves for the meningeal arteries, the opening of the aqueduct of the vestibule, the subarcuate fossa, the notch for the glosso-pharyngeal nerve, and the external opening of the cochlear canaliculus.

The **cerebellar fossa** is the wide concavity between the transverse groove and the foramen magnum. Faint grooves made by meningeal vessels are seen in its floor.

The **transverse groove** begins at the side of the internal occipital protuberance and sweeps round the cranial wall to the lateral end of the upper margin of the petrous temporal, where it joins the sigmoid groove.

The **sigmoid groove** curves downwards and descends along the side-wall of the skull to the floor, extends in a medial direction on the floor for an inch, and, finally, curves forwards to end at the jugular foramen. Its curves resemble those of the letter S; hence the name "sigmoid" [*sigma* is the Greek name for the letter S].

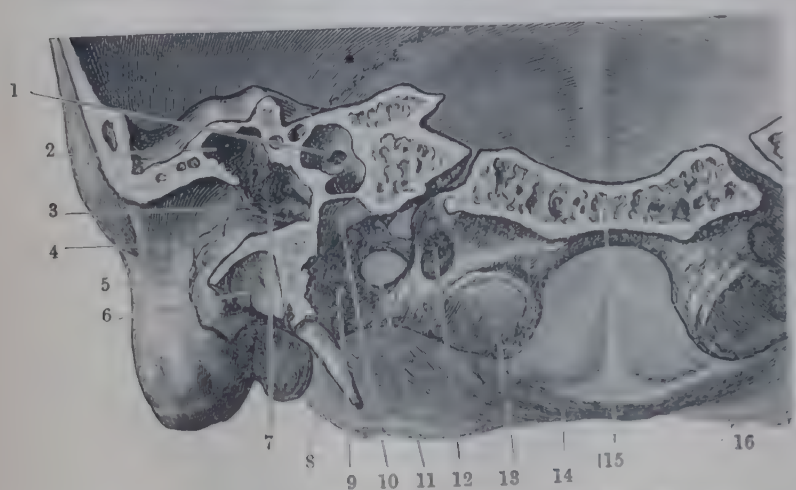

Fig. 160.—Vertical Section through Base of Skull immediately in Front of Root of Styloid Process.

1. Cochlea.
2. Entrance to the antrum.
3. Tympanic sulcus.
4. Tympanic plate.
5. Tympano-mastoid fissure.
6. Tympanic plate.
7. Tympanic cavity (floor).
8. Styloid process.
9. Jugular fossa.
10. Lower end of carotid canal.
11. Jugular foramen.
12. Anterior condylar canal.
13. Occipital condyle.
14. Foramen magnum.
15. Basi-occipital.
16. Squama of occipital bone.

The position of the two grooves corresponds, on the exterior of the skull, to a line (1) which begins at the side of the external occipital protuberance and is drawn almost horizontally, but with a slight upward convexity, to a point a little behind the place where the posterior root of the zygoma joins the supramastoid crest, and that point, on the living head, is where the skin of the upper part of the back of the root of the auricle joins the skin of the head; (2) from that point the line is drawn almost vertically downwards to a point about a finger's breadth behind the lower margin of the external auditory meatus; (3) from there, forwards to the lower border of the meatus. The first or horizontal part of the line is opposite the transverse sinus and the attachment of the tentorium; the posterior part of the infero-lateral border of the cerebrum is above it; the margin of the cerebellum is below it. The second and third parts of the line correspond to the sigmoid sinus—which is the continuation of the transverse sinus.

The sigmoid groove is deeper than the transverse groove; in some skulls its upper part is so deep (at the expense of the petrous temporal) that it is quite close to the tympanic antrum, and the sigmoid sinus would be in considerable danger during an operation on the antrum.

The **mastoid foramen** is an aperture of variable size that leads from the exterior of the skull into the sigmoid groove on the side-wall of the posterior fossa. The **posterior condylar canal**, when present, passes from the condylar fossa into the posterior cranial fossa and opens into or near the sigmoid groove on the floor of the fossa.

The posterior part of each transverse groove is situated on a thick, blunt ridge that extends in a lateral direction from the internal occipital protuberance for some distance. Above that ridge, on the posterior wall of the cranial cavity, there is a wide, well-marked depression, called the *posterior cerebral fossa*, which lodges the posterior end of the occipital lobe of the cerebrum. The right cerebral fossa is separated from the left by a thick vertical ridge which descends to the internal occipital protuberance. Along that ridge the sagittal groove, seen already on the vault of the skull, runs down to the protuberance and becomes continuous with one or other of the transverse grooves, usually the right; occasionally it splits and becomes continuous with both transverse grooves.

The **transverse groove** begins at the internal occipital protuberance, passes across the occipital squama to its lateral angle, and then crosses the posterior inferior angle of the parietal bone to reach the mastoid temporal, where it becomes the sigmoid groove. The **sigmoid groove** turns downwards, grooving the mastoid temporal and the petrous temporal, where it is separated by very thin bone from the mastoid air-cells and may be very close to the tympanic antrum; reaching the floor, it passes off the mastoid temporal on to the upper surface of the jugular process of the occipital bone, on which it passes first in a medial direction and then forwards to the jugular foramen.

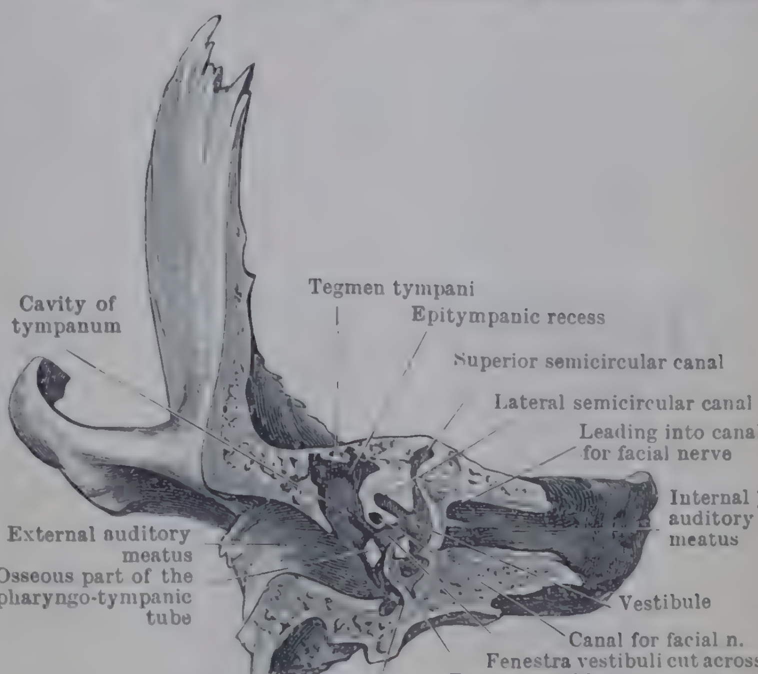

Fig. 161.—Vertical Transverse Section through Left Temporal Bone (Anterior Half of Section).

The right and left transverse grooves are seldom of equal size; the wider of the two is that which is joined by the sagittal groove, and it is usually the right; and the jugular foramen also is wider on that side than on the other.

The circumferential margin of the **tentorium cerebelli** is attached to the internal occipital protuberance, to the lips of the transverse groove, to the lips of the narrow, ill-marked groove along the upper margin of the petrous temporal, and then is prolonged medially to be attached to the posterior clinoid process. Along the transverse groove it encloses the transverse sinus; along the margin of the petrous temporal it encloses the superior petrosal sinus, which runs from the cavernous sinus to the transverse sinus; and at the trigeminal notch the trigeminal nerve crosses beneath the sinus and the margin of the tentorium. The internal margin of the tentorium, *i.e.*, the margins of the door of the tentorium, is continued forwards, on each side, across the attached, circumferential margin at the apex of the petrous temporal, to be fastened to the anterior clinoid process.

The **cerebellar fossa** is of variable depth, and is often unequal on the two sides. Its floor is thin and translucent, and may be the thinnest part of the cranial wall. The cerebral fossæ also are seldom symmetrical.

Faint, narrow grooves are seen here and there in the walls of the posterior cranial fossa for the posterior meningeal vessels, which are derived from the vertebral, the occipital, and the ascending pharyngeal arteries; and some twigs of the posterior branch of the middle meningeal artery may descend into the fossa.

The **jugular foramen** is a large aperture with irregular margins. It is in the anterior and medial part of the floor of the lateral division of the fossa, between the petrous temporal and the jugular process of the occipital bone. It leads downwards and slightly forwards to the lower surface of the skull, where it is opposite the lower margin of the external auditory meatus.

The **jugular foramen** transmits three sets of structures, and small spicules of bone projecting from its margins may partly or completely divide it into corresponding compartments. By

far the most important structures that pass through the foramen are the sigmoid sinus and the ninth, tenth and eleventh cranial nerves. The *antero-medial compartment* transmits the inferior petrosal sinus and a meningeal branch of the ascending pharyngeal artery. The *middle compartment* transmits the glosso-pharyngeal, vagus and accessory nerves—in that order from before backwards. The *postero-lateral compartment* is larger than the other two, and transmits the sigmoid sinus (as it becomes the internal jugular vein), a meningeal branch of the occipital artery, a meningeal branch of the vagus, and lymph-vessels from the meninges. (See also p. 175.)

The posterior surface of the petrous temporal is the anterior wall of the lateral part of the fossa; the only conspicuous aperture in it is an oblique opening which is the medial end of the **internal auditory meatus** (Fig. 164). The meatus is a short canal in the petrous temporal, nearly horizontal and nearly transverse; its lateral end is separated by thin bone from the internal ear. It is almost opposite the external meatus, and is about an inch and a half from the surface of the head (Fig. 161).

The **internal auditory meatus** is about 10 mm. long and 3 to 5 mm. wide. It transmits the motor and sensory roots of the facial nerve, the auditory nerve, the internal auditory branch of the basilar artery and the internal auditory vein, which joins the inferior petrosal sinus. The lateral end of the meatus is called the **fundus** or bottom. The part of the petrous temporal bone that forms the fundus separates the meatus from the vestibule and cochlea of the internal ear. In the fundus there are several apertures that transmit the auditory vessels and the facial and auditory nerves (Fig. 1020, p. 1195). If the skull has been split into halves so that one can see into the meatus, the fundus and the holes in it are visible at the far end. The position of the internal ear can be gauged by an examination of the meatuses. The fundus of the internal meatus is the medial wall of the internal ear. The lateral wall of the internal ear is the medial wall of the tympanum or middle ear; that wall can be seen through the external auditory meatus, and the bulge called the promontory seen there is produced by the basal curve of the cochlea, which is coiled like a snail-shell [κοχλίας (cochlias) = a snail, a spiral]. The arcuate eminence of the anterior surface of the petrous temporal also is a guide, for it overlies the superior semicircular canal, which stands up from the posterior part of the vestibule of the inner ear like the handle of a pail. The facial nerve passes through one of the holes in the fundus of the internal meatus and enters the facial canal to pass through the temporal bone, first in a lateral direction above the vestibule to the anterior part of the upper border of the medial wall of the tympanum, then backwards in the medial wall near its upper border, and finally downwards behind the tympanum. The canal ends as the stylo-mastoid foramen on the lower surface of the skull.

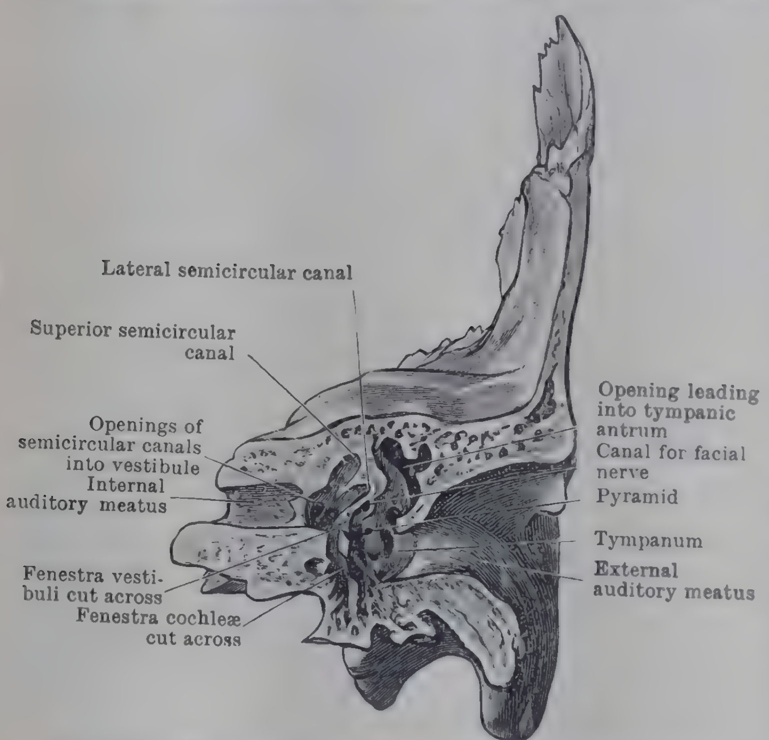

FIG. 162.—VERTICAL TRANSVERSE SECTION THROUGH LEFT TEMPORAL BONE (Posterior Half of Section).

A narrow canal about 8 mm. long, the **aqueduct of the vestibule**, passes backwards from the vestibule and opens on the posterior surface of the petrous temporal; this *external opening* is at the bottom of a small slit seen about half an inch lateral to the opening of the internal meatus; the slit is overhung by a thin lip of bone. The canal transmits a tiny artery and vein and a delicate membranous *endolymphatic duct*; this duct emerges from the external aperture and its blind, terminal portion dilates to form the *endolymphatic sac*, which lies under cover of the dura mater.

The **subarcuate fossa** is a small, ill-defined depression about midway between the opening of the meatus and the aperture of the aqueduct, but at a higher level than either of them. It is larger and better defined in the skull of a child than of an adult (Fig. 188, C, p. 224). Small vessels pass through its floor into the bone.

The **notch for the glosso-pharyngeal nerve** (Fig. 186) is a rounded notch on the anterior margin of the jugular foramen directly below the opening of the internal meatus: the ninth cranial nerve enters the jugular foramen through this notch, and the notch is cut off from the rest of the foramen by a fibrous band. This band is sometimes ossified, but more usually the margins of the notch are prolonged backwards as little spurs of bone that partially or completely divide

the jugular foramen into compartments. The notch is the upper end of a groove that runs downwards, forwards, and laterally from it, immediately in front of the jugular fossa. The groove lodges the ninth nerve; it is seen on the lower surface of the skull, for it ends at the ridge between the jugular foramen and the carotid canal.

At the bottom of the notch for the ninth nerve there is a small pit hidden under an overhanging lip of bone, although it may in some specimens be seen from the lower surface of the skull. At the bottom of the pit there is the **external opening of the cochlear canaliculus**—a narrow canal about 15 mm. long, which leads from the cochlea and conducts a small vein to the inferior petrosal sinus and a tubular prolongation from the dura mater to the cochlea.

CAVITY OF NOSE

The term **Nose** includes the **external nose**, which juts from the face, and also the **cavity of the nose**, of which merely a small part lies in the external nose.

The **cavity of the nose** extends from the posterior bony apertures on the base of the skull to the anterior bony aperture on the front—or to the nostrils when the soft parts are in place. It is above the cavity of the mouth, being separated therefrom by the hard palate; and it lies below the anterior and middle cranial fossæ and the frontal and sphenoidal air-sinuses. In round numbers its length increases from 50 mm. at the floor to 75 mm. at the roof; its greatest height, about its middle, is 50 mm., and it diminishes to 30 mm. at the anterior aperture and 25 mm. at the posterior apertures.

It is divided into **right** and **left halves** by a median partition or **septum**, and the term "cavity of nose" or "nasal cavity" is applied sometimes to the whole cavity and sometimes to one or other of the halves—according to the context. Each of the two cavities is narrow from side to side. The widest part, near the floor, measures only about 10 mm., while near the roof, except in its posterior section, it is only 1 or 2 mm.

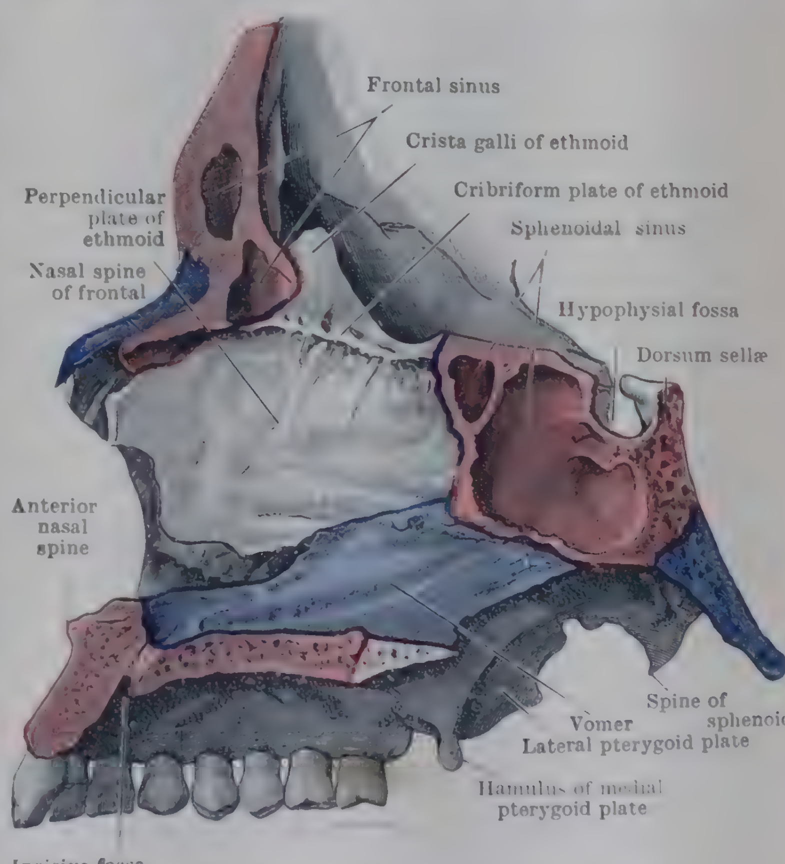

Fig. 163.—Roof, Floor, and Septum of Nose.

Red : Parts of frontal, sphenoid and maxilla.
Blue : Vomer ; basi-occiput ; part of nasal.
White : Perpendicular plate of ethmoid ; horizontal plate of palatine.

Boundaries.— Each of the two nasal cavities has a *roof*, a *floor*, a *lateral* wall, and a *medial* wall — the medial wall being the septum between the cavities.

The **roof** is very narrow from side to side except at its posterior end. It is horizontal in the middle, but slopes downwards in front and behind, and the anterior and posterior parts of the cavity are therefore of lesser vertical depth than the middle part. The **middle** part is the cribriform plate of the ethmoid. The **anterior** sloping part is formed by a small part of the frontal bone and by the nasal bone below that; and, still lower down, when the soft parts are in place, by the cartilages of the nose. The **posterior** sloping part—a very steep slope—is formed by the anterior and inferior surfaces of the body of the sphenoid.

The **roof of each nasal cavity**, in nearly the whole of its length, is only 1 or 2 mm. in width, but its most posterior part, which is formed by the lower surface of the body of the sphenoid, measures about 10 mm. across; in a dried skull, that is also the lowest part of the roof—being on a level with the zygomatic arch at the side of the skull. Though the anterior part of the lower surface of the body of the sphenoid is reckoned as part of the roof, yet the ala of the vomer and the sphenoidal process of the palatine bone, which are closely applied to it, shut it off from the nasal cavity and are the actual bones clothed with the muco-periosteum of the posterior part of the roof. The **palatino-vaginal canal** (p. 170) is situated in that part of the roof, between the sphenoidal process and the body of the sphenoid.

The part of the roof formed by the anterior surface of the body of the sphenoid looks forwards rather than downwards, and diminishes to 2 mm. in width as it is traced upwards and forwards, for the greater part of each half of the front of the body of the sphenoid articulates with the labyrinth of the ethmoid, leaving the smaller part alongside the median plane free to form a boundary for the nasal cavity. In that area there is a round opening of considerable size which leads back into the *sphenoidal sinus.*

The anterior surface and anterior part of the lower surface of each half of the body of the sphenoid is made of bone which in early life is separate and is called the *sphenoidal concha.*

The part of the nasal cavity which is highest, and also nearest the cranial cavity, is the middle part; it is roofed by the cribriform plate, which is at the level of the nasion and is perforated by the olfactory nerves; infection from the nose has, at that part, only a very short distance to travel to reach the brain and its membranes.

The nasal surface of the frontal bone is only a very narrow strip that appears in the roof of the nose in front of the cribriform plate; it separates the nasal cavity from the frontal sinus, and it slopes downwards and forwards to the nasal bone. Those two bones form the anterior sloping part of the roof; along that part of the roof the anterior ethmoidal nerve (with companion vessels) runs downwards and forwards to emerge between the nasal bone and cartilage, under the name of the external nasal nerve, for the supply of the skin of the lower half of the external nose; the nerve leaves a narrow groove on the surface of the bone on which it runs.

The **floor** is smooth, nearly horizontal from before backwards, and slightly concave from side to side. It is considerably wider than the roof—measuring 10-12 mm. across—and is slightly wider in the middle than at its ends. It is shorter than the roof, for the posterior apertures slope from above downwards and forwards, and the anterior aperture slopes downwards and backwards. Its posterior fourth or third is formed by the palatine bone, an L-shaped bone consisting mainly of a perpendicular plate which lies in the lateral wall of the nose and a horizontal plate which forms the posterior part of the bony palate. The palatine process of the maxilla forms the remainder of the floor of the nose. Near the front, close by the septum, is the opening of the incisive canal, which is covered over with mucous membrane before maceration. The **incisive canal** passes downwards through the bone and divides into two parts which open, as the lateral and median incisive foramina, into the incisive fossa on the bony palate.

The three chief constituents of the **septum** are: (1) the perpendicular plate of the ethmoid, situated above and behind; (2) the vomer, situated below and behind; (3) the septal cartilage of the nose, which, in a dried skull, is destroyed; it is situated anteriorly and fills in the wide, angular interval between the other two. The superficial area of the septum is usually too great for the height of the cavity, and it is therefore bent to one side near its middle, or it is bent first to one side and then to the other.

The **osseous septum** is composed almost entirely of the perpendicular plate of the ethmoid superiorly and the vomer below and posteriorly, but it is completed by the following small projections: (1) The *crest of the sphenoid*, which projects forwards from the median line of the front of the body of the sphenoid to articulate with the perpendicular plate. (2) The *nasal spine*, which projects from the nasal part of the frontal bone downwards and forwards between the perpendicular plate and the nasal crest. (3) A *nasal crest* is formed by the lips of the margins of the nasal bones that articulate with each other; that crest articulates, from above downwards, with the nasal spine of the frontal bone, the perpendicular plate, and the septal cartilage. (4) A *nasal crest*, to articulate with the lower edge of the vomer, is formed by sharp ridges that stand up from the horizontal part of the palatine bone and the palatine process of the maxilla where they articulate with their fellows of the other side. The anterior part of this crest stands up from the junction of the alveolar processes of the maxillæ; it is thicker and higher than the rest; and it articulates posteriorly with the vomer and superiorly with the subvomerine cartilage.

The upper part of the perpendicular plate of the ethmoid shows numerous small branching grooves that lodge olfactory nerves. Indistinct grooves for vessels may be seen on the vomer, and one long groove for the long spheno-palatine nerve and the spheno-palatine vessels, which

enter the nose through the spheno-palatine foramen in the lateral wall, cross the roof and run downwards and forwards, grooving the vomer, to reach the incisive canal.

The *cartilaginous septum* is formed almost wholly by the septal cartilage, which, however, is aided by (1) the subvomerine cartilage (*i.e.*, a small strip along its lower margin); and (2) the medial part of the right and left lower nasal cartilage, at the tip of the nose.

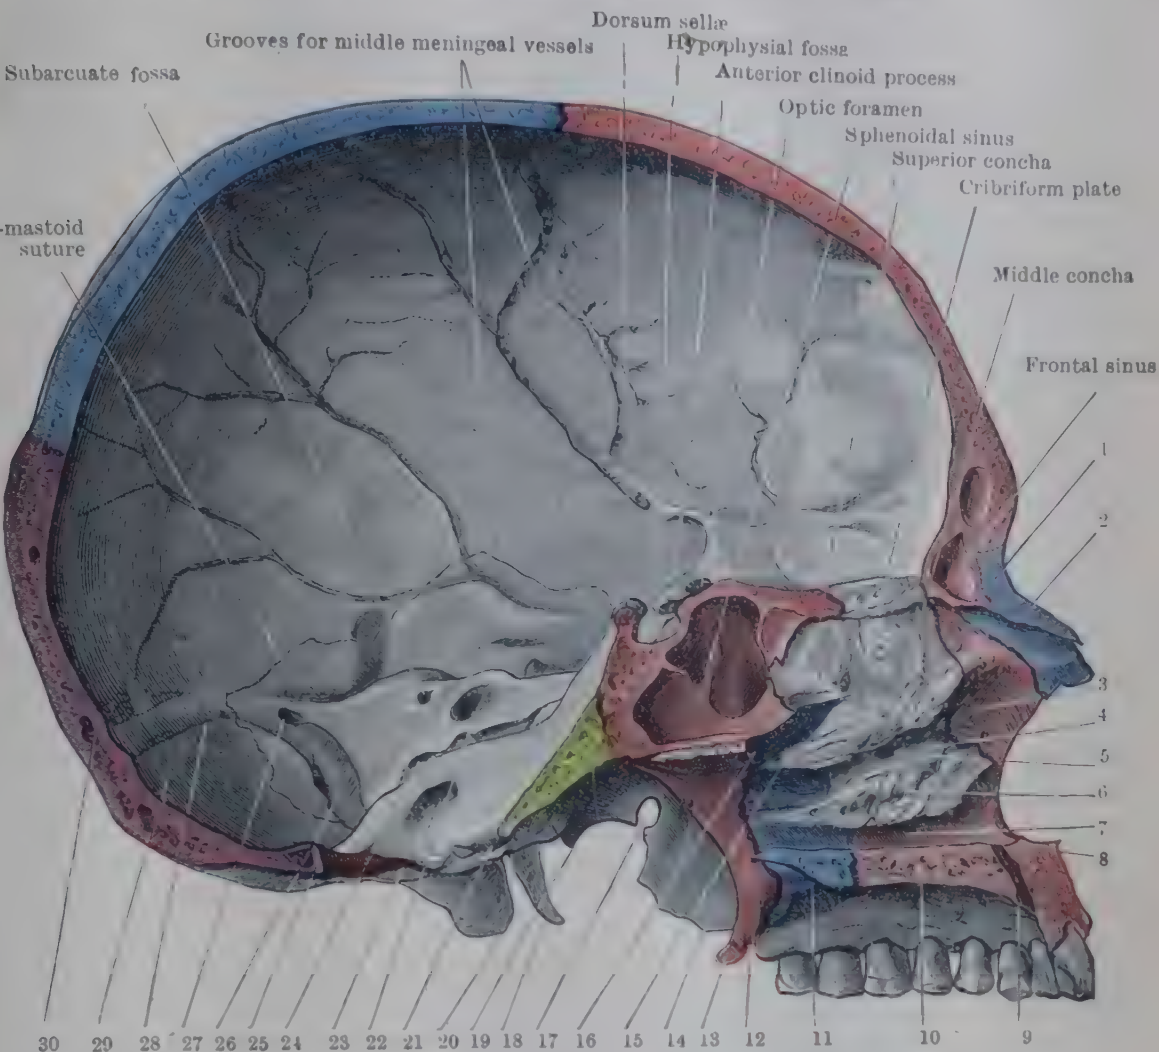

FIG. 164.—MEDIAL ASPECT OF LEFT HALF OF SKULL SAGITTALLY DIVIDED.

Red: parts of frontal, maxilla, and sphenoid. **Blue**: palatine; nasal; part of parietal.
Purple: part of occipital squama. **Yellow**: part of basi-occiput.
Uncoloured: left ala of vomer; inferior concha; ethmoid; and other bones.

1. Near nasal spine of frontal.
2. Nasal bone.
3. Frontal process of maxilla (and atrium).
4. Lower part of middle meatus.
5. Near opening of maxillary sinus.
6. Inferior concha.
7. Inferior meatus.
8. Anterior nasal spine.
9. Incisive fossa and canal.
10. Palatine process of maxilla.
11. Horizontal plate of palatine.
12. Posterior nasal spine.
13. Hamulus of medial pterygoid plate.
14. Lateral pterygoid plate.
15. Superior meatus.
16. Spheno-palatine foramen.
17. Foramen formed by ossified pterygo-spinous lig.
18. Styloid process.
19. Spine of sphenoid.
20. Mastoid process.
21. Basion.
22. Internal auditory meatus.
23. Anterior condylar canal.
24. Groove for inferior petrosal sinus.
25. Opisthion.
26. Sigmoid groove.
27. Opening of mastoid foramen.
28. Transverse groove.
29. Cerebellar fossa.
30. Internal occipital protuberance.

The **lateral wall** is very uneven and is composed of several bones, namely, the *nasal*, the *maxilla* and its *frontal process*, the *lacrimal*, the *labyrinth* of the ethmoid and its *conchæ*, the *inferior concha*, the perpendicular plate of the *palatine* and the *medial pterygoid plate* (Fig. 164; see also Fig. 1041, p. 1210).

Identify the conchæ first. The **inferior nasal concha** is the rough plate of bone that projects from the side-wall into the lower part of the nasal cavity for a little distance and then curves downwards; it is a separate bone, and if it has been broken away, the line along which it was attached is seen as an irregular, broken

ridge about half an inch above the floor of the nose. The **middle nasal concha** is attached about an inch above the inferior concha, which it resembles; it is not a separate bone, but projects from the ethmoid labyrinth a little way into the nasal cavity and then turns downwards. The **superior nasal concha** is the small ridge of bone situated a little above the posterior half of the middle concha and is also a projection from the labyrinth. If a pair of forceps is passed into the living nose and opened vertically, it must be kept close to the septum, else the upper leg will be intercepted by the conchæ.

The **nasal bone** lies in the anterior and upper part of the lateral wall, as well as in the roof. The **frontal process of the maxilla** lies immediately behind and below the nasal bone. Those two bones form also the bony skeleton of the external nose. The **lacrimal bone**, seen already in the orbit, lies behind the frontal process, but only its lower and anterior part appears in the nose.

The **medial pterygoid plate** is the most posterior bone in the lateral wall of the nose, and forms the lateral boundary of the posterior aperture.

The medial surface of the **body of the maxilla** is in the lower part of the side-wall of the nasal cavity, extending from the lower part of the anterior aperture backwards almost to the medial pterygoid plate. It is to a large extent concealed by other bones, among which there are two openings out of the maxillary sinus.

The **perpendicular plate of the palatine bone** lies in the posterior part of the lateral wall in front of the medial pterygoid plate. The horizontal plate is easily identified in the floor. The perpendicular plate lies directly above the lateral margin of the horizontal plate and extends upwards to the body of the sphenoid in the roof. It is wider, as well as longer, than the horizontal part. It separates the nasal cavity from the pterygo-palatine fossa and, behind that, it overlaps the medial pterygoid plate. Anteriorly, the greater part of it is applied to the posterior part of the medial surface of the maxilla, shutting off that part from the nasal cavity and helping to close in the opening of the maxillary sinus.

The lateral surface of the **labyrinth of the ethmoid** is the smooth plate seen already in the orbit behind the lacrimal bone. Its **medial surface** is very uneven and rough, and is now seen in the nose below the cribriform plate; it extends from the frontal process of the maxilla to the body of the sphenoid—forming the greater part of the upper half of the lateral wall of the nose. The superior and middle conchæ project from the medial surface of the labyrinth; and hidden under cover of the middle concha there is a rounded, bulging part of the labyrinth, called the **bulla ethmoidalis,** which can partly be seen when examined from the front [*bulla* = a bubble]. The bulla is bounded in front and below by a curved groove or slit called the **hiatus semilunaris.**

Meatuses of the Nose.—The lateral part of the cavity of the nose is divided into the *superior*, *middle*, and *inferior* meatuses, the *spheno-ethmoidal recess*, and the *atrium* of the middle meatus; and, when the soft parts are in place, the portion above the nostril is called the *vestibule* of the nose.

The **spheno-ethmoidal recess** is the small space above and behind the superior concha. The **superior meatus** is an oblique, cleft-like space in the posterior half of the labyrinth of the ethmoid; its slit-like orifice is below the superior concha and above the middle concha. The **middle meatus** is much larger than the superior; part of it is lateral to the middle concha and part of it is below—extending down to the inferior concha. The lower part is roomy; the part that lies under cover of the middle concha is greatly narrowed by the bulge of the bulla ethmoidalis. The **atrium** of the middle meatus is the wide region in front of the middle meatus [*atrium* = an entrance hall]. The **inferior meatus** is the space lateral to and below the inferior concha.

The **lateral wall** of the nasal cavity is more uneven and complicated than the other boundaries. It is also the most variable and most liable to injury in the dried skull, and the student may therefore have difficulty in applying any given description to the specimen he is using for study.

The groove made by the anterior ethmoidal nerve may be on the part of the **nasal bone** that lies in the lateral wall, rather than on the part in the roof.

The **frontal process of the maxilla** presents a wide area which forms the side-wall of the *atrium* of the middle meatus. At the lower boundary of that area, where the frontal process

joins the body of the maxilla, there is a horizontal ridge, called the *conchal crest*, which articulates with the anterior part of the inferior concha. At the upper boundary of the area there is a ridge called the *ethmoidal crest*. The anterior part of that ridge produces the elevation called the *agger nasi* in the unmacerated head. The posterior part articulates with the anterior end of the middle concha; the portion of the frontal process above that articulation is applied to the front of the labyrinth of the ethmoid and helps to close in the anterior ethmoidal sinuses.

The **lacrimal bone** also is applied to the labyrinth, forming a boundary to the anterior ethmoidal sinuses; but its antero-inferior portion appears in the side-wall of the nose, and its lowest part projects downwards and helps to close the opening of the maxillary sinus.

The **labyrinth of the ethmoid**, situated between the orbit and the nasal cavity, bulges into the nasal cavity and greatly reduces the width of its upper part. It is composed of exceedingly thin, fragile bone. The upper half of its medial side is a wide area which, though far from smooth, is relatively even; it shows narrow grooves which lodge the lateral group of olfactory nerves and lead up to the holes in the cribriform plate. Inferiorly, the posterior half of the area is bounded by the **superior concha**; the anterior half is continuous with the medial surface of the middle concha.

The **spheno-ethmoidal recess** is situated above and behind the posterior part of the superior concha, in front of the body of the sphenoid; and the sphenoidal sinus opens into it through a round hole.

The **middle concha** forms the roof and medial wall of the upper, narrow part of the middle meatus, and its medial surface is the lower and lesser part of the medial side of the labyrinth. It extends forwards to the frontal process of the maxilla and backwards to the perpendicular part of the palatine bone—its anterior end being at a considerably higher level than the posterior end. The lower border is convex from before backwards, its lowest point being about the level of the floor of the orbit; this border is thickened and curled in a lateral direction, so that the lateral surface of the concha is concave and the medial surface is convex.

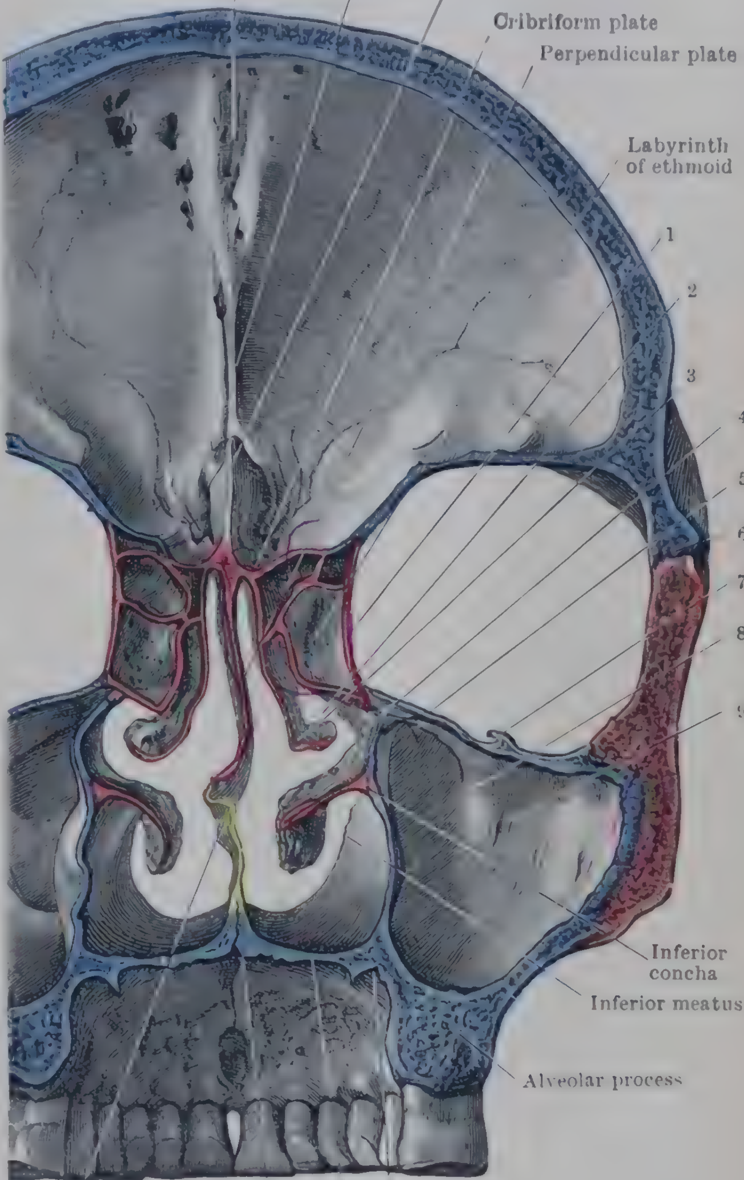

FIG. 165.—CORONAL SECTION PASSING INFERIORLY BETWEEN THE FIRST AND SECOND MOLAR TEETH.

Red: ethmoid; inferior concha; zygomatic.
Blue: frontal; maxilla. **Yellow**: vomer.

1. Orbital plate of ethmoid.
2. Middle meatus of nose.
3. Middle concha.
4. Opening of maxillary sinus.
5. Orbital surface of maxilla.
6. Zygomatico-frontal suture.
7. Infra-orbital groove.
8. Maxillary sinus.
9. Canal for the anterior dental nerve and vessels exposed.
10. Palatine process of maxilla.
11. Nasal crest of maxillæ.

The **superior meatus** is bounded inferiorly by the posterior half of the middle concha, and superiorly by the superior concha and the walls of posterior ethmoidal sinuses; these sinuses open into it by two or three orifices in the dried skull, but mucous membrane covers one or two of the openings during life. The **spheno-palatine foramen** also opens into it at its posterior part, but is covered over with mucous membrane before maceration.

The **bulla ethmoidalis** bulges from the lateral wall into the upper part of the middle meatus, and is therefore hidden under cover of the middle concha; it varies considerably in size, and it encloses some of the middle ethmoidal sinuses.

From the labyrinth, in front of the bulla, there springs a long, thin **uncinate process**; this process curves downwards and backwards (Fig. 195), first in front of the bulla and then below it, and has a considerable share in covering the opening of the maxillary sinus.

The curved interval between the bulla and the uncinate process is the **hiatus semilunaris**; as

the mucous lining passes from the bulla to the process, it dips into the hiatus to form a floor for it and convert it into a gutter-like groove. In some skulls, however, the uncinate process is closely applied to the bulla, and the hiatus is then a gutter-like groove on the process, the margins of which are curled to form the margins of the groove. The **infundibulum** [= a funnel], which leads downwards through the anterior part of the ethmoid labyrinth from the frontal sinus, opens into the hiatus.

The **middle meatus** extends from the attached margin of the middle concha down to the inferior concha, and is therefore of considerable height. The middle concha constitutes a medial wall for the upper, narrow part of the meatus; this part is at the level of the orbit, and is separated from the orbit by the lower part of the labyrinth, including the bulla. The lower, wide part of the meatus is open medially. It is situated below the labyrinth, opposite the upper part of the maxillary sinus, from which it is separated by the bones that close the opening of the sinus.

The *sinuses* that lead into the meatus open into its upper part. The *middle ethmoidal* sinuses open into it on the surface of the bulla; the *maxillary* sinus opens into the lower part of the hiatus semilunaris; the infundibulum, leading from the *frontal* sinus, opens into the upper part of the hiatus; the *anterior ethmoidal* sinuses also open into the upper part of the hiatus and into the infundibulum. In the dried skull there are one or more additional openings out of the maxillary sinus into the lower part of the meatus, but they are closed with mucous membrane when the soft parts are in place.

The **perpendicular plate of the palatine bone** is a very thin plate of bone situated in the posterior part of the side-wall of the nose. Its posterior edge articulates with the medial pterygoid plate and often overlaps it. Anteriorly, it is applied to the medial surface of the maxilla and takes a considerable share in closing the opening of the maxillary sinus. Between the upper parts of the maxilla and pterygoid process, it forms the medial wall of the pterygo-palatine fossa, from which the **greater palatine canal** descends to the bony palate; the canal is situated in the side-wall of the nose between the palatine bone and the maxilla. Two processes project upwards from the upper end of the palatine bone, namely, the sphenoidal and orbital processes; they are separated by the spheno-palatine notch, which is converted by the body of the sphenoid into the **spheno-palatine foramen**. The *sphenoidal process* inclines medially to form part of the roof of the nose. The *orbital process* is wedged in between the body of the sphenoid, the labyrinth of the ethmoid, and the body of the maxilla, and forms the posterior corner of the floor of the orbit; it often contains a cavity, called the *palatine sinus*, which opens into the sphenoidal sinus or into a posterior ethmoidal sinus. At the root of the orbital process, a ridge called the *ethmoidal crest* articulates with the posterior end of the middle concha; about 10 mm. from the lower end of the palatine bone, a ridge called the *conchal crest* articulates with the posterior end of the inferior concha.

The **inferior concha** extends between the conchal crests of the palatine bone and the maxilla, and its anterior attachment is the higher. It reaches a little farther forward and a little farther back than the middle concha does. Its lower border is slightly thickened, curled laterally, convex from before backwards, and is only a little distance above the level of the lower margin of the anterior bony aperture of the nose. The inferior concha passes across the lower part of the opening of the maxillary sinus and sends off processes which assist in closing the opening.

The **inferior meatus** extends from the attached margin of the inferior concha to the bony palate; the medial surface of the lower part of the maxilla is its lateral wall; and the concha provides it with a roof and a partial medial boundary. It is related laterally to the maxillary sinus and inferiorly to the mouth. The **naso-lacrimal canal** opens into it under cover of the anterior part of the inferior concha.

The junction of the middle meatus and its atrium is opposite the fossa for the lacrimal sac in the orbit, and the mucous lining of the nose is separated from the sac by the lacrimal bone and the frontal process of the maxilla. The **naso-lacrimal canal** is situated in the side-wall of the nose between the nasal cavity and the maxillary sinus. It is 10 or 12 mm. in length, and it is bounded laterally and antero-medially by the walls of a deep groove in the maxilla, while postero-medially it is bounded by the lower part of the lacrimal bone and the inferior concha.

The apertures which lead into or out of the nose are the following :—

The *posterior bony aperture*; the *anterior bony aperture*, or, when soft parts are present, the *nostril*; the *naso-lacrimal canal*; and the *openings of the sinuses*, namely, sphenoidal, ethmoidal, frontal, and maxillary. The **sphenoidal sinus** opens into the spheno-ethmoidal recess; the **posterior ethmoidal sinuses** open into the superior meatus; the **middle** and **anterior ethmoidal sinuses**, the **frontal sinus** *via* the infundibulum, and the **maxillary sinus** open into the middle meatus. The *naso-lacrimal canal* opens into the inferior meatus.

Besides the foregoing there are certain apertures in the dried skull which are covered over with mucous membrane before maceration, viz.: The *spheno-palatine foramen* opens out of the pterygo-palatine fossa into the posterior part of the superior meatus; there is an additional opening out of the maxillary sinus into the middle meatus; the *incisive canal* leads down from the anterior part of the floor of the nose into the incisive fossa; and the *foramina in the cribriform plate* in the roof

transmit the olfactory nerves from the nose to the median part of the anterior cranial fossa.

General Relations of the Nose (Fig. 165).—**Superior,** from before backwards: the frontal sinus; the anterior or ethmoidal part of the median division of the anterior cranial fossa; the sphenoidal sinus, separating the nose from the posterior part of that fossa and from the median division of the middle cranial fossa. **Inferior**: the mouth. **Posterior**: the nasal part of the pharynx. **Lateral**: the pterygoid fossa, the pterygo-palatine fossa, and the greater palatine canal opposite the posterior section of the cavity; farther forward, the ethmoidal sinuses, the infundibulum, and the orbit, opposite the upper half of the middle section of the cavity, while opposite the lower half there are the maxillary sinus and the naso-lacrimal canal; the anterior section is situated in the external nose and is related laterally to the exterior.

PARANASAL SINUSES

The **paranasal air-sinuses** (Figs. 165, 166) are cavities in the interior of certain of the skull-bones, namely, the *frontal*, the *ethmoid*, the *sphenoid*, the *maxilla*, and the *palatine*. They all communicate either directly or indirectly with the cavity of the nose. The sphenoidal, ethmoidal, and maxillary communicate directly; the frontal and the palatine, indirectly. They are all lined with mucous membrane which is continuous, round the lips of the apertures of communication, with the mucous lining of the nose; and disease can readily spread from the nose to the sinuses. During a severe "cold in the head", the inflammation often extends from the nasal mucous lining to the mucous lining of sinuses, giving rise to frontal headaches (frontal sinus), pain in the cheek (maxillary sinus), pain between the eyes (ethmoidal sinuses), deep-seated pain at the back of the eyes (sphenoidal sinus). (See also p. 1213, where references to radiographs are given.)

The walls of the sinuses are composed of compact bone; for, in the ethmoid, spongy bone is not formed, and in the other pneumatic bones the sinuses take the place of the spongy substance and its marrow, which have been absorbed to make room for them. They are lined with endosteum, which is blended with the mucous lining; and the mucous lining, like that of the nose, is covered with ciliated epithelium.

At birth the ethmoidal and sphenoidal sinuses are present but are very small; the maxillary sinus is a mere groove; the frontal appears during childhood. They all enlarge gradually till puberty, and rapidly after puberty till they attain their full adult size; in old age they enlarge further, owing to the absorption of the diploë adjoining them.

The sinuses act as resonating chambers for the voice; and by means of them the bones containing them, without increase of weight, gain increase of bulk and the shape necessary for the formation of the walls of the cavities of the nose, mouth, and orbits. They are relatively larger in men than in women.

The **maxillary sinus** (Figs. 165, 166) is a large cavity that occupies the body of the maxilla. It is *lateral* to the lower half of the nasal cavity, *below* the orbit, *in front of* infratemporal fossa, and *above* the molar and premolar teeth—its deepest part being above the first molar and second premolar tooth. The opening out of it is on the medial side; in a separated maxilla the opening is very wide, but, when in position in the skull, is overlapped by adjoining bones and reduced to two small apertures, or perhaps three. When the mucous membrane is in place, only the uppermost of these apertures is left uncovered, to open out of the **uppermost** part of the sinus into the lower or posterior part of the hiatus semilunaris of the middle meatus.

The **maxillary sinus** is the largest of the sinuses; it is variable in size and may differ in the two sides of the same skull. Average measurements, in round numbers, are 35 mm. in height, 30 mm. in antero-posterior depth, and 25 mm. in width. In shape it resembles a pyramid laid on one side. The **apex** is situated in the zygomatic process of the maxilla. The **base** or **medial wall** separates it from the inferior meatus and the lower, wide part of the middle meatus, and is formed by the medial or nasal surface of the maxilla and the bones that almost completely

close the large opening in the upper part of that surface, namely, portions of the uncinate process of the ethmoid, the palatine, the lacrimal, and the inferior concha.

The secretions of the mucous lining of the sinus are swept towards the orifice in the medial wall by the cilia of the epithelial covering of the mucous membrane; in inflammatory conditions, when the quality of the secretion clogs the action of the cilia or the quantity is too great for them to cope with, the sinus fills up, since the orifice is at its uppermost part.

The **floor** of the sinus is the alveolar process of the maxilla, and is the thickest wall of the sinus, though the process is excavated by the sockets for the teeth. The teeth whose roots are in relation to the floor vary from the three molars as a minimum to the molars, premolars, and the canine as a maximum. The roots of the first two molars produce eminences in the floor, and, though usually covered with thin bone, they may perforate the floor. Incomplete septa springing from the intervals between teeth may partially divide the sinus into compartments. The floor is below the level of the floor of the nose; the lowest part is about

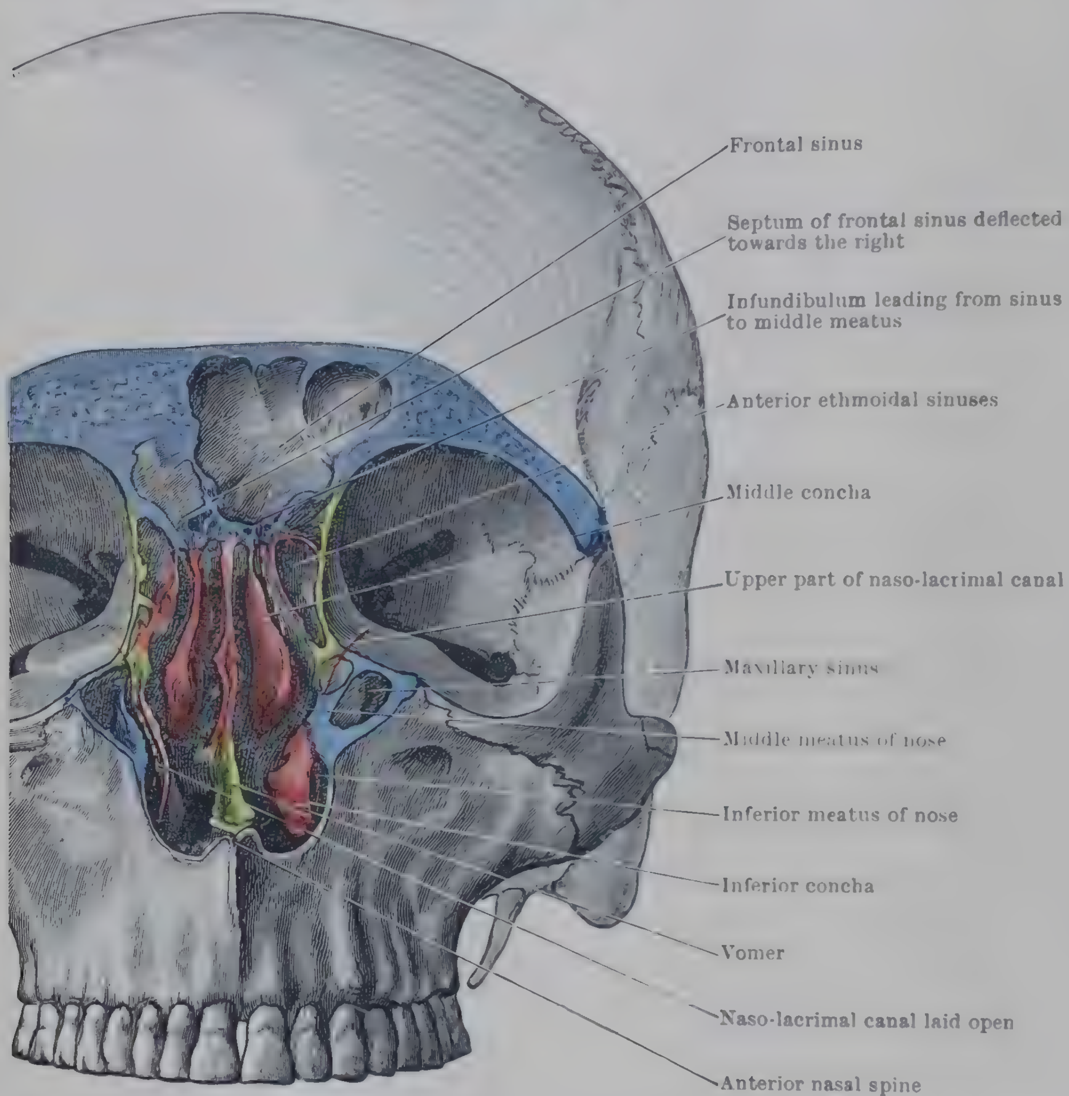

FIG. 166.—PART OF THE FRONTAL, NASAL, AND MAXILLARY BONES REMOVED IN ORDER TO DISPLAY THE RELATION OF THE VARIOUS CAVITIES EXPOSED.

Red: ethmoid; inferior concha. **Blue**: frontal and maxillary (where cut). **Yellow**: lacrimal; vomer.

10 mm. below the level of the nose, and overlies the roots of the first molar and second premolar teeth. The **posterior wall** is the bone of the posterior surface of the maxilla, which separates the sinus from the infratemporal and pterygo-palatine fossæ. The **posterior dental canals**, which convey the vessels and nerves to the molar and premolar teeth, are in the lower part of the posterior and **lateral** walls. The **roof** is the bone of the orbital surface of the maxilla, which separates the sinus from the orbit. The **infra-orbital groove and canal** are in the roof and may produce a ridge, especially at the angle between roof and anterior wall. The **anterior wall** is the bone of the anterior surface of the maxilla. The branches of the infra-orbital vessels and nerve to the canine and incisor teeth descend through canals in the anterior wall, but occasionally one or more of the canals may be defective; the corresponding vessels and nerve then lie between the bone and the mucous lining. The upper and anterior part of the sinus extends far enough forwards to be in front of the naso-lacrimal canal as well as lateral to it.

The maxillary sinus is the first sinus to appear; though, at birth, it is merely a groove on the medial side of the bone in the region of the middle meatus, yet that groove began to appear in the fourth month of intra-uterine life.

The **frontal sinus** is a cavity in the frontal bone; it is separated from its fellow by a complete bony septum which is usually bent to one or other side. It is immediately above the supra-orbital margin and above the root of the nose. If large, it extends backwards in the roof of the orbit between the two tables of the orbital plate. The frontal sinus may open directly into the nasal cavity through an opening in the nasal part of the frontal bone, but more commonly one of the anterior ethmoidal sinuses is converted into a passage, called the **infundibulum**, by means of which the sinus drains into the middle meatus, for the upper end of the infundibulum opens into the sinus and its lower end opens into the upper or anterior end of the hiatus semilunaris.

The **frontal sinus** varies greatly in size in different skulls, and may vary on the two sides of the same skull—the left usually being the larger. Average measurements are 30 mm. in height, 25 mm. in transverse width, and 20 mm. in antero-posterior depth. The configuration of the brow in the living person gives no indication of its size; in a well-formed skull one or both may be absent, or it may extend laterally as far as the temporal fossa and backwards in the roof of the orbit as far as the optic foramen. The septum between the right and left sinuses is usually median inferiorly and bent to one side above. The sinus is related *inferiorly* to the orbit, the nose, and the anterior ethmoidal cells; *postero-superiorly* to the cranial cavity and the brain.

An indication of the frontal sinus may be met with at the second year, but it cannot be definitely recognized till the seventh.

The **ethmoidal sinuses** are numerous small, thin-walled, intercommunicating cavities that occupy the labyrinth of the ethmoid. They are therefore between the orbit and the nasal cavity, and below the cranial cavity, from which they are separated by the medial part of the orbital plate of the frontal bone. They are divided into three groups—anterior, middle, and posterior. The **posterior sinuses** open into the superior meatus of the nose by one or more apertures. The **middle sinuses** open into the middle meatus on the surface of the bulla ethmoidalis by one or two apertures. The **anterior sinuses** open into the hiatus semilunaris of the middle meatus and into the infundibulum.

The walls of the **ethmoidal sinuses** are completed by the bones with which the ethmoid labyrinth articulates—the body of the sphenoid, the orbital process of the palatine bone, the orbital plate of the frontal bone, the lacrimal bone, the frontal process and the medial margin of the orbital surface of the maxilla. They are related *laterally* to the orbit; *medially* to the upper half of the cavity of the nose; *posteriorly* to the sphenoidal and palatine sinuses; *superiorly* to the sphenoidal sinus, the frontal sinus, the anterior cranial fossa, and to the ethmoidal canals between the orbital plate and the ethmoidal labyrinth; *inferiorly* the posterior sinuses are related to the superior meatus, into which they open, and the middle and anterior sinuses are related to the lower part of the middle meatus.

The ethmoidal sinuses begin to develop during the latter half of intra-uterine life, and the papery bone of the ethmoid is deposited around them in the cartilage of the nasal capsule.

The **sphenoidal sinus** is a large cavity in the body of the sphenoid bone. It is situated above the cavities of the naso-pharynx and nose, and below the median part of the cranial cavity. It is divided into right and left halves by a complete bony septum, which is usually bent to one or other side: each half may be referred to as a sphenoidal sinus, and it opens into the spheno-ethmoidal recess of the nose by a round aperture 4 or 5 mm. in diameter.

The **sphenoidal sinus** may be small and limited to the anterior part of the body of the sphenoid; or it may occupy the whole of the body and extend into the roots of the wings and pterygoid processes, and backwards into the basilar part of the occipital bone. Its average dimensions are about 20 mm. each way.

Inferiorly it is related to the cavity of the naso-pharynx and posterior part of the nose and to the pterygoid canal with its contained nerve and vessels. *Anteriorly* it is related to the upper part of the middle section of the cavity of the nose and to the posterior ethmoidal sinuses. *Laterally* it is related: (1) to the optic nerve in the optic foramen, and to the apical part of the orbit; (2) behind that, to the cavernous venous sinus, in the walls of which the internal carotid artery, the third, fourth, sixth, and ophthalmic nerves are imbedded; (3) to the maxillary nerve as it runs forwards along the lower border of the cavernous sinus and as it passes through the foramen rotundum. *Superiorly* it is related: (1) to the frontal lobes of the brain and the olfactory tracts, lying on the anterior part of the body of the sphenoid; (2) more remotely, to the optic chiasma, which is above the optic groove; (3) to the hypophysis cerebri, lying in the hypophysial fossa; (4) to the pons and the basilar artery, lying on the clivus.

The rudiments of the sphenoidal sinuses appear in the fifth month of intra-uterine life or a little later. They are recesses of the nasal cavity that are partly cut off from it and are enclosed within

the sphenoidal conchæ (p. 225) when they begin to ossify. But those rudiments do not begin to extend into the body of the sphenoid till the seventh or the eighth year.

The **palatine sinus**, when present, occupies the orbital process of the palatine bone, and it opens either into the sphenoidal sinus or into a posterior ethmoidal sinus.

Mandible

The **mandible** or lower jaw-bone lies below the anterior part of the cranium and is the skeleton of the lower part of the face. It has a horseshoe-shaped **body** and a pair of flat, broad **rami**, which stand up from the posterior part of the body. Each ramus is surmounted by two processes, the anterior of which is named the **coronoid process**, and the posterior is the **condyloid process** ; the condyloid process has an articular part, called the **head**, supported on a more constricted part called the **neck**.

The right and left halves of the **body** of the mandible are fused together in the median plane in front but are widely separated behind. Their junction is called the **symphysis menti** [σύν (syn) = together ; φύω (phyō) = grow ; *mentum* = the chin]. The halves are joined together by fibrous tissue at birth, but they are fused together into one bone during the second year.

On the front of the mandible, along the line of the symphysis, there is a faint, vertical ridge. This ridge swells out inferiorly into a triangular elevation, of varying prominence, called the **mental protuberance**; the lower angles of the triangle form the *mental tubercles* ; in the region of the protuberance, the bone is bent forwards to produce the prominence of the **chin**. The forward projection of the lower part of the middle of the mandible to make the chin is a Human characteristic : among lower animals, not even the higher apes (Gibbon, Gorilla, Orang-utan, and Chimpanzee) have chins as an outstanding feature ; and the prominence of the chin is not so marked in the primitive races of Man as in the higher, though the mandible as a whole may be a heavier bone.

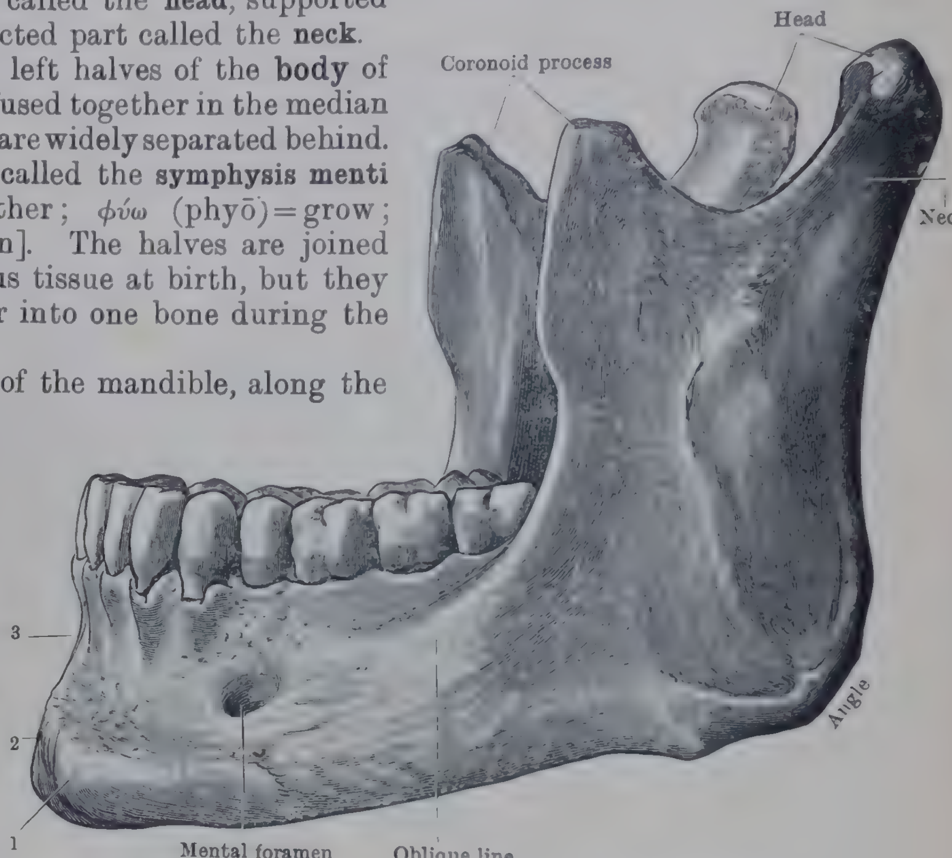

FIG. 167.—MANDIBLE AS SEEN FROM THE LEFT SIDE.
1. Mental tubercle. 2. Mental protuberance. 3. Symphysis.

Each half of the body of the mandible has an outer and an inner surface and an upper and a lower border. The surfaces slope so that the lower border of the whole bone makes a wider arch than the upper border.

The upper part is called the **alveolar** part, because it is occupied by a row of pits or **alveoli** forming the sockets for the teeth. They are visible on the *upper border* if the teeth have fallen out after death. On each side the sockets for the two incisors, the canine, and the two premolars are single, but those for the three molars are double, for each mandibular molar has two roots—an anterior and a posterior. When teeth are removed during life the walls of the sockets are gradually absorbed until no evidence of them is left ; the upper border of the mandible in the region of the lost teeth is smooth, and the vertical diameter of the bone is reduced.

The *lower border* is the **base** of the mandible. On or behind this border, at the

side of the symphysis, there is a broad, rough mark or depression called the **digastric fossa.** The rest of the border is smooth and rounded and has a slight fullness or downward convexity about its middle.

The **outer surface** is slightly convex, but has a broad, shallow depression alongside the symphysis below the incisor teeth. An oblique opening is seen about an inch from the symphysis, below the second premolar or the interval between the premolars; it is called the **mental foramen** and is about midway between the upper and lower borders if the sockets are present, but is near the upper border if the walls of the sockets have been absorbed. Below the mental foramen there is an ill-defined ridge called the *oblique line*; it extends from the mental tubercle to the anterior border of the ramus but is not well marked till it approaches the ramus.

The **inner surface** is undulating—being convex and concave at different parts. Low down on the back of the symphysis there is a rough mark which, when well developed, is divided into two pairs of little eminences called the **genial tubercles** [γένειον (geneion) = the chin].

At the side of the symphysis, a little above the digastric fossa, there is a smooth, shallow depression, about the width of a thumb-print, called the **sublingual fossa.** Farther back there is an elongated, shallow depression, the **submandibular fossa,** which extends on to the ramus; inferiorly it reaches the lower border of the mandible; superiorly it is bounded by an oblique ridge, called the **mylo-hyoid line,** which begins at the level of the socket of the last molar tooth and passes downwards and forwards to the posterior margin of the digastric fossa; the lower or anterior part of the line is faint, and separates the submandibular and sublingual fossæ from each other.

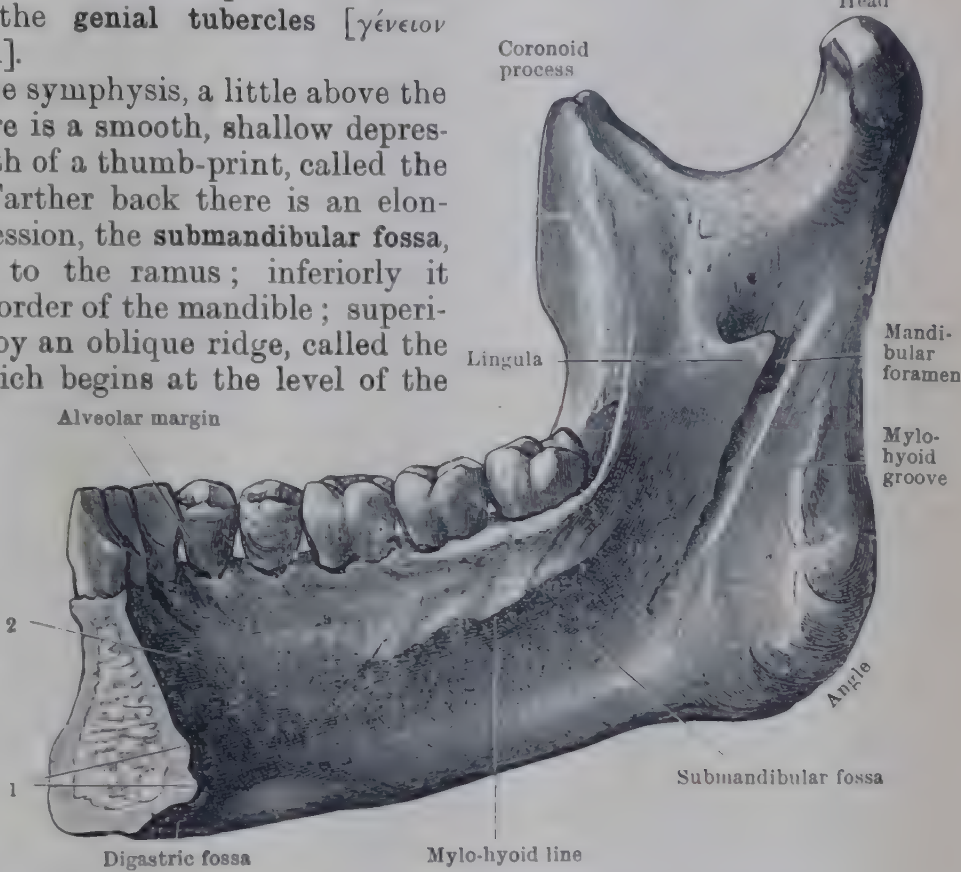

FIG. 168.—MEDIAL SURFACE OF RIGHT HALF OF MANDIBLE.

1. Upper and lower genial tubercles. 2. Above sublingual fossa.

The **ramus** of the mandible is, properly, the broad, flattened plate that rises up above the level of the posterior part of the body; but, to simplify the description of the attachment of muscles, it is convenient to include the bone down to the lower border under the term *ramus*; at the same time it is not necessary to divide the lower border: it is the lower border of the mandible, irrespective of division into body and ramus. Each ramus has a lateral and a medial surface, an anterior and a posterior border, and an upper end or border surmounted by the coronoid and condyloid processes, which are separated by a wide gap called the **mandibular notch.**

The **lateral surface** is fairly flat, and rather rough. Where the ramus and body join, at the lower border of the bone, a faint groove may be detected; if the finger-tip is placed on the corresponding point in a living person the pulsing of the facial artery can be felt as it crosses the lower border of the mandible to enter the face. The **medial surface** is more uneven. About its centre there is an oblique opening, the **mandibular foramen,** leading into a **canal** which runs downwards and forwards in the substance of the bone and carries the vessels and nerves for the teeth. The spur of bone that overlaps the foramen anteriorly is the **lingula.** A narrow groove, called the **mylo-hyoid groove,** begins at the lower margin of the

foramen, runs downwards and forwards and fades away in the sub-mandibular fossa. The **anterior border** of the ramus is sharp, and is continuous with the oblique line of the body. The **posterior border** is smooth and rounded; the point where it meets the lower border is the **angle of the mandible**—a landmark easily felt in the living subject.

The **coronoid process** is flattened and pointed; it is triangular in outline, and is named from its resemblance, when looked at sideways, to the beak of a bird [κορώνη (corōnē) = a sea-crow]. Its anterior border is continuous with the anterior border of the ramus, and both can be felt inside the mouth above and behind the last molar tooth. Its posterior border bounds the mandibular notch anteriorly. Its surfaces are continuous with those of the ramus; on its medial side a low blunt ridge begins near its top and extends down to the medial margin of the socket of the last molar tooth.

The **condyloid process** has two parts—an articular head or condyle supported on a constricted neck.

The **head** of the mandible is elongated transversely with its long axis directed medially and slightly backwards. It includes only the part that is smooth and coated with cartilage; it has therefore an upper and a posterior surface and a small, negligible anterior surface. The head articulates with the articular fossa and eminence of the temporal bone—but not directly: an articular disc of fibro-cartilage separates the head from the temporal bone, and, since its circumference is attached to the capsular ligament of the joint, it divides the joint-cavity into an upper and a lower compartment. When the mandible is at rest, with the mouth shut, the upper surface of the head is in contact with the disc below the articular fossa; as the mouth is opened the mandible rotates, and at the same time the head and the articular disc travel downwards and forwards till they come to lie beneath the articular eminence. The head can be felt in front of the auricle, and the finger can follow its movements as the mouth is opened and shut.

The **neck** of the mandible is obliquely compressed from before backwards. The *medial* and *lateral surfaces* are narrow, but widen out inferiorly as they merge into the surfaces of the ramus. The *posterior surface* is smooth, and is continuous with the back of the head and the posterior border of the ramus. The *anterior surface* is rough and hollowed out, and is overhung by the anterior margin of the head; it is continuous inferiorly with the medial surface of the ramus, and the sharp margin between it and the lateral surface is the posterior boundary of the mandibular notch.

The **alveolar part** is thicker behind than in front; it is covered on both surfaces with mucous membrane, and it gives attachment to the gums around the mouths of the sockets. The socket of the canine tooth may produce a vertical eminence on the labial surface of the bone, and the incisor sockets also may do so.

The mucous membrane of the mouth covers the **outer surface** of the body down to a line drawn from the last molar socket to the apex of the mental protuberance. The lower part of the buccinator arises from the lateral surface opposite the *molar sockets*; the incisive muscle, opposite the *incisor sockets*; the mentalis, from a point opposite the bottom of the *canine socket*; the depressor labii inferioris, from a line that joins the mental tubercle and foramen; the depressor anguli oris, from the anterior part of the **oblique line** below the mental foramen. The **mental foramen** opens obliquely upwards and slightly backwards, and it transmits the mental vessels and nerve; it may be double on one or both sides. The facial artery lies on the mandible at the junction of body and ramus. The **lower border** of the mandible gives attachment to the deep fascia of the neck; and the platysma is inserted into the anterior half of it.

The mucous membrane covers the **inner surface** of the body down to a line drawn from the posterior end of the mylo-hyoid line to a point immediately above the genial tubercles. A small vascular foramen is situated opposite the interval between the incisor sockets on each side; and another is placed in the symphysis above the genial tubercles; the genio-glossus and genio-hyoid arise from the upper and lower **genial tubercles** respectively; the anterior belly of the digastric from the floor of the **digastric fossa**; the mylo-hyoid from the **mylo-hyoid line**, the posterior end of which gives attachment also to fibres of the superior constrictor and the buccinator and to the lower end of the pterygo-mandibular ligament. The two mylo-hyoid lines are the sides of an arch which is smaller than the arches made by the upper border and the lower border; for the surface above the lines slopes upwards and outwards, and the surface below slopes, to a still greater degree, downwards and outwards. The sublingual gland lies in the **sublingual fossa**; and the submandibular gland lies in the **submandibular fossa**.

The **mandibular foramen** transmits the inferior dental vessels and nerve; their mylo-hyoid branches run along the **mylo-hyoid groove**, which may be partly converted into a tunnel. The medial pterygoid muscle is inserted into the rough patch that separates the foramen and groove from the angle of the mandible. The spheno-mandibular ligament is attached to the **lingula**; the stylo-mandibular ligament is attached to the **posterior border** *of the ramus* and also to the angle. The **angle** is usually everted and is slightly obtuse in a well-formed adult jaw, more obtuse in childhood, and still more in old age after the teeth have been lost. In a young adult the slope of the jaw from angle to chin expresses almost the whole degree of obtuseness of the angle, for the posterior border of the ramus is nearly vertical; but not so in old edentulous persons, for in them the posterior border of the ramus slants downwards and forwards, chiefly owing to the backward tilt of the condyloid process. In mandibles of old people the increase of obtuseness is not so much in the angle proper as in the angle between the anterior margin of the ramus and the upper margin of the body.

The masseter is inserted into the **lateral surface** of the ramus and covers the ramus and the coronoid process, leaving the head and neck without a covering of muscle; the temporalis is inserted into the medial surface and the margins of the **coronoid process** and also into the anterior margin of the ramus and the blunt ridge on the medial side. In some specimens an oblique canal traverses that ridge; the canal transmits the buccal nerve. The coronoid process varies considerably in length, but its tip usually lies under cover of the anterior part of the zygomatic arch.

The long axis of the **head** is nearly horizontal and is directed latero-medially and backwards. The posterior surface is slightly convex; so also is the upper surface, which overhangs the front of the neck and ends in little tubercles that overhang the sides of the neck. The capsular ligament of the mandibular joint is attached to the margins of the articular surfaces of the head; a thickened part of the capsule, called the temporo-mandibular ligament, is attached to the lateral side of the **neck**. The lateral pterygoid muscle is inserted into the front of the neck and the capsule. If the finger is placed in the auditory meatus, the meatus can be felt widening as the mouth is opened, for when the mouth is shut the back of the head exerts pressure on the meatus, though it is separated by a portion of the parotid gland; the lateral side of the head and neck also is overlapped by the parotid gland and is crossed by the temporal and zygomatic branches of the facial nerve, which may be rolled between the finger and the bone. The external carotid artery ends behind the neck; the superficial temporal artery, accompanied at that level by the posterior facial vein, runs upwards behind the lateral end of the head; the maxillary artery passes forwards medial to the root of the neck; the auriculo-temporal nerve winds round the medial side and the back of the neck and joins the superficial temporal artery. The vessels and nerves to the masseter pass in a lateral direction,

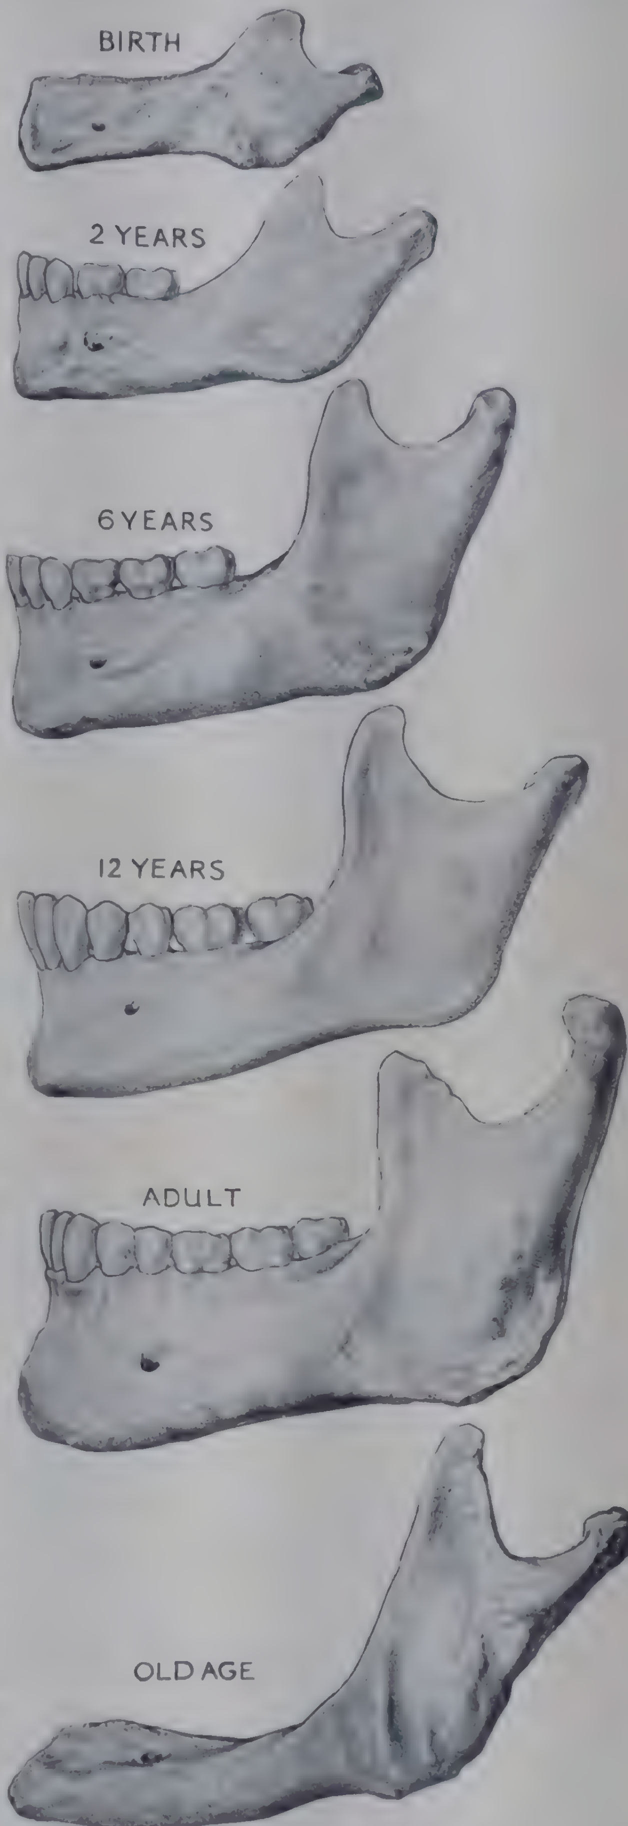

Fig. 169.—Form of Mandible at different Ages. By the sixth year the first permanent molar has erupted behind the milk teeth; by the twelfth year the milk teeth have been replaced by the corresponding permanent teeth, and the second permanent molar has erupted.

through the **mandibular notch**, in front of the neck. When the mandible is in position in the head, a stilette inserted in front of the neck of the mandible can be thrust from one mandibular notch to the other; it passes below the foramen ovale, and therefore would transfix the mandibular nerve.

Differences due to Age.—At birth the two halves are united by fibrous tissue; the body is a mere shell that encloses the rudimentary *teeth*, which are imperfectly separated from one another; the *mandibular canal* is relatively wide and is near the lower border; so also is the *mental foramen*, which is opposite the cavity for the first milk molar tooth. The *ramus* is relatively short; the *condyloid process* is almost in line with the body, and the angle is therefore very obtuse; the *head* is relatively large, and the *coronoid process* rises to a higher level than the head.

During the first year the halves unite from below upwards, and union is completed during the **second** year. As the teeth erupt and the child begins to chew, the depth of the body increases by the growth of the walls of the sockets, the lower part thickens, the rami enlarge and the angle becomes less obtuse, being about 140° in the fourth year. As growth advances the depth increases, and the body elongates, especially behind the mental foramen to provide room for the permanent molars; the mental foramen assumes its adult position and the angle is reduced to 110°.

In **old age** after teeth are lost the walls of the sockets are absorbed; the chin appears therefore more prominent, and the mental foramen is near the upper border. The angle opens out to 140° and the condyloid process is bent back so that the mandibular notch is wider.

Structure.—The body of the mandible is thicker than the rami, and it is thickest near the rami at the level of the mylo-hyoid and oblique lines, for there the mandible is subject to the greatest strain when the elevating muscles bring it into contact with the resisting upper jaw. The tables of compact bone are exceptionally dense and are very thick where they join together at the lower border. The lingual walls of the sockets are considerably thicker than the labial walls, except in the case of the **third molar** socket, where the labial wall is the thicker. The spongy substance is open-meshed below, but finer and more condensed in the walls of the sockets. The *canal* of the mandible is in the spongy substance, about the level of the mylo-hyoid line, and does not have a definite wall; the mental foramen branches off the canal, and so do the channels that carry blood-vessels and nerves to the teeth.

Development and Ossification.—The **mandible** begins to ossify during the sixth week of intra-uterine life—before any other bone in the body, except the clavicle. Each half is developed from (1) the membrane that overlies Meckel's cartilage, (2) the anterior portion of Meckel's cartilage, (3) certain accessory cartilages that appear between the eleventh and fourteenth weeks. The greater part of the mandible is developed from the membrane. The extreme anterior end of Meckel's cartilage disappears, but a part of it is incorporated in the mandible from a point near the symphysis backwards to the level of the mental foramen. One of the accessory cartilages forms the head and a narrow wedge-like part in the ramus; another forms a narrow strip along the front of the coronoid process; and some accessory nodules take a share in forming the symphysial part of the bone. These different structures are not ossified from separate centres. Each **half** of the mandible is ossified from **one** centre, and it appears in the membrane that overlies the anterior part of Meckel's cartilage. The ossifying process spreads through the membrane and envelops and invades the cartilages. Some small nodules, called *ossicula mentalia*, which appear at the symphysis shortly before birth and fuse with the mandible shortly after birth, may be derived from independent ossific centres in the accessory cartilages. (See Low, 1909; Fawcett, 1924, 1930.)

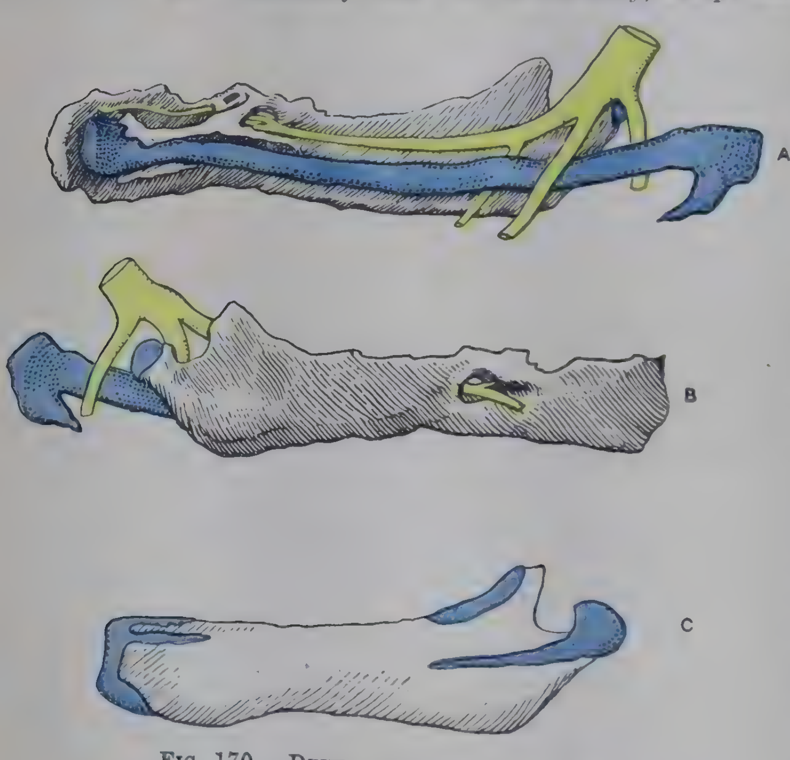

Fig. 170.—Development of Mandible.

A, As seen from the medial side; B, from the lateral side; C, showing accessory (metaplastic) cartilages (blue).

(In A and B Meckel's cartilage is coloured blue.)

Meckel's cartilage is the cartilage of the first or **mandibular** arch of the embryo. Its posterior end is in the region of the ear; its anterior end almost meets its fellow of the other side. The posterior end ossifies to form two of the auditory ossicles, namely, *incus* and *malleus*; part of its anterior end is included in the mandible. The rest disappears; but the mylo-hyoid groove is the remains of the furrow in which part of it lay; and the *spheno-mandibular ligament* is derived

from the fibrous sheath around it, though it has been argued that that ligament is the remnant of a muscular slip.

Growth.—The mandible grows in width between its angles as well as in length, height, and thickness. Increase of thickness is brought about chiefly by addition to the outer surfaces.

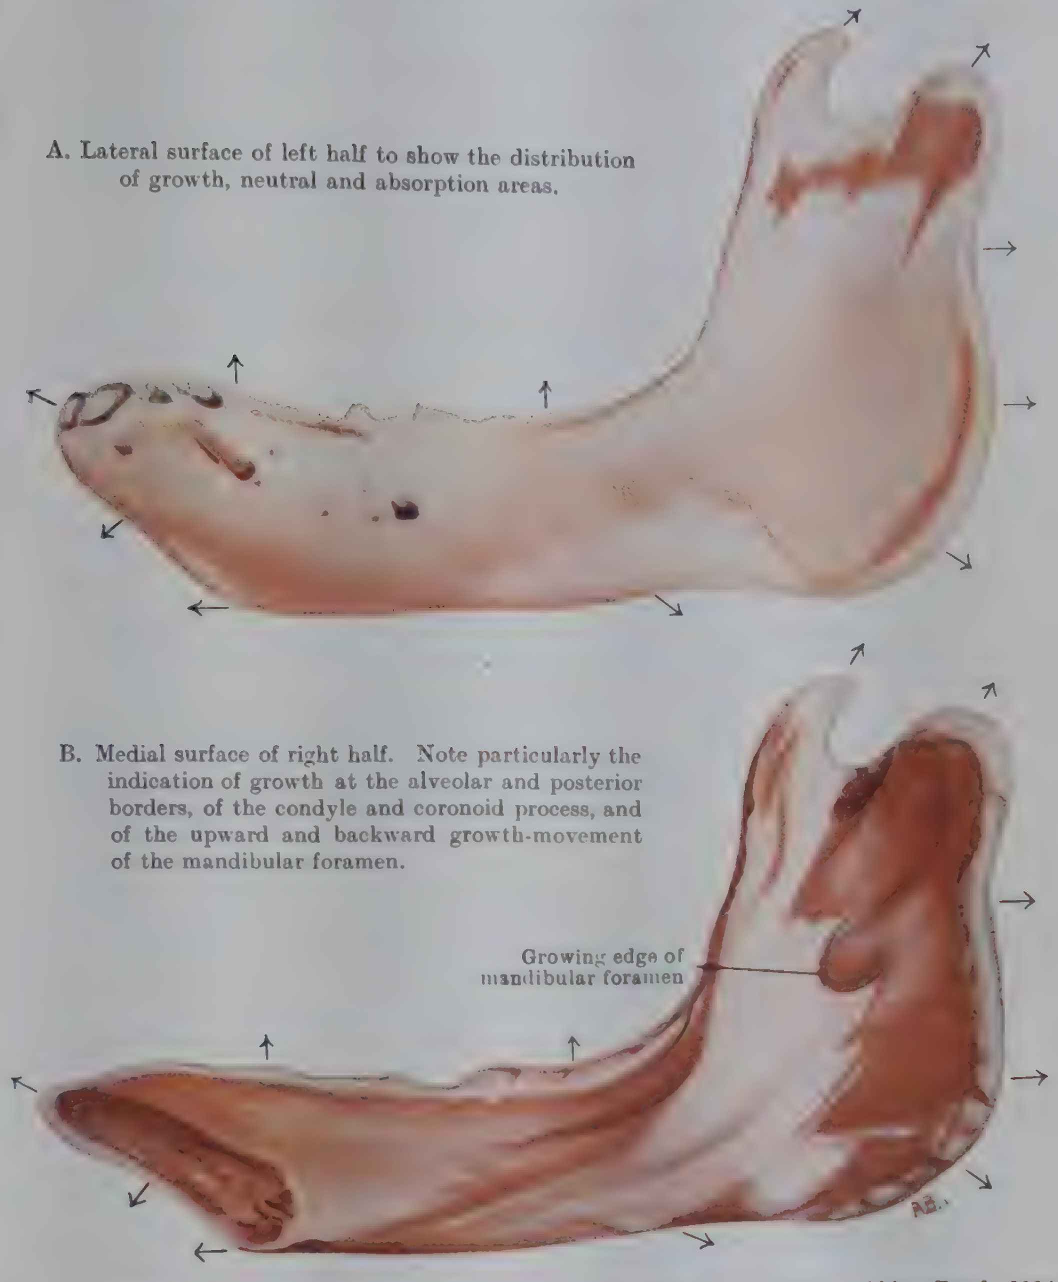

FIG. 171.—MANDIBLE OF MADDER-FED PIG TO SHOW THE SITES OF GROWTH. (After Brash, 1934.)

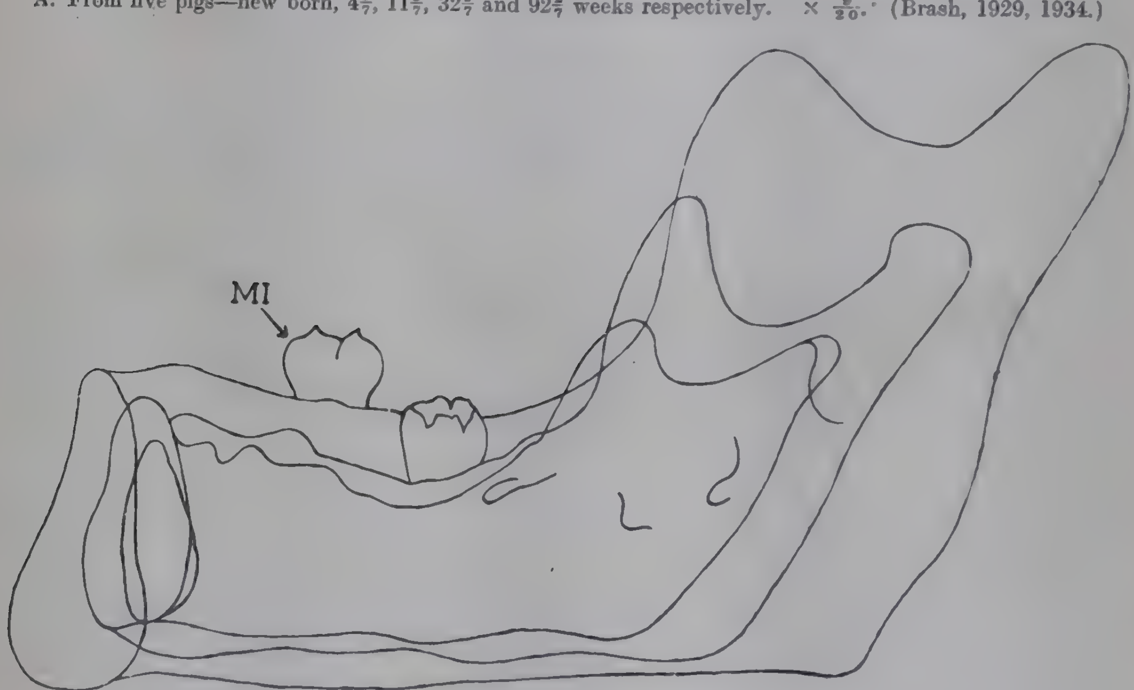
The animal was $20\frac{1}{7}$ weeks old and the madder had been omitted from the food for 19 days. The new bone added during that period is white in contrast to the old, red bone; and the main directions of growth are indicated by arrows.

Increase in height of the body is due mainly to growth at the alveolar border, and there is an associated continuous upward and forward movement of the teeth in the bone before, during, and after their eruption. The lengthening process is chiefly backwards. It takes place partly by addition to the posterior border, and, owing to the lateral slope of the body from before backwards, that accounts for increase of width also. But the main increase depends upon the obliquity of the ramus and its processes in a young jaw. The growth of the condyloid process is not only upwards but also backwards and sidewards, and it thus contributes to the total length as well as to height and width—a contribution that diminishes as the ramus becomes more vertical. The coronoid process grows upwards and backwards by addition to its tip. As the process grows, its sloping, anterior margin is encroached upon by the rising alveolar border, which thus becomes longer. This is the chief means of providing more room for the teeth as they rise with the alveolar border. As growth proceeds, modelling absorption maintains the shape of the condyle and the undulating curves of the anterior margin of the ramus and coronoid process. During the upward and backward growth of the ramus and coronoid process, the mandibular foramen maintains its relative position by a corresponding extension of its anterior lip, and the mandibular canal is thus lengthened. The mental foramen also changes its position during growth by moving backwards relative to the teeth (Fig. 169). In the young jaw its sharp edge is below and behind, but in the adult it is below and in front, an indication of its direction of movement as in the case of the mandibular foramen and of the nutrient canals of long bones (p. 117). (For further details and historical references see Brash, 1924, 1926, 1929, 1934.)

Teeth

There are two sets of **teeth**: the *deciduous* or milk teeth, which are shed during childhood; and those that are potentially *permanent*. For an account of the teeth and their arrangement in the jaws, see the Section on the Digestive System, pp. 566-574.

A. From five pigs—new born, $4\frac{3}{7}$, $11\frac{3}{7}$, $32\frac{1}{7}$ and $92\frac{2}{7}$ weeks respectively. $\times \frac{9}{20}$. (Brash, 1929, 1934.)



B. From three human mandibles—2 years, 6 years, and adult respectively—superimposed on the analogy of the known directions of growth in the pig. $\times \frac{1}{1}$.

FIG. 172.—SUPERIMPOSED OUTLINES OF PIG AND HUMAN MANDIBLES TO DEMONSTRATE THE DIRECTIONS OF GROWTH AND FORWARD MOVEMENT OF MOLAR TEETH.

Hyoid Bone

The **hyoid bone** lies in the front of the neck at the root of the tongue between the mandible and the larynx. It is named from its resemblance to the letter U [the Greek letter υ aspirated thus ὑ = hy; εἶδος (eidos) = shape]. It does not articulate with any other bone. It has a *body*, a pair of *greater horns*, and a pair of *lesser horns*.

The **body** is the middle part or bottom of the U. It can be felt in the

median line of the neck about a finger's breadth above the laryngeal prominence when the chin is held up. When the chin is depressed the hyoid bone is at or above the level of the point of the chin and is closer to the larynx. If one swallows or gulps while the finger is placed on the hyoid bone, the bone is felt rapidly ascending, for the tongue, the hyoid bone, and the larynx are all suddenly jerked upwards in the movement of swallowing.

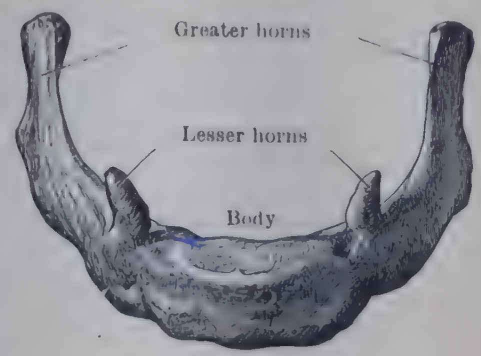


FIG. 173.—HYOID BONE.

The **greater horns** are the limbs of the U. They spring from the body about a finger's breadth from the median plane and extend backwards in the sides of the throat; they can be gripped between finger and thumb, but the tip of the greater horn, though often referred to as a landmark, is overlapped by the anterior edge of the sterno-mastoid muscle and cannot always be felt easily.

The **lesser horns** are small pointed nodules of bone that project upwards from the junction of the body with the greater horns.

The **body** is compressed from before backwards and is curved from side to side with the convexity forwards. It has an upper and a lower border, and an anterior and a posterior surface. The **anterior surface** is divided into an upper and a lower part by a transverse ridge on which there is sometimes a small median tubercle; the upper part looks upwards rather than forwards and is divided by a median ridge into right and left halves. The genio-hyoid is inserted into the upper part and a small adjoining area of the lower part. The anterior fibres of the hyoglossus arise at the side of the genio-hyoid; part of the mylo-hyoid is inserted below the genio-hyoid. The deep fascia of the neck is attached below the mylo-hyoid. The levator glandulæ thyroideæ, when present, arises below the attachment of the fascia near the median line.

The **lower border** gives insertion to the sterno-hyoid. The median thyro-hyoid ligament passes upwards behind the body to be attached to the **upper border**, which gives attachment also to the hyo-epiglottic ligament and, occasionally, to some fibres of the genio-glossus. The **posterior surface** is smooth and concave; it is separated by some fat and a *bursa* from the median thyro-hyoid ligament, which, in turn, is separated by a pad of fat from the stem of the epiglottis. When the larynx is pulled up during swallowing, the posterior surface of the hyoid bone overlaps the thyroid cartilage of the larynx, and the bursa lessens the friction between them.

The **greater horns** not only pass backwards, but have an upward and lateral inclination as well; they taper as they pass backwards, but each ends in a slightly swollen **tip**, to which the lateral thyro-hyoid ligament is attached. They are compressed, so that each has a lateral and a medial surface and an upper and a lower border, but the compression is oblique, and the surfaces are sometimes named upper and lower respectively, and the borders medial and lateral.

The **medial surface** is related to the thyro-hyoid membrane, which passes upwards between it and the mucous membrane of the pharynx to be attached to the **upper border**. The **lateral surface** is continuous with the front of the body. It gives origin to the middle constrictor near the upper border, and to the hyo-glossus below that; the attachment of the fascial sling of the digastric tendon and the insertion of the stylo-hyoid are close to the junction with the body. The deep fascia of the neck is attached near the lower border. The **lower border**, in its anterior two-thirds, gives insertion to the thyro-hyoid; the superior belly of the omo-hyoid is inserted into the anterior third, superficial to the thyro-hyoid, and overlaps the insertion of the sterno-hyoid on the body.

The **lesser horn** is situated on the upper aspect of the junction of the body and the greater horn, and is often in line with the transverse ridge on the front of the body. It projects backwards and slightly in a lateral direction as well as upwards; usually it is only a few millimetres in length, but may be 10 or 12 mm. A few fibres of the middle constrictor arise from its lateral surface, and the stylo-hyoid ligament is attached to its tip.

Development and Ossification.—The hyoid bone is developed from the cartilages of the second and third pharyngeal arches, the anterior ends of which are fused together. On each side, the greater horn and the greater part or whole of the body are derived from the cartilage of the third arch. The lesser horn and possibly the upper median part of the body are derived from the cartilage of the second or hyoid arch, which gives rise also to the stylo-hyoid ligament, the styloid process, and one of the auditory ossicles, namely, the *stapes*. Occasionally the stylo-hyoid ligament is ossified, and may be mistaken for a foreign body in the wall of the pharynx.

The hyoid bone is **ossified** from three pairs of centres. A pair (which soon unite into one) for the body and one for each greater horn appear shortly before birth, and one for each lesser horn appears during the first year. The greater horn is united to the body of the bone by a plate of cartilage which ossifies at middle age. The lesser horn is united by a synovial joint, which may disappear in old age.

The Skull at Birth

At birth the skull, compared with other parts of the skeleton, is large—especially the vault. The facial region, however, compared with the rest of the skull, is small (Fig. 176); in the adult the facial region, including the mandible, accounts for about one-half of the whole skull, but in the new-born child it is only one-eighth, for the teeth and the air sinuses are only rudimentary, and the mandible, the maxillæ, and the nasal cavities are therefore relatively small. A boy's head at birth is larger than a girl's, but so also is his body.

In the **vault**, the edges of the bones are not yet serrated, and they are separated by linear intervals filled with strips of fibrous tissue continuous with the pericranium on the outer surface of the bones, and with the dura mater on the inner

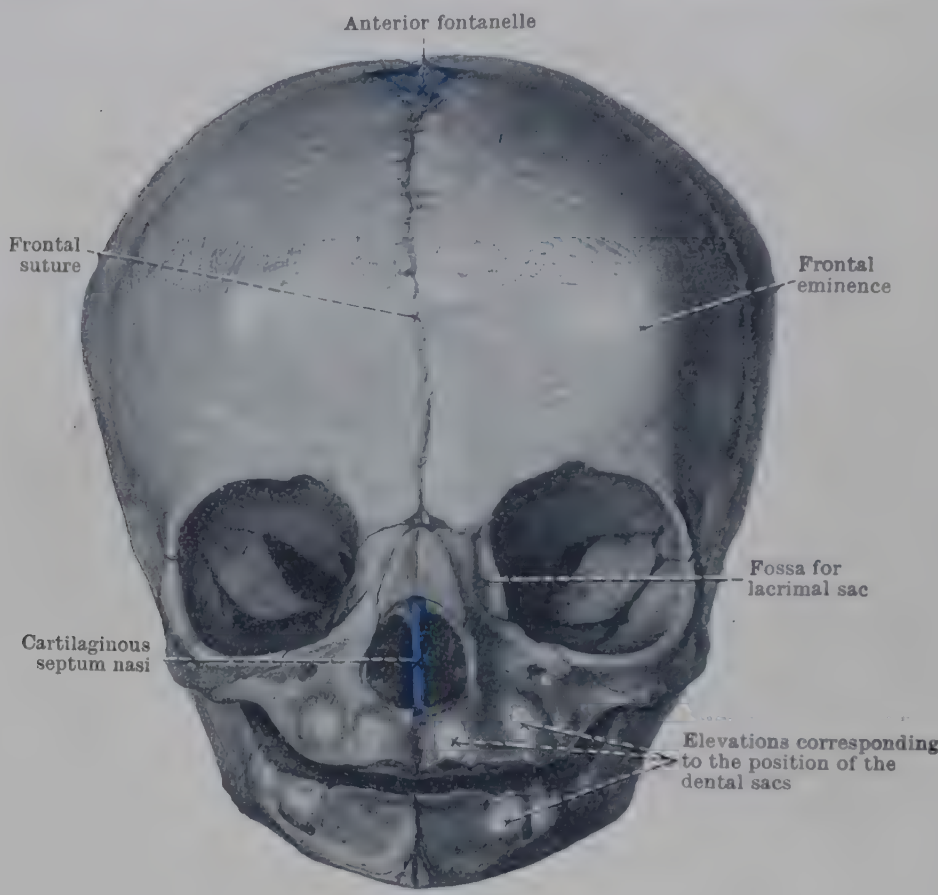

Fig. 174.—Frontal Aspect of Skull at Birth. (Cf. Pl. V, Fig. 1, p. 150.)

surface. Owing to the presence of these intervals, the bones of the vault have a degree of mobility that enables the head to be moulded into the required shape during the birth of the child. The bones are very thin, but they are little liable to fracture, for, in addition to their mobility, they are less brittle than in an adult, and the pericranium is very tough.

In certain situations there are areas, rather than linear intervals, between the bones of the vault. Those areas are called fontanelles. They are seven in number—anterior, sagittal, posterior, right and left antero-lateral and postero-lateral.

The **anterior fontanelle** is much the largest and is easily felt in the fore part of the top of the head in the new-born child. It is lozenge-shaped and measures about an inch and a half antero-posteriorly and an inch across. It is situated between the two halves of the frontal bone and the two parietal bones. The ossifying process going on in those bones spreads into the fibrous membrane of the fontanelle; the bones meet and the fontanelle is closed during the second year.

The **sagittal fontanelle** is a small unossified space at the *obelion*; it extends like a cleft from the sagittal suture into the upper part of each **parietal bone**; it is often quite closed at birth. The parietal foramina in the adult are derived from it and indicate its position.

The **posterior fontanelle** is situated at the apex of the occipital bone between the two parietal bones. It is closed two months after birth.

The **antero-lateral fontanelle** is situated at the anterior inferior angle of the parietal bone. It is closed three months after birth.

The **postero-lateral fontanelle** is situated at the postero-inferior angle of the parietal bone. It is closed at the end of the first year.

From irregularities in ossification, **sutural bones** may be developed in various sutures and at the fontanelles. Those formed at the antero-lateral fontanelle, being in the region of the pterion, are called **epipteric bones**.

At birth the *occipital* bone is in four separate pieces, and on each side of the squama there is a cleft that partially separates the upper (interparietal) part of the bone from the rest; occasionally the two clefts meet. The *sphenoid* bone is in three parts—a median and a pair of lateral parts—in addition to the two sphenoidal conchæ (p. 225). The median part comprises the body with the lesser wings; each lateral part comprises the greater wing and the pterygoid process. The dorsum sellæ is still cartilaginous, and ossifies slowly (Fig. 306 B, p. 335). The lower surface of

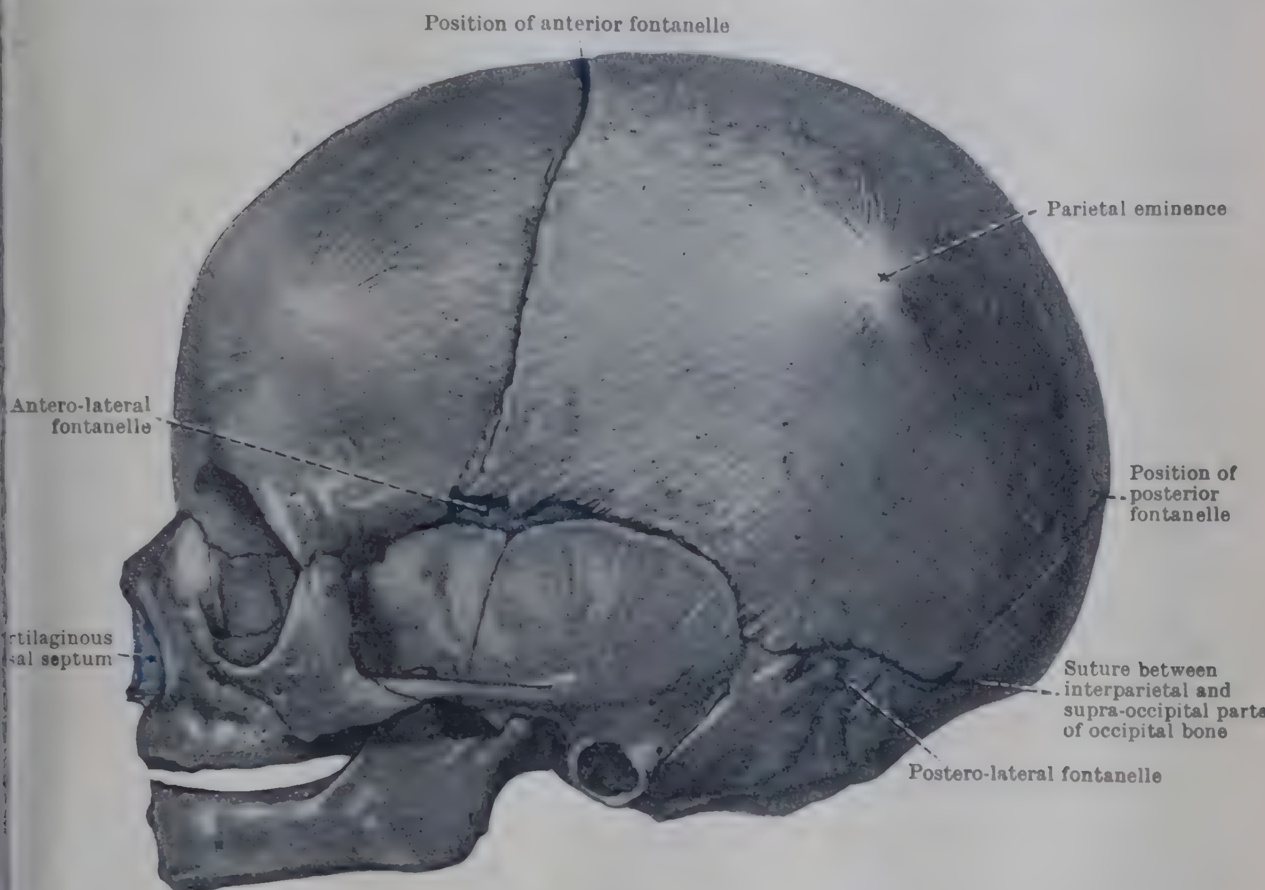

Fig. 175.—Lateral Aspect of Skull at Birth. (Cf. Pl. V, Fig. 2, p. 150.)

the body, between the conchæ, has a bullate appearance which it maintains for some years. The rudiments of the sphenoidal sinuses are present in the conchæ. The *temporal* bone is in four parts—petro-mastoid, squamous, tympanic, and the styloid process. The mastoid process has not begun to develop. The jugular fossa is poorly marked. The subarcuate fossa is large. The hiatus for the greater superficial petrosal nerve is an open groove. There is no *osseous* part of the external auditory meatus, for the tympanic part of the temporal bone is not a plate as yet, but is a mere ring—incomplete superiorly. The tympanic membrane is therefore near the surface of the head; the obliquity of the membrane is greater than in the adult; it looks downwards and forwards more than in a lateral direction. The styloid process and stylo-mastoid foramen also are near the side of the head, but they gradually recede from it, after the second year, when the mastoid process begins to grow and the tympanic ring begins to become a plate. The articular fossa is shallow and relatively large, and it looks in a lateral direction as well as downwards.

The halves of the *mandible* are separate. The ramus is relatively short but wide, the angle is very obtuse, and the coronoid process is at a higher level than the head. The body has little substance beyond the walls of a wide groove incompletely divided into compartments for the dental sacs; the mental foramen is near the lower border. (See also p. 204.)

The *maxilla* is vertical and of small height, for the maxillary sinus is a mere groove in the lateral wall of the middle meatus; the distance between palate and orbit is therefore short. The alveolar process is small, reaching only a little below the level of the zygomatic arch; and it is hollowed out for the dental sacs.

The perpendicular plates of the *palatine bones* are short; the *posterior apertures* and *cavity of the nose* are low. But the *bony anterior aperture* is relatively large and is a broad ovoid in outline; its lower margin is not far below the inferior orbital margin; for the nasal cavity is situated almost entirely between the orbits. The *nasal bones* are nearly flat.

The *ethmoid* is small. Its *perpendicular plate* is still cartilaginous, and is united to the labyrinth by a fibrous lamina. The *labyrinth* is already bony and contains the *sinuses* in the form of narrow pouches.

The *vomer* consists of two small plates of bone—a right and a left—separated by cartilage, but united along their lower edges; and they are not completely fused till puberty.

The *orbital opening* is large and nearly circular, and it has sharp margins; the orbital fissures

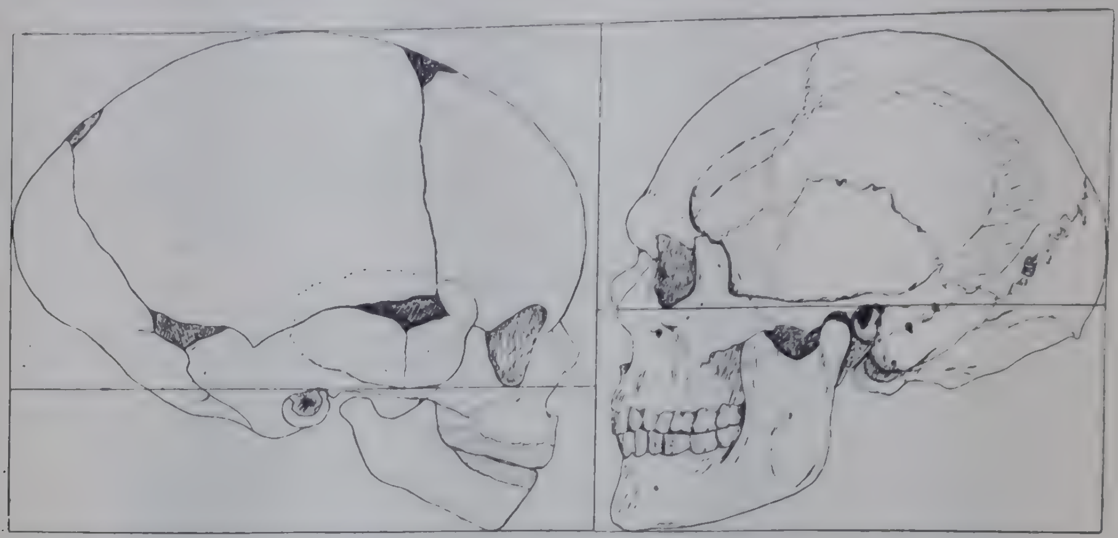

FIG. 176.—SKULLS OF NEW-BORN CHILD AND ADULT MALE, CONTRASTED IN LATERAL VIEW TO DEMONSTRATE THE ALTERATION IN PROPORTIONS. (Brash, 1924.)

They are oriented on the Frankfurt plane, the child's skull × $\frac{1}{2}$, that of the adult × $\frac{1}{4}$ nat. size.

are wide; the fossa for the lacrimal gland is deep, and the fossa for the sac looks forwards rather than sidewards. The supra-orbital notch is near the middle of the supra-orbital margin.

The *frontal* bone is divided into halves by the frontal suture. The frontal eminences are very prominent; their prominence, combined with the absence of superciliary arches, gives the bulging appearance to the child's forehead. The *parietal eminences* are even more prominent and convex, and are situated at the widest part of the head, and that is not always the case in the adult. The frontal and parietal eminences are more convex in the child than in the adult because the child's head is a smaller sphere.

Growth and Age-Changes of Skull

The skull grows rapidly from birth till the seventh year, but in the brain-box the greatest increase takes place during the first year. At the seventh year the orbits are almost as large as in the adult; the cribriform plates of the ethmoid, the body of the sphenoid, the petrous parts of the temporal bones and the foramen magnum have reached their full size; the jaws have enlarged in preparation for the eruption of the teeth and enlarge during their eruption—the chief enlargement being in the alveolar processes (Brash, 1926). For some years after the seventh, growth is slower, but at puberty a rapid increase in the rate of growth takes place in all directions, especially in the frontal and facial regions, owing to the great increase in size of the air-sinuses.

In the base of the skull, where cartilage is the precursor of bone, growth takes place in the cartilage between centres of ossification and so, for a time, growth takes place between bones such as the basi-sphenoid and basi-occipital which are joined by cartilage (Fig. 306 B). After the cartilage has ossified, growth can only take place on a surface of the bone covered with membrane—named periosteum, endosteum, or outer layer of dura mater, according to its position.

In the *vault of the skull* growth no doubt takes place between the edges of the bones until they meet and articulate with their neighbours but the essential mode of growth in the vault is by deposit of bone on the external surface and absorption from the internal surface. Consequently, sutures which are perpendicular to the surface, such as the sagittal suture or, to a less extent, the coronal, maintain their position during growth. Sutures which are set obliquely to the surface, so as to bevel the edges of the bones, migrate as the skull grows. This is because growth of the overlapping superficial edge of one bone, such as the squamous temporal, carries it over the surface of its neighbour. The deep edge of the neighbouring bone, being part of its internal surface, is absorbed according to the rate of absorption on the inner surface of the skull. If the two processes keep pace the suture will retain its width.

Simple accretion outside and absorption inside produce enlargement of the cranial cavity with a simultaneous reduction in curvature. Differential growth and modelling take place, as in the long bones, to produce and maintain the proper proportions and shape of the skull and the correct thickness of the bones.

In the *bones of the face* growth and modelling are accomplished in a similar manner by surface accretion and absorption wherever it is necessary to change the surface contours. It has been

known since the time of John Hunter that "modelling absorption" (p. 116) can occur in a marrow cavity or on the surface of a bone. Brash (1934) used bones from madder-fed animals to demonstrate the essential principles of bone-growth in the skull and the similarity of the growth processes in the skull to those in long bones. He also adduces evidence that the same processes are applicable to the human skull.

Up to maturity the age of the person can be ascertained approximately from the skull and the teeth. The dates of eruption of the teeth are given on page 573.

During the *first year* the portions of the temporal bone and of the sphenoid unite; the jugum sphenoidale is ossified by extension medially from each lesser wing; and the perpendicular plate of the ethmoid begins to ossify. During the *second year*, the halves of the mandible unite; the anterior fontanelle closes up; the cribriform plate ossifies and unites with the other parts of the ethmoid; and the mastoid process appears. The lateral parts of the occipital bone unite with the occipital squama during the *third year*, and with the basi-occiput during the *fourth or fifth year*. The halves of the frontal bone have almost completely united at the *sixth year*, and during that year the first of the permanent teeth—a first molar—erupts.

When the third molar is present the *seventeenth year* has been passed. If that tooth is present, and also the plate of cartilage between the body of the sphenoid and the occipital bone, the age is between 17 and 25. If the sphenoid and occipital are completely fused the age is over 25, for before that time (earlier in the female) the cartilage that unites the body of the sphenoid to the ethmoid and to the occipital bone disappears.

After maturity, the wear of the teeth and the degree of obliteration of the sutures may give a rough indication of the age. The work of Wingate Todd & Lyon (1924-1925) shows that the condition of the sutures in the interior of the skull-vault is a more reliable indication of age than the condition on the exterior. Fusion of the outer tables is less regular, slower and often incomplete although fusion starts about the same time. The irregularity of fusion on the outer surface may account for the common statement that the inner table starts to fuse about ten years earlier than the outer table.

In the interior of the skull, fusion of the sagittal suture normally begins at about 22 years of age and should be completed by 31 years. The coronal suture follows at 24 years and is for the most part fused by about 30 years though not completely so till about 40 years. Its lower pteric part is delayed a couple of years. The lambdoid suture does not start to fuse until about 26 years but joins rapidly at first and then lags so that fusion is not complete until after 40 years. Other sutures close considerably later

The work of Todd & Lyon on adult skulls and Bolk (1915) on young skulls indicates that failure of one suture to conform to pattern is likely to be associated with similar anomalies in the remaining sutures, *i.e.*, there is likely to be a slowing up or an acceleration of closure in other sutures as well, the whole pattern being slowed or speeded up in its presentation. Very considerable variation is possible as shown by Bolk's finding that 19 per cent of 1820 Dutch skulls aged 3-20 years showed some premature closure and there were 71 cases of premature closure of the sagittal suture. It must be noted, however, that the normal mode of growth by accretion and absorption can produce a normally shaped skull without the assistance of sutures. Complete obliteration of the sutures does not normally take place till an advanced age.

In old age the skull-vault may be thicker owing to deposit of bone on the inner surface (Humphry, 1858); but in nearly all cases the skull-bones are thinner, and the skull is lighter owing to absorption of diploë and the associated extension and enlargement of the sinuses. Consequent on loss of teeth there is diminution of the size of the jaws owing to absorption of the walls of the sockets; the chin protrudes and the angle of the mandible becomes more obtuse. For a review of the literature on age-changes in the skull see Ashley-Montagu (1938).

Sex Differences in the Skull

There is little difference between the skulls of boys and girls till the age of puberty; but the skull of a woman is, as a whole, smaller than that of a man, and the air-sinuses are small relatively to the size of the skull. The capacity of the cranial cavity is one-tenth less than in a man of the same race, and that is more or less in conformity with the relative size of the whole body of women and men of respective average build. Very often it is not possible to say with certainty whether a given adult skull is that of a man or of a woman, but the sex may be determined if the following differences are well marked.

The skull of a *woman* is lighter than that of a man and retains more of the character of a young skull; the muscular ridges are less pronounced; the mastoid processes are relatively small. The glabella and superciliary arches are less prominent; the forehead is therefore more vertical, and the frontal eminences appear to bulge more; the upper margin of the orbital opening is sharper (a fact appreciated better by touch than by sight); the parietal eminences are more convex. The facial region is rounder, and the jaws and teeth are smaller. The vertex is said to be more flattened and the relative height of the skull to be less.

Development and Morphology of the Skull

At an early stage of development, the cerebral vesicles are enclosed in a membranous envelope derived from the mesoderm and called the **primordial membranous cranium.** In certain lower vertebrates (*e.g.*, elasmobranch fishes) a complete, thick-walled cartilaginous capsule—the

primordial cartilaginous cranium—is developed in the membranous envelope. In mammals, cartilage is developed only in the basal part; the roof, the greater part of the sides, and even part of the base of the skull remain membranous till bone is formed in them.

The **notochord** or chorda dorsalis [νῶτον (nōton) = the back] is imbedded in the basal part of the membranous envelope, but does not extend through the whole length of the base; its cephalic extremity reaches only to a point beneath the anterior end of the middle cerebral vesicle; and in the mammalian cartilaginous base it is related to that part which extends from the foramen magnum to the root of the dorsum sellæ. The cartilaginous base can therefore be divided into a **chordal** part and a **prechordal** part.

In the **human embryo** chondrification of the base of the cranium begins early in the second month and has almost attained its maximum about the end of the third month. Cartilage appears in the following situations.

(1) A basal or parachordal plate of cartilage forms behind the hypophysis cerebri and round

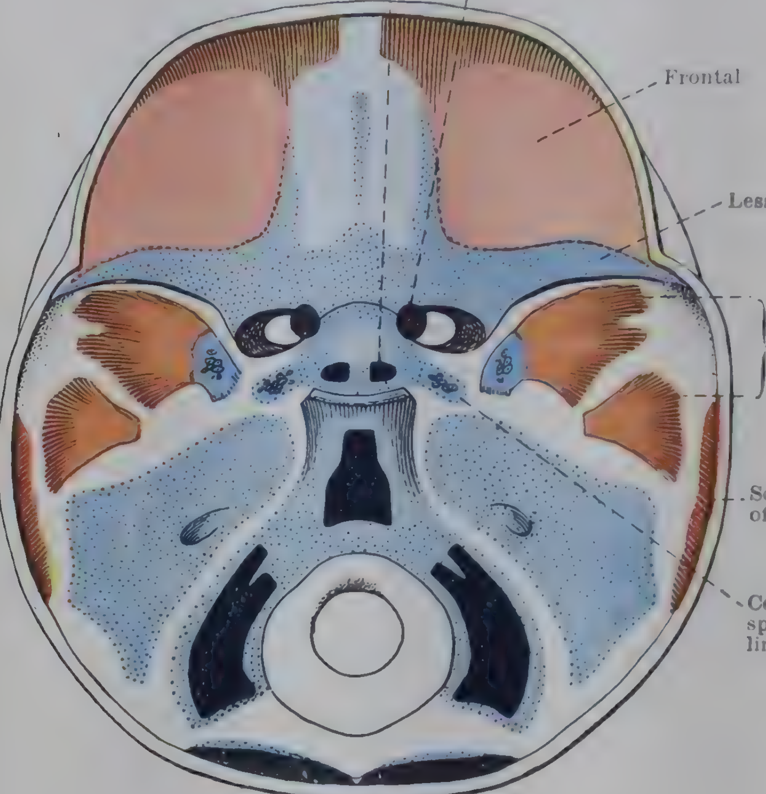

Fig. 177.—Ossification of Base and Side-walls of Skull of a Four and a Half Months' Fœtus (Schultze's method).

Cartilage, blue; cartilage-bone, black; membrane-bone, red.

the terminal part of the notochord (Levi, 1900; Fawcett, 1910). The notochord lies in a groove on the posterior part of the cerebral surface of the plate, pierces it to reach its pharyngeal surface and then turns upwards to terminate in the anterior end of the plate (Robinson, 1903). Extensions grow from its sides to form the cartilaginous precursors of the *condylar parts of the occipital bone*; and they grow backwards to form the thin plate of cartilage in which the part of the *occipital squama* below the superior nuchal lines ossifies; the halves of the plate are tardy in uniting, so that the part immediately behind the foramen magnum remains membranous till shortly before birth and is the commonest site for a cerebral meningocele.

(2) Chondrification takes place in the mesoderm around the internal ear, giving rise to the **auditory capsule**, in which the *petrous* and *mastoid* parts of the *temporal* bone ossify.

(3) A small transverse strip of cartilage appears in front of the parachordal plate and gives rise to the *dorsum sellæ* (Fawcett, 1910).

(4) Farther forward, a nodule of cartilage appears above and in front of the end of the notochord and gives rise to the cartilaginous *body of the sphenoid* bone. It enlarges and sends forwards two extensions which pass one on each side of the cranio-pharyngeal canal—*i.e.*, the passage through which the pharyngeal part of the hypophysis enters the cranial cavity. These extensions join together in front of the canal to form the anterior part of the cartilaginous body of the sphenoid, and so provide the canal with cartilaginous boundaries. The boundaries grow medially and usually occlude the canal during the third month, though occasionally it may remain open.

(5) Chondrification occurs in the region that corresponds to the root of the *pterygoid process* and the root of the *greater wing* of the sphenoid, including the *lingula* and the part around the *foramen rotundum*.

(6) Chondrification occurs in the whole of the region of the lesser wing; in the cartilaginous state it is therefore bigger than the greater wing.

(7) Chondrification occurs in the region of the nose to form a cartilaginous **nasal capsule** during the third month. A cartilaginous plate, called the **paranasal cartilage**, appears in the lateral wall of the nasal cavity. It gives rise to the *labyrinth* of the ethmoid (including its *conchæ*) to the *inferior concha*, and to the *sphenoidal concha*; part of it is included in the maxilla; and part persists through life as the *cartilages of the side* of the nose. Chondrification in the primitive septum takes place partly by extension from the cartilaginous sphenoid, and partly by the development of independent **paraseptal cartilages** in each side of the anterior part of the septum. The perpendicular plate of the ethmoid ossifies in the cartilaginous septum, but a great part of the cartilaginous septum persists throughout life; and the pair of subvomerine cartilages are persistent parts of the paraseptal cartilages. The cartilaginous roof is formed partly by fusion of the cartilage in the side-wall with that in the septum, and partly by independent chondrification of the mesoderm around the filaments of the olfactory nerve. Chondrification in the floor is very incomplete.

All the various chondrified areas of the mesoderm fuse together and form a cartilaginous platform in the base of the skull from which the cartilages of the pharyngeal arches are suspended. Most of the cartilage is ossified; part is replaced by bone ossified in the surrounding membrane; parts persist as the cartilages in the *sides* and *septum* of the nose and in the *foramina lacera*; and parts survive till maturity in the cartilaginous joints that unite the sphenoid to the ethmoid and to the occipital and between the occipital and the petrous temporal.

Some of the bones of the skull are ossified in the cartilage of the base, namely: the occipital bone, except the part of its squama above the nuchal lines; the petrous and mastoid parts of the temporal bone; the body of the sphenoid, the lesser wings, the roots of the greater wings and of the pterygoid processes; the ethmoid; the inferior concha.

Some of them are ossified in the membrane that overlies the cartilages of the nose, namely, the vomer, the lacrimal, the nasal, and the upper part of the maxilla.

Some are ossified from the membrane that underlies the mucous lining of the bucco-pharyngeal cavity, namely, the lower part of the maxilla, the palatine, and the greater part of the pterygoid process.

The frontal, the parietal, the squamous temporal, the upper part of the occipital squama, and the greater wing of the sphenoid (all but its root) are ossified in the membranous brain-envelope. The zygomatic bone ossifies in membrane which is continuous with the brain-case round the lateral margin of the orbit. The tympanic plate ossifies in membrane that overlies the cartilaginous auditory capsule.

Although the skull never shows evidence of segmentation, probably owing to the need of stability even in the early evolutionary forms, it is assumed that the chordal part of the base has arisen by the fusion of segments equivalent to vertebræ, because of—(1) the presence of myotomes in the head region, (2) the connexion with the series of pharyngeal arches, and (3) the segmental arrangement of nerves. The guide to the disposition of the nerves is their points of exit through the dura mater, for that is derived from the inner part of the primitive brain-envelope; owing to the evolutionary changes that have taken place in the outer parts of the mammalian brain-envelope, the apertures through which the nerves leave the skull—though very constant in position—do not in every case correspond to the points where they pierce the dura, *e.g.*, the oculomotor and the abducent nerves in the human head.

The mammalian occipital bone is regarded (Froriep, 1882) as the equivalent of four fused vertebræ, and there is reason to believe that in some vertebrates the occipital region of the primordial cranium is increased by inclusion of vertebræ from the cephalic end of the vertebral column. The primitive cranial nerves are related to the chordal part of the primordial cranium (except the olfactory and the optic nerves, which are parts of the brain); Gegenbauer (1872) concluded, from a study of the metameric arrangement of cranial nerves, that the chordal part was the equivalent of nine fused vertebræ, and he called the chordal part the **vertebral** part of the cranium. The prechordal part he called **evertebral** or non-vertebral, and regarded it as a new formation developed to contain and protect the enlarging brain and the organs of smell and sight.

The outstanding features that distinguish the human skull are the large size of the brain-case, the small size of the face, and the fact that the skull is poised on the end of the backbone. Its position on the vertebral column reacts on its outward configuration; the occipito-vertebral joints are placed so that the fore and hind parts of the head nearly balance each other; there is therefore an absence of the prominent ridges and crests for the attachment of the muscles and ligaments required to hold the head in position in lower mammals. The small size of the face is due chiefly to reduction of the bulk and length of the jaws and reduction of the size of the teeth. Diminution of the mandible reacts on the form of the skull, for the muscles of mastication do not need to be so large, and there is corresponding reduction in the fossæ that lodge them and in the surfaces and crests that give origin to them.

For a complete account of the development of the vertebrate skull, with full references, see de Beer (1937), and for variations of the bones of the skull, the standard works of Le Double (1903, 1906).

INDIVIDUAL BONES OF CRANIUM

Frontal Bone

The *main part* of the **frontal bone** is the shell-like bone in the front of the skull above the orbital openings. A *nasal part* is in the roof of the nose; and a pair of *orbital plates* roof in the greater part of the orbits.

Six ~~Four~~ surfaces can be recognized in the main part of the bone—frontal in front, cerebral behind, and a pair of temporal surfaces at the sides. [illegible] orbital surf

The ~~*frontal*~~ *surface* is rounded from side to side and from above downwards. The most pronounced parts of the convexity are a pair of **frontal eminences** seen about 35 mm. above the orbit. The surface ends inferiorly in a pair of concave edges separated by an articular area called the **nasal notch.** The concave edges are **supra-orbital margins.** Each margin ends later-

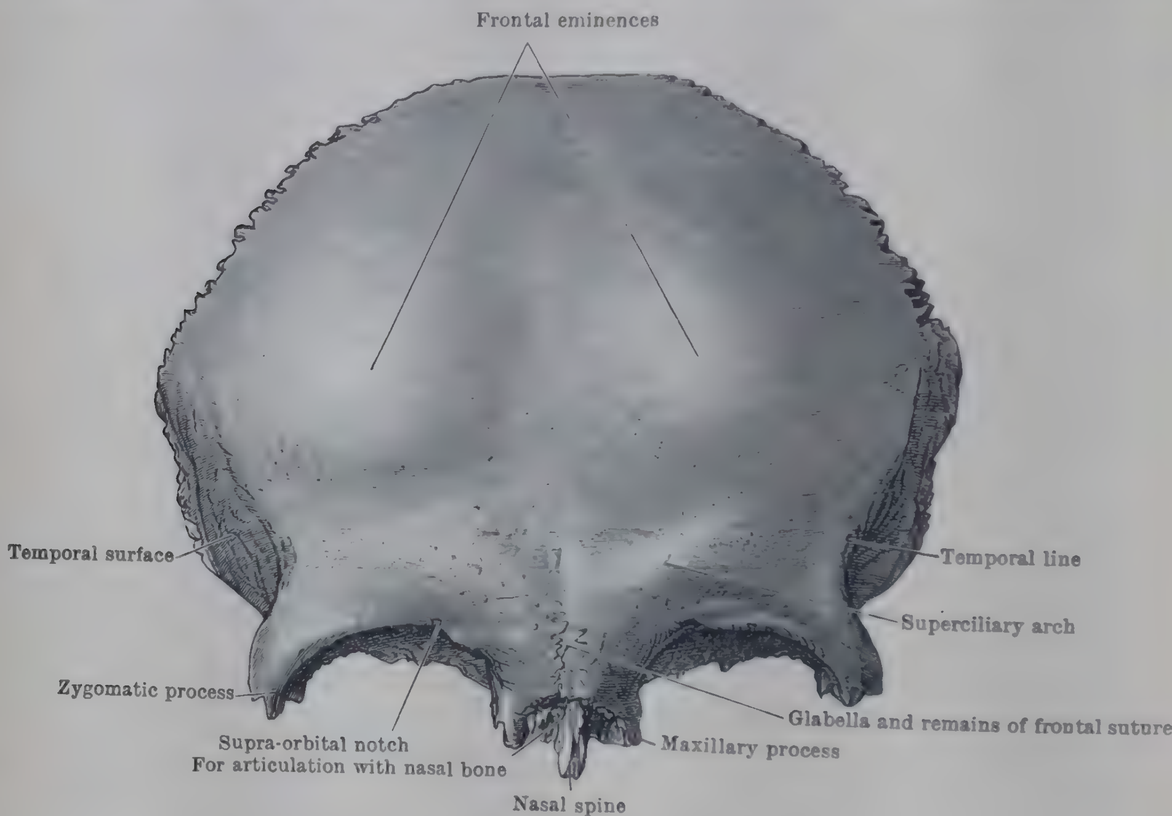

Fig. 178.—Frontal Bone (Anterior View).

ally in a prominent **zygomatic process.** The medial end descends to a slightly lower level as the **maxillary process.** Between its medial and intermediate thirds the margin is crossed by a groove, often converted into a foramen—the **supra-orbital notch** or **foramen.** Above the nasal notch the **glabella** forms a low elevation in which the remains of the frontal suture may be seen. On each side, the glabella is continuous with a curved elevation, of varying length and prominence, called the **superciliary arch,** which is a little above the supra-orbital margin.

From the zygomatic process the **temporal line** curves upwards and backwards, as a ridge separating the frontal from the *temporal surface.*

The *cerebral surface* is concave; it is marked by **impressions for the gyri** of the brain, and by narrow grooves for meningeal vessels; on each side of the median plane there are **granular pits,** varying in number and size, for the lodgment of arachnoid granulations. On the lower part of the surface there is a median ridge, called the **frontal crest,** which fades away as it is traced upwards. A groove called the **sagittal sulcus** begins on the crest and extends upwards to the margin of the bone, widening as it proceeds. A small hole, called the **foramen cæcum,** which is situated usually between the ethmoid and the lower end of the frontal crest, may sometimes be seen in its entirety on the separate frontal bone.

Each **orbital plate** is a thin, brittle, curved plate which is convex upwards and has a triangular outline. Its upper or *cerebral surface* is convex and uneven, showing ridges and depressions corresponding to the sulci and gyri of the frontal lobe, which lies on it; it shows also narrow grooves for meningeal vessels.

The larger, lateral part of the *inferior surface* is smooth and concave, and forms the greater part of the roof of the orbit, extending forward to the supra-orbital margin. In its antero-medial part there is either a very small depression **(trochlear fossa),** or a spicule of bone

(trochlear spine), or both, for the attachment of the trochlea or pulley of the superior oblique muscle of the eyeball. Laterally the surface is overhung by the supra-orbital margin and the zygomatic process, so that a wide depression or **fossa for the lacrimal gland** is formed. The medial part of the inferior surface is a wide strip that overlies the labyrinth of the ethmoid, roofing in ethmoidal sinuses; it presents therefore a number of irregular depressions that correspond to the sinuses. Anteriorly the opening from the frontal sinus is seen (see p. 199). Farther back there are two narrow, nearly transverse grooves which, with corresponding grooves on the ethmoid labyrinth, form the **anterior** and **posterior ethmoidal canals**. The medial margins of the two orbital plates are parallel with each other. Their posterior halves, or more, are separated by an interval called the **ethmoidal notch** because it is occupied by the cribriform plates of the ethmoid when the bones are articulated. The anterior halves of the margins are united to the nasal part of the bone.

The **nasal part** is the small portion of bone in front of the ethmoidal notch. From its centre the **nasal spine** projects downwards and forwards into the nasal septum between the nasal crest of the nasal bones and the perpendicular plate of the ethmoid, articulating with both. On each side of the root of the spine the nasal part presents a smooth, grooved surface that slopes from above downwards and forwards and forms part of the roof of the nasal cavity.

Articulations.—The zygomatic process articulates with the frontal process of the zygomatic bone. Behind that, a rough, triangular area articulates with the greater wing of the sphenoid. Above that, the whole serrated *parietal margin* articulates with the two parietal bones. The

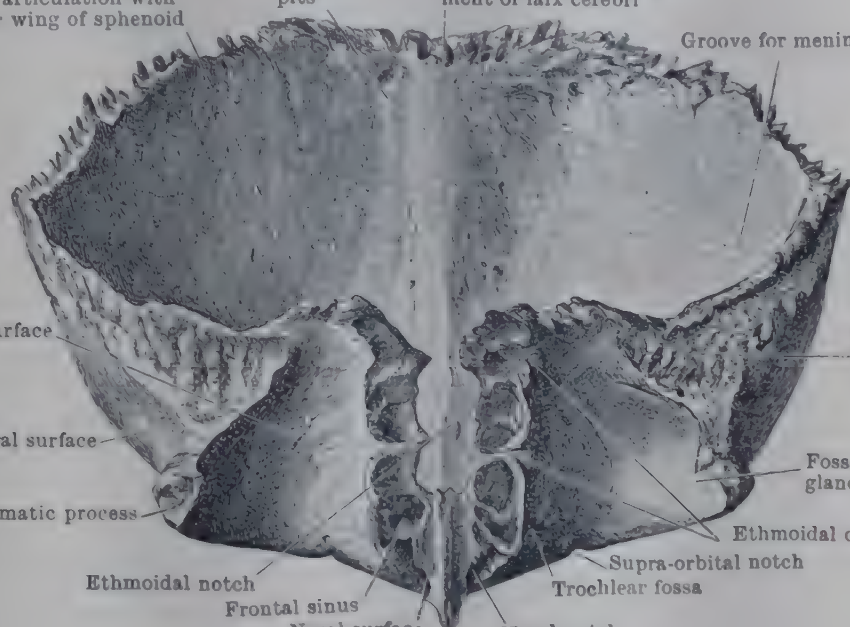

FIG. 179.—FRONTAL BONE AS SEEN FROM BELOW.

posterior margin of the orbital plate articulates with the lesser wing of the sphenoid. The medial part of the inferior surface articulates with the labyrinth of the ethmoid. The maxillary process articulates with the frontal process of the maxilla and with the lacrimal bone. Each half of the floor of the nasal notch articulates with the upper end of the nasal bone. The nasal spine articulates with the nasal bones and the perpendicular plate of the ethmoid.

Ossification.—Ossification begins in membrane from one centre for each half. Each centre appears about the sixth or seventh week in the region above the zygomatic process. Three pairs of centres are said to appear a little later—in the zygomatic processes, in the nasal spine, and at the trochlear fossæ. Fusion between these and the rest of the bone is complete about the sixth or seventh month of intra-uterine life. At birth the halves of the bone are separated by the *frontal suture*. Obliteration of the suture begins usually at the level of the frontal eminences, and gradually proceeds till, at the fifth or sixth year, the suture is almost closed, traces being left only above and below. In about 8 per cent of Europeans the suture persists in the adult.

Structure and Variations.—Like other bones of the skull-vault the frontal bone has two tables of compact substance with a layer of **diploë** between them. The diploë disappears from the part that encloses the frontal air-sinuses. The zygomatic process is dense throughout and is shaped so as to meet the pressure transmitted through the zygomatic bone from the closed jaws.

The commonest variation is a persistence of the frontal suture. A persisting frontal suture is called a **metopic suture**; it is more common in some races than in others, and has been said to be more frequent in the brachycephalic than in the dolichocephalic type. Ashley-Montagu (1937) believes it to be an inherited condition. An example of persistence of the metopic suture with absence of the coronal suture is recorded by Rau (1934). Sutural bones may occur at the

anterior fontanelle ; their fusion with one or other half of the frontal explains how the metopic suture is not always in line with the sagittal suture ; occasionally they coalesce to form a *bregmatic bone*. In rare cases the frontal bone articulates directly with the orbital surface of the maxilla behind the lacrimal—a condition which exists normally in the skulls of the chimpanzee and gorilla. There is sometimes a small arterial groove close to the medial side of the supra-orbital notch ; occasionally there is a second supra-orbital foramen a little lateral to the middle of the supra-orbital margin. Frequently the bone of the floor of the lacrimal fossa is cribriform. Independent ossicles (*supranasal bones*) have been found in the anterior part of the metopic suture ; and a *metopic fontanelle, metopic canals* and *ossicles* (ossa interfrontalia) have been described.

Parietal Bones

The **parietal bones** form a great part of the vault. They articulate with each other, with the frontal *anteriorly*, with the occipital *posteriorly*, and with the temporal and the sphenoid *inferiorly*. Each bone has an outer and an inner surface, four borders, and four angles.

The **outer surface** is convex. The most convex region is the **parietal eminence**, and it marks the position of the ossific centre. At a variable distance from the inferior border of the bone, and more or less parallel to it, there are two parallel curved lines about half an inch apart. These are the **superior** and **inferior temporal lines**, and are continuous with the two branches

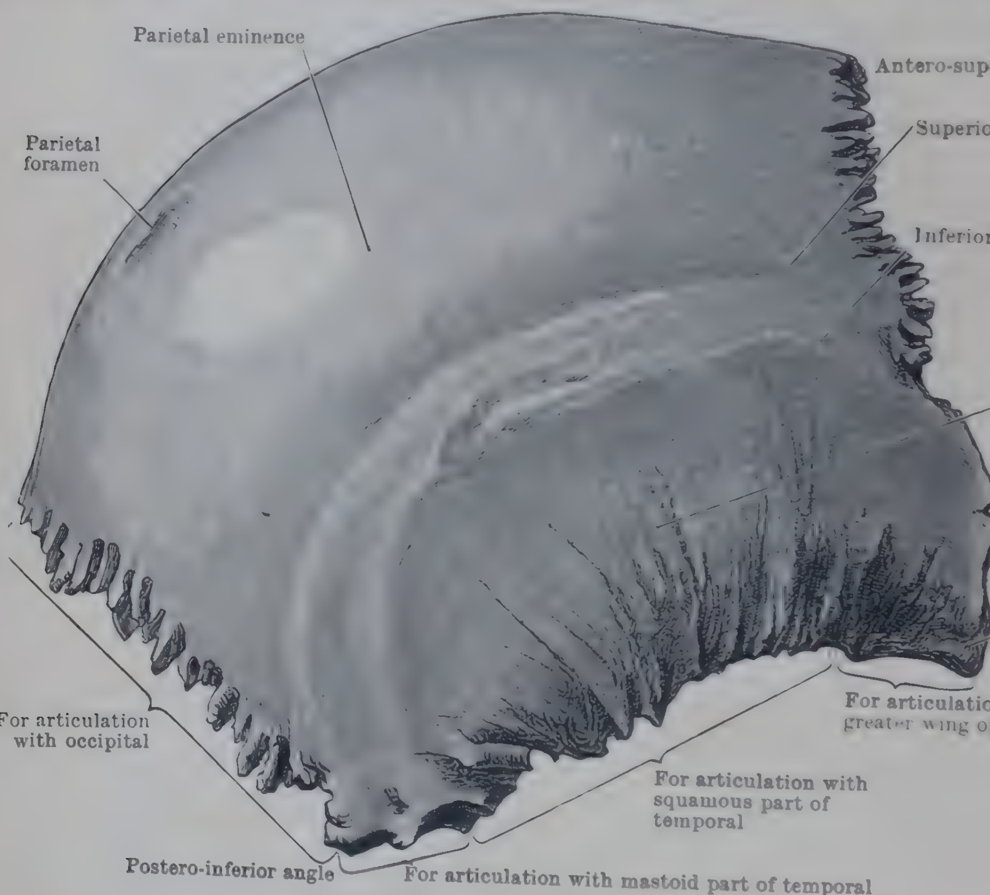

FIG. 180.—RIGHT PARIETAL BONE (Outer Surface).

of the temporal line of the frontal bone. The **parietal foramen** is a small aperture near the upper border of the bone and about an inch from its postero-superior angle.

The **inner surface** is concave. It displays impressions for the gyri of the brain and also well-marked grooves for the branches of the middle meningeal vessels ; the grooves radiate from the antero-inferior angle and the lower margin of the bone. Close to the upper margin there is a series of pits for arachnoid granulations, and along the margin the bone is grooved to form one half of the **sagittal groove**. At the postero-inferior angle the bone is slightly grooved by the transverse sinus.

The *anterior*, *superior*, and *posterior borders* are deeply serrated. The **anterior border** articulates with the frontal bone, forming with it the *coronal suture*. In the upper part of the suture the frontal bone overlaps the parietal, while the parietal overlies the frontal below. The **posterior border** is united with the occipital bone to form the *lambdoid suture*. The **superior border** articulates with its fellow to form the *sagittal suture* which shows, until synostosis occurs, a characteristic arrangement of reciprocal pegs and sockets. The **antero-superior angle** is almost rectangular ; the **postero-superior angle** is obtuse. The **inferior border** is sharp and curved, and is shorter than the others. It articulates with the squamous part of the temporal bone, which overlaps the parietal bone ; the parietal bone, at its lower edge, is therefore bevelled at the

expense of the outer table, and it is grooved or fluted. The **antero-inferior angle** is acute; it articulates with the greater wing of the sphenoid and is wedged into the angle between the greater wing and the frontal bone. It is bevelled at the expense of its inner table anteriorly, but inferiorly it is thinned at the expense of its outer table. The **postero-inferior angle** is truncated and deeply serrated, and articulates with the mastoid part of the temporal bone.

Ossification.—The parietal bone ossifies in membrane by two centres that appear, one above the other at the parietal eminence, in the eighth week of intra-uterine life, and gradually unite during the fourth month. Ossification spreads radially towards the edges and angles; but at the angles the membranous condition persists for some time—hence the fontanelles. Ossification is a little delayed also in the region of the parietal foramina, so that a sagittal fontanelle is sometimes present at birth.

Structure and Variations.—The parietal bone is made of two tables of compact bone with a layer of diploë between them. It is thin towards its lower part and is thickest along the upper border. Occasionally the outer table is very thin above the temporal lines.

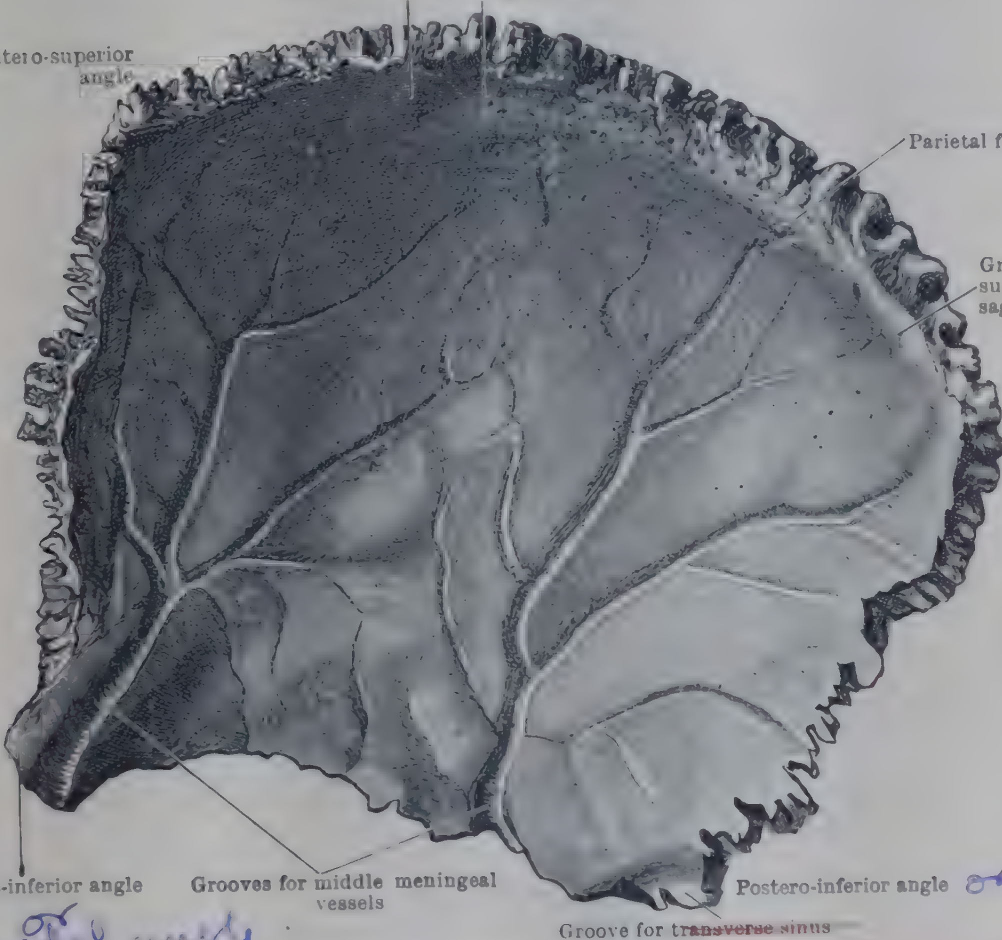

FIG. 181.—RIGHT PARIETAL BONE (Inner Surface).

The parietal bone is sometimes divided into an upper and lower part by an antero-posterior suture; in one case it was incompletely divided into an anterior and a posterior part by a vertical suture; and a tripartite condition also has been recorded. The parietal foramina vary greatly in size, and to some extent in position. They are sometimes absent on one or both sides. They correspond in position to the sagittal fontanelle. Sometimes the ossification of the sagittal fontanelle is incomplete and a small transverse fissure remains. Occasionally in the region of the anterior fontanelle an ossicle of variable size may be met with. According to its fusion with adjacent bones it may disturb the direction of the sagittal suture.

Occipital Bone

The four parts of the **occipital bone** are arranged around the foramen magnum. The expanded plate behind the foramen is the **squamous part**. The thick, rod-like portion in front of the foramen is the **basilar part**. The pair of **condylar parts** are at the sides of the foramen.

The **squamous part** resembles a Gothic arch in outline, and it is curved in every direction. Inferiorly it forms a small portion of the middle of the posterior boundary of the foramen magnum, and it unites, on each side of that, with the condylar part of the bone.

The **external occipital protuberance** is a prominence about the centre of its *external surface*, and a pair of **superior nuchal lines** curve from it towards the lateral angles of the bone; above them there is occasionally another pair of curved ridges called the **highest nuchal lines**. The part below the superior nuchal lines is divided into a right and a left half by a median ridge, the **external occipital crest**, which extends from the protuberance to the foramen magnum. From the middle of the crest a pair of **inferior nuchal lines** extend towards the lateral margins of the bone.

The *internal surface* is concave and is divided into four fossæ by a cruciate arrangement of grooved ridges that meet at a prominence called the **internal occipital protuberance**, at one side of which there may be a fossa for the confluence of sinuses. The upper pair of fossæ lodge the occipital lobes of the cerebrum, and the hemispheres of the cerebellum occupy the lower pair. The ridge that extends from the protuberance to the foramen magnum is the **internal occipital crest**; the *grooves for the transverse sinuses* pass sidewards from the protuberance; the *sagittal groove* descends to it and usually runs into the right transverse groove.

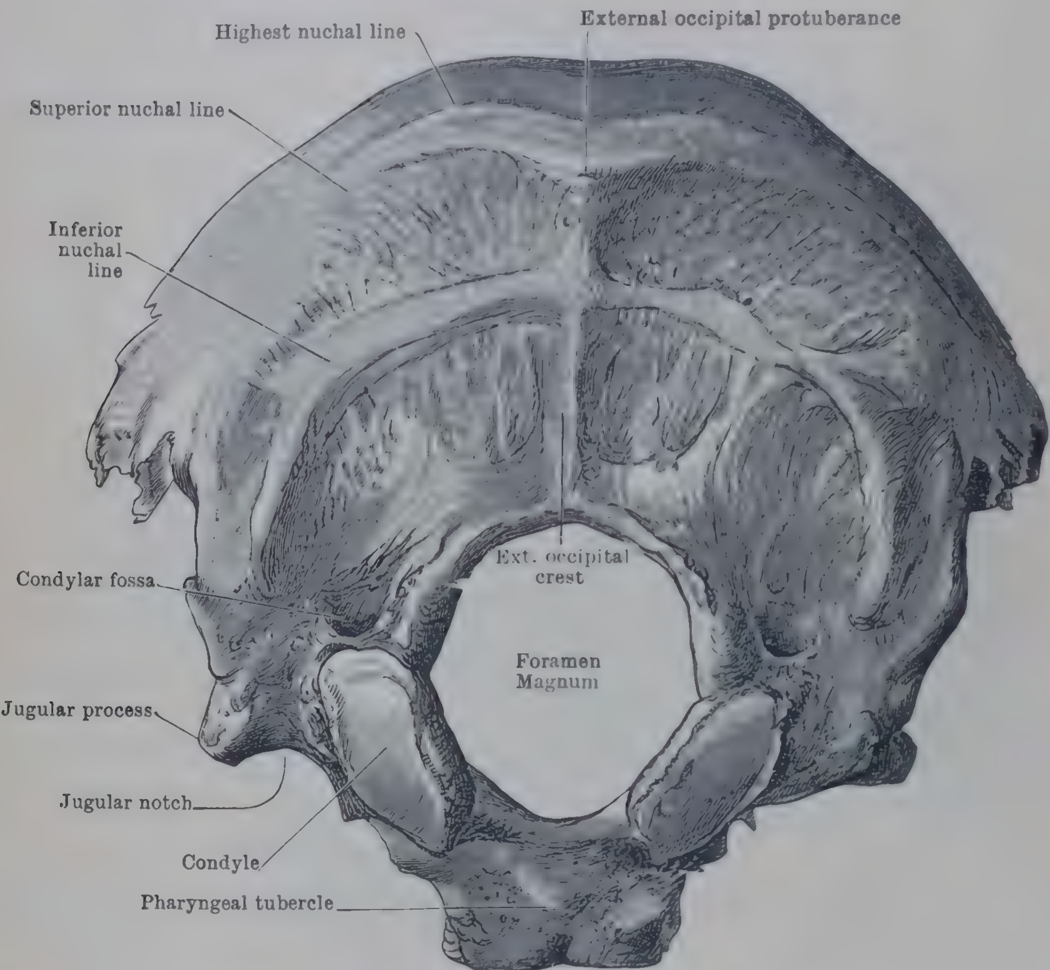

FIG. 182.—OCCIPITAL BONE AS SEEN FROM BELOW.

The **superior angle**, more or less sharp and pointed, is wedged in between the two parietal bones, and the **superior borders**, much serrated, articulate with them—forming the **lambdoid suture**. The **lateral angle** and **border** articulate with the mastoid portion of the temporal bone.

Each **condylar part** is placed at the side of the foramen magnum; on their lower surfaces they bear the **occipital condyles**, by which the skull articulates with the atlas. The condyles are elongated and oval; they are situated at the side of the anterior half of the foramen magnum; their anterior ends are closer together than their posterior ends; their articular surfaces are convex from before backwards and look in a lateral direction as well as downwards. Each articular surface is supported on a boss of bone through which the **anterior condylar canal** passes. The canal opens externally into a depression immediately lateral to the anterior part of the condyle; its internal opening is a little above the margin of the foramen magnum. The wide depression behind the condyle is the **condylar fossa**; the *posterior condylar canal* (when present) opens into it. The bone lateral to the posterior half of the condyle is the **jugular process**; its *anterior* border, free and rounded, is the posterior margin of the jugular foramen and bounds the **jugular notch**. *Laterally*, the jugular process is united by cartilage to the petrous part of the temporal bone. *Posteriorly*, it joins the occipital squama. Its *lower* surface is rough. The *upper* surface is grooved by the sigmoid sinus, and the internal opening of the posterior condylar canal is in or near the groove. The **jugular tubercle** is a smooth eminence on the upper surface of the condylar part between the foramen magnum and the anterior part of the jugular

foramen; its posterior part is often slightly grooved by the ninth, tenth, and eleventh cranial nerves.

The **basilar part** extends forwards and upwards from the foramen magnum. Its anterior extremity is usually sawn across, as, after the twenty-fifth year, it is fused with the body of the sphenoid bone; the sawn surface is quadrilateral in outline. Posteriorly, where the basilar part bounds the foramen magnum, it is broad and thin. At the centre of its *lower surface* there is a small elevation called the **pharyngeal tubercle**. The *upper surface* is the posterior part of the clivus of the skull, and it is transversely concave. Each *lateral margin* is faintly grooved for the inferior petrosal venous sinus, and, below that, it is rough for the cartilage that unites it to the petrous part of the temporal bone.

The **foramen magnum** is variable in size and outline, but is usually ovoid, with the long axis antero-posterior. Anteriorly the condyles encroach upon it, and reduce its transverse diameter.

Ossification.—The part above the nuchal lines (*interparietal part*) is ossified in membrane, and the rest in cartilage.

The **basilar part** is ossified from one centre which appears in the sixth week of intra-uterine

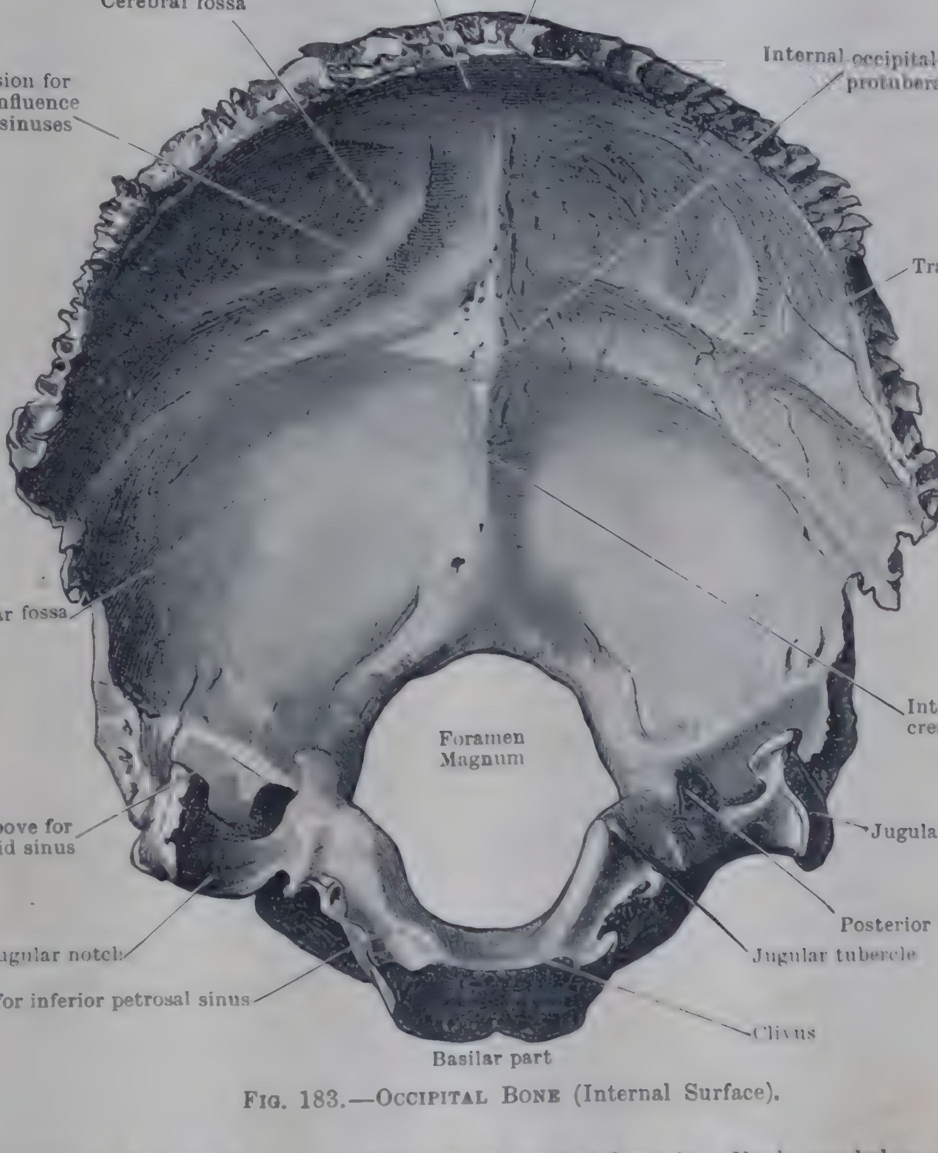

FIG. 183.—OCCIPITAL BONE (Internal Surface).

life; the anterior fourth of each condyle also is ossified from it. Each **condylar part** (including only the posterior three-fourths of the condyle) is ossified from one centre which appears at the eighth week. The *supra-occipital part* of the **squama** (*i.e.*, the part below the highest nuchal line) is ossified from a pair of centres that appear at the position of the protuberance in the seventh week and rapidly unite; the *interparietal part* also is ossified from a pair of centres that appear in the eighth week and soon fuse; osseous union of the two parts of the squama begins in the median plane during the third month but is not quite completed at birth.

At birth the four component parts are separable bones united by cartilage. The two condylar parts fuse with the squama during the third year, and with the basilar part during the fourth or fifth year. The basilar part is united to the sphenoid by cartilage (Fig. 306 B) which begins to disappear between the eighteenth and twentieth years (earlier in the female), and is completely replaced by bone by the twenty-fifth year.

The single basilar centre may be the result of the speedy fusion of two centres—an anterior and a posterior—each of which may be a fused pair; and each of the two interparietal centres may

be a fused pair. Small centres are sometimes seen in the cartilage between the squama and the condylar part; and occasionally an independent centre appears in the posterior margin of the foramen magnum at the end of the fourth month and produces a nodule, called the *ossicle of Kerkring*, which fuses with the squama before birth.

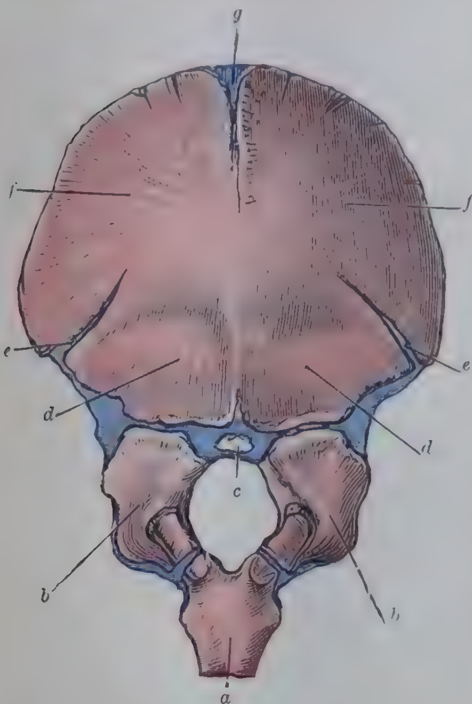

FIG. 184.—OSSIFICATION OF OCCIPITAL BONE.

a, Basilar centre ; *b*, Condylar part ; *c*, Ossicle of Kerkring ; *d*, Supra-occipital ; *e*, Fissure between supra-occipital and interparietal ; *f*, Interparietal ; *g*, Fissure between interparietals.

Osseous union between the upper and lower parts of the squama and between its right and left halves is incomplete near the margins of the bone at birth. Occasionally in the adult a suture extends medially from the lateral angle of the squama and indicates partial failure of union between its supra-occipital and interparietal parts. In some skulls the suture is complete, and the upper part of the squama is a separate *interparietal bone*.

Structure and Variations.—The squama shows thickenings of compact bone at the ridges and crests, and it is thickest at the protuberances; the floors of the lower pair of fossæ are thinner than the upper pair and their lower parts have no diploë. The basilar part is made of spongy substance surrounded by compact substance which is thickest on the lower surface. In the condyles the spongy substance is arranged radially to the convex articular surfaces. The anterior condylar canal is surrounded by very dense bone.

The *torus occipitalis transversus* is the term applied to an occasional elevation which includes the external occipital protuberance and extends laterally along the superior nuchal line. Occasionally an emissary vein pierces the bone opposite the occipital protuberance. In about 15 per cent. of skulls the anterior condylar canal is double; much more rarely there are three or even four foramina. The most striking of the many variations is the separation of the upper part of the squama to form the *interparietal bone*. The interparietal bone may exist as separate, symmetrical halves; or it may be in three pieces—or even four, in which case the upper two are called *pre-interparietal* bones. Instances are recorded of a separate epiphysis between the basi-occipital and the sphenoid called the *os basioticum* or the *os pre-basi-occipitale*. An oval pit, called the *pharyngeal fossa*, is sometimes seen in front of the pharyngeal tubercle; it marks the site of the pharyngeal bursa. Occasionally the basilar part is pierced by a small vein. The **third occipital condyle** is an occasional process which juts from the anterior border of the foramen magnum and articulates with the odontoid process. The third condyle may have a double origin—one part ossified in the sheath of the notochord, and the other in the hypochordal bow of the lowest occipital vertebra; that view gains support from a fœtal skull in which the condyle was represented by two tubercles. The *paramastoid process* is an occasional eminence on the lower surface of the jugular process; it may be a mere elevation, rough or smooth; or it may be a projecting spine whose apex articulates with the transverse process of the atlas. The size and shape of the foramen magnum vary much in different people and races, as also the disposition of its plane. The atlas is often fused with the occipital bone. Sometimes there is evidence of the intercalation of a new vertebral element (*pro-atlas*) between the atlas and the occipital bone.

Temporal Bones

Each **temporal bone** lies about the middle of the lower half of the side of the skull, and enters largely into the formation of the cranial base. It is placed between the occipital behind, the parietal above, the sphenoid in front, and the occipital and sphenoid medially and below. It has four main parts—squamous, petrous, mastoid, and tympanic.

The **squamous part** is a thin, scale-like plate of bone placed vertically in the side of the skull. It has a semicircular upper border, and cerebral, temporal and infratemporal surfaces; the zygomatic process projects forwards from the lower part of its temporal surface; most of its infratemporal surface is occupied by the articular eminence and fossa.

The anterior part of the **upper border** is nearly vertical and articulates with the greater wing of the sphenoid. The remainder of the border is bevelled at the expense of the inner table, overlaps and articulates with the parietal bone, and ends posteriorly by joining the mastoid part at an angle that accommodates the posterior inferior angle of the parietal bone.

The **cerebral surface** joins the petrous part inferiorly, and the remains of the suture between them can often be seen in the adult skull. The surface is marked by *impressions for gyri*, and it is crossed by a groove or grooves for branches of the middle meningeal vessels. The **temporal surface**, smooth and slightly convex, is larger than the cerebral surface.

The **zygomatic process** or **zygoma** springs from the lower and anterior part of the temporal surface by two roots, and curves forwards to end in an oblique, serrated edge which articulates with the temporal process of the zygomatic bone. The *upper border* of the process is continuous with the posterior root. The *posterior root* is a salient ridge that extends backwards above the external auditory meatus and becomes continuous with a blunt, low ridge, called the **supramastoid crest**, which curves upwards and becomes continuous with the temporal lines of the parietal bone. The *lower border* of the zygomatic process is continuous with the *anterior root*, which is a broad, thick bar of bone that turns abruptly in a medial direction to join the side of the skull. The lateral end of the root is prominent and is called the **tubercle** of the root of the zygoma; the medial end is continuous with the **articular eminence**—the lower surface

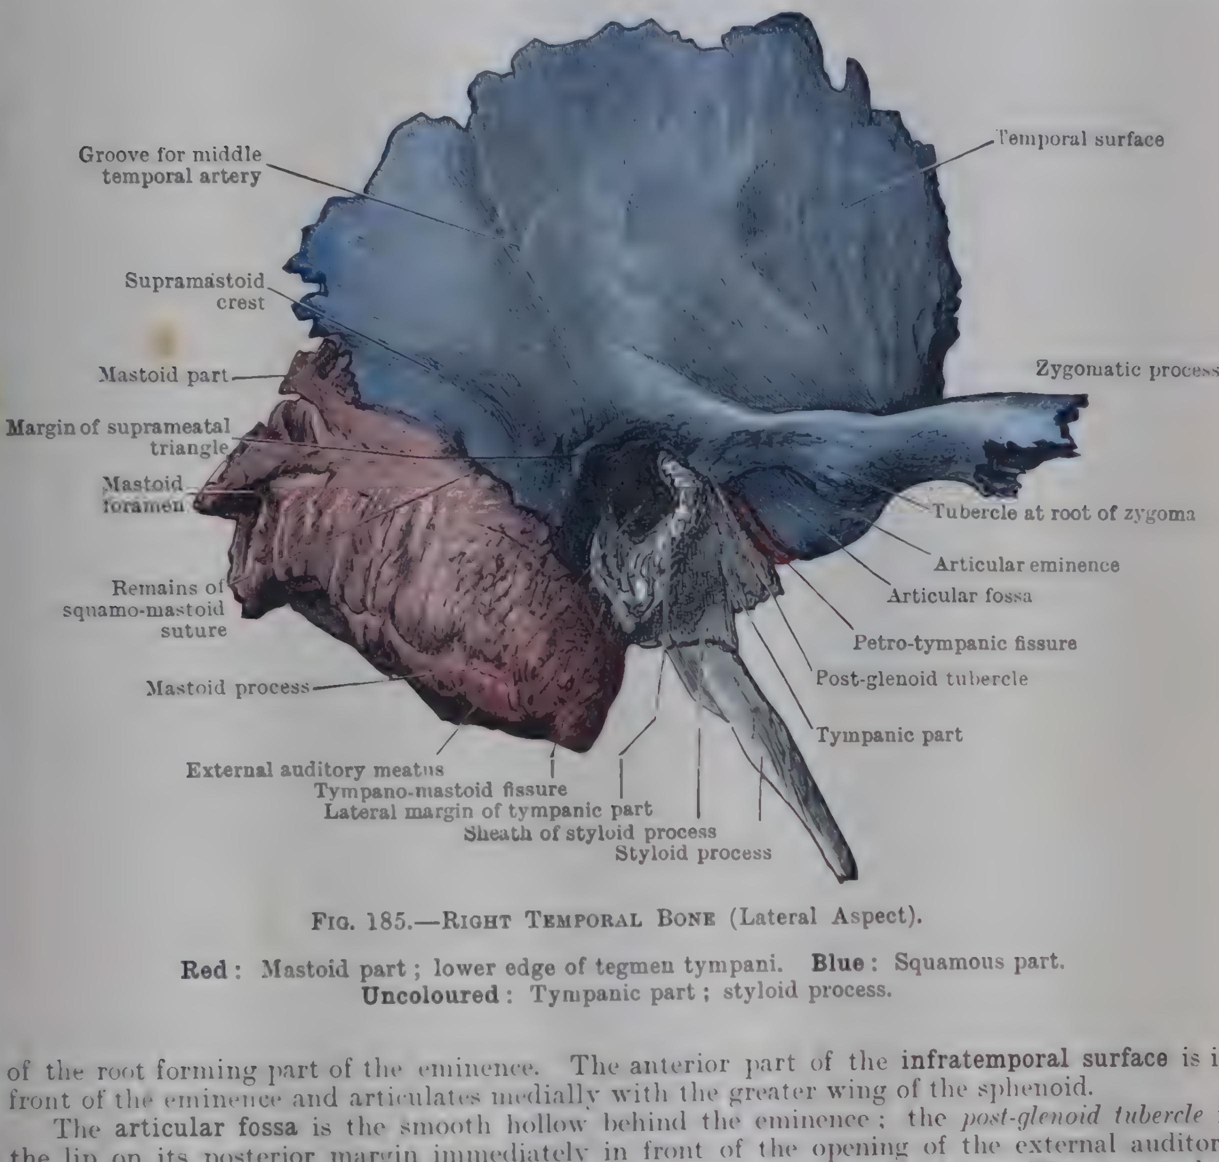

FIG. 185.—RIGHT TEMPORAL BONE (Lateral Aspect).

Red: Mastoid part; lower edge of tegmen tympani. **Blue:** Squamous part. **Uncoloured:** Tympanic part; styloid process.

of the root forming part of the eminence. The anterior part of the **infratemporal surface** is in front of the eminence and articulates medially with the greater wing of the sphenoid.

The **articular fossa** is the smooth hollow behind the eminence; the *post-glenoid tubercle* is the lip on its posterior margin immediately in front of the opening of the external auditory meatus. The sloping plate behind the fossa is the tympanic part of the bone. The narrow cleft between them is the **squamo-tympanic fissure**. A thin edge of bone (the lower edge of the tegmen tympani) is usually seen in the medial part of the fissure, dividing it into two clefts—the *petro-tympanic fissure* behind the edge and the *petro-squamous fissure* in front (see pp. 176, 223).

Behind the external auditory meatus, and below the supramastoid crest, the squamous element extends downwards as a pointed process, called the *post-auditory process*; this process forms the lateral wall of the tympanic antrum and helps to form the posterior wall of the meatus. Its lower end unites with the tympanic part. In the adult the process is occasionally sharply defined posteriorly by an oblique irregular fissure—the remains of the squamo-mastoid suture—which is often not closed till puberty. The **suprameatal triangle** is a small depression immediately above and behind the meatus.

The **tympanic part** of the temporal bone is a curved plate the concave **upper surface** of which forms the anterior, lower, and part of the posterior wall of the external auditory meatus. *Medially* it is fused with the petrous temporal. Its **anterior surface** is free and concave and has three borders. The *upper border* forms the posterior boundary of the squamo-tympanic and petro-tympanic fissures. The *lower border* is sharp and uneven, and partly ensheathes the root of the styloid process. The *lateral border*, curved, thick, and rough, gives attachment to the cartilage of the auricle. The part of the plate that curves upwards in the posterior wall of the meatus is united with the mastoid temporal and with the post-auditory process of the squamous temporal; but between it and the mastoid there is a narrow cleft—often very indistinct—called the **tympano-mastoid fissure**.

The **external auditory meatus** is a canal about 15 mm. long; it is directed obliquely medially and a little forwards, with a slight upward convexity. It is oval in outline, the long axis of the oval being nearly vertical near the lateral end, but oblique from above downwards and backwards near the medial end. The upper margin of the lateral orifice overhangs the lower margin, but the medial orifice, which is closed by the tympanic membrane, is so oblique that the lower wall of the meatus is almost, or quite, as long as the upper wall.

The **mastoid part** lies behind the squamous and tympanic parts. *Anteriorly* it is fused with those parts, and, more deeply, with the petrous part. Its *upper border* articulates with the parietal bone, and its *posterior border* with the occipital squama. *Inferiorly* it sends down a blunt projection, called the *mastoid process*, the root of which is bounded medially by a well-marked **mastoid notch**. Between the notch and the lower part of the occipito-mastoid suture there is an uneven strip of bone on which the occipital artery makes a shallow groove nearly parallel to the notch. The *lateral surface* is convex and slightly roughened; the **mastoid foramen** opens on it near its posterior border or into the occipito-mastoid suture. The *medial surface* is in the side-wall of the posterior cranial fossa. The *sigmoid groove* courses over the anterior

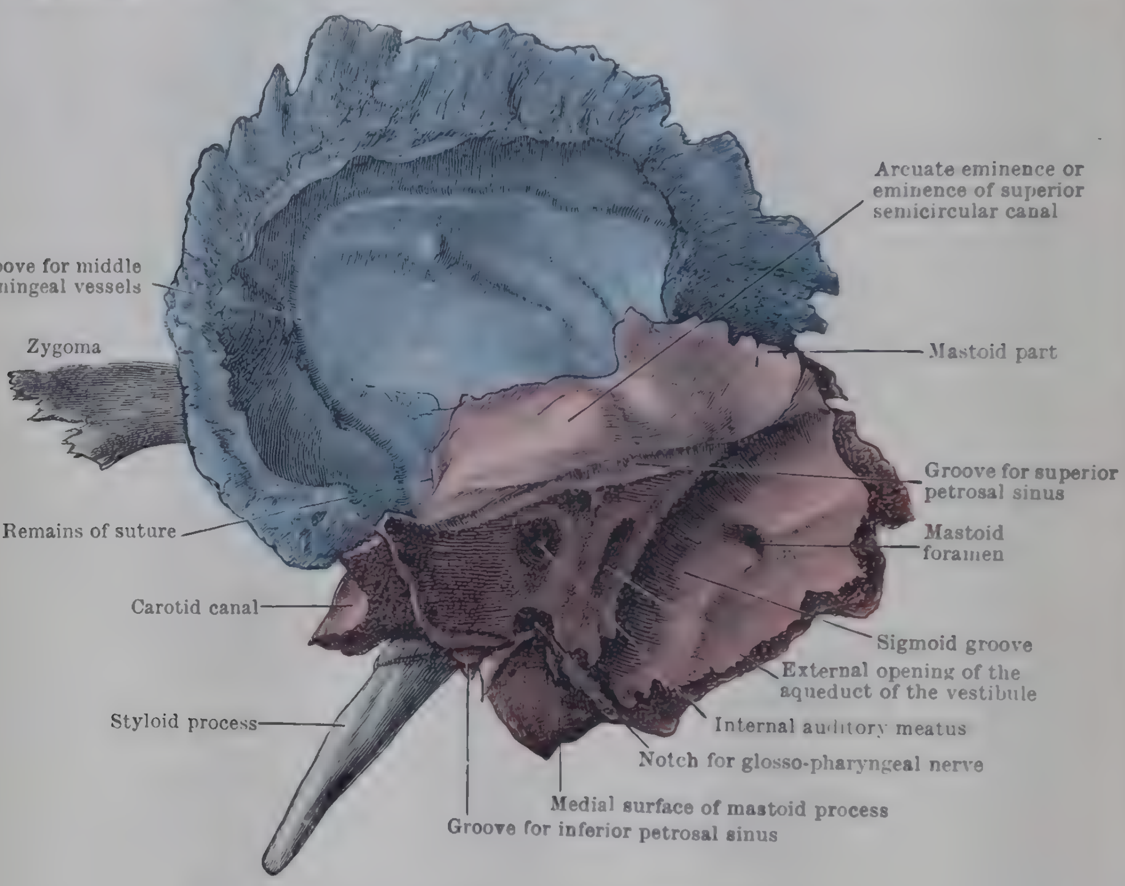

FIG. 186.—RIGHT TEMPORAL BONE (Cerebral Aspect).
Red: Petro-mastoid. **Blue**: Squamous. **Uncoloured**: Zygoma; styloid process.

part of this surface, and is partly on the petrous temporal. It has on it the internal opening of the mastoid foramen.

The **petrous part** is shaped like a three-sided pyramid. By its base it is partly united obliquely to the other parts of the temporal bone, and is partly free, forming the medial wall of the tympanic cavity. Its apex is directed medially, forwards, and a little upwards. Its three surfaces are arranged as follows: The **anterior** looks upwards, slightly forwards, and a little laterally, and it forms part of the posterior wall of the middle cranial fossa. The **posterior** is directed backwards and medially, and it forms part of the anterior wall of the posterior cranial fossa. The **inferior** is seen on the lower surface of the skull and is directed downwards. The margins are named anterior, superior, and posterior.

The **anterior margin** is partly united to the squamous temporal, but its medial part is a free edge that articulates with the posterior border of the greater wing of the sphenoid and forms an acute angle with the anterior border of the squamous part; within the angle is wedged the posterior corner of the greater wing. At the apex of the angle the openings of two canals are seen. These canals are separated by a thin, bony septum, and they lead backwards and laterally to the tympanic cavity. The upper is the *canal for the tensor tympani*. The lower is wider, and is the *bony part of the pharyngo-tympanic tube*.

The **posterior margin** is in part articular. Posteriorly and laterally it corresponds to the upper margin of an area on the inferior surface which articulates with the jugular process of the occipital. Medial to that it is irregularly notched, and bounds the jugular foramen anteriorly. The remaining, antero-medial part articulates with the basilar part of the occipital bone; the inferior petrosal sinus runs along the articulation, grooving both bones.

The **superior margin** is a sinuous edge grooved lengthways for the superior petrosal sinus, and slightly depressed near the apex where it is crossed by the trigeminal nerve.

The **inferior surface** of the petrous part is rough and uneven. On it the following parts are to be noted :—The **styloid process** projects downwards, forwards, and medially from behind the lower edge of the tympanic plate. The **stylo-mastoid foramen** is between the root of the styloid process and the mastoid notch. The **jugular fossa** is the concavity medial to the root of the styloid process. A small area behind and lateral to the fossa is united by cartilage to the jugular process of the occipital bone. A tiny aperture on the lateral part of the wall of the fossa is the medial end of the **mastoid canaliculus**, which opens laterally in the tympano-mastoid fissure. The oval or circular opening in front of the jugular fossa is the lower end of the **carotid canal**; the canal passes upwards for a short distance, and then, becoming horizontal, it passes medially and forwards, and ends at the apex as an oblique opening with jagged margins. On the lateral wall of the ascending part of the canal there are two or more small openings of **carotico-tympanic canaliculi**, which communicate with the tympanum. On the ridge between the carotid canal and the jugular fossa, there is the lower opening of the **tympanic canaliculus**, which leads up to the tympanum. The groove on the small area between the medial parts of the canal and fossa leads up to the **notch for the ninth nerve** on the margin of the jugular foramen. The *external opening of the cochlear canaliculus* is at the bottom of a pit in the notch. The **quadrate area** is the rough part medial to the opening of the carotid canal; a strip along its antero-lateral border articulates with the greater wing of the sphenoid and helps to form the groove for the cartilage of the pharyngo-tympanic tube; its postero-medial border is united to the occipital bone by dense fibrous tissue or cartilage—the gutter between the two bones being called the *petro-basilar fissure*.

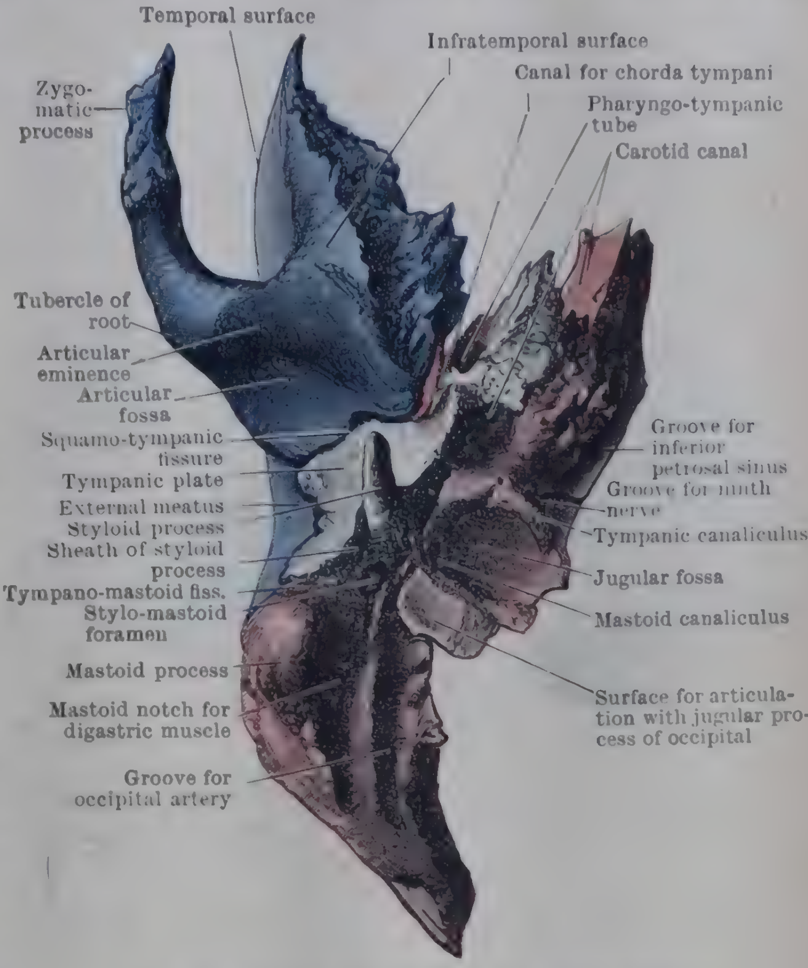

FIG. 187.—RIGHT TEMPORAL BONE (Inferior Aspect).

Red : Petro-mastoid, including lower edge of tegmen tympani. **Blue** : Squamous. **Uncoloured** : Tympanic part ; styloid process.

The **anterior surface** of the petrous part bears the impress of gyri of the cerebrum ; in addition, there is a distinct but shallow depression near the apex for the trigeminal ganglion. Lateral to the middle of the anterior surface, there is an elevation, the **arcuate eminence**, which marks the position of the superior semicircular canal of the ear. A little below and medial to this, there is the small slit or *hiatus for the greater superficial petrosal nerve*, which is continued downwards and medially as a narrow groove ; lateral to them there are a smaller opening and groove for the lesser superficial petrosal nerve. The bone forming the lateral part of the anterior surface, lateral to and in front of the arcuate eminence, is the **tegmen tympani** ; it roofs over the tympanic cavity and antrum and the canal for the tensor tympani. The anterior part of the tegmen is turned down so that its lower edge lies between the tympanic plate and the squamous temporal. It thus divides the squamo-tympanic fissure into a petro-squamous portion anteriorly and a petro-tympanic portion posteriorly which leads into the tympanic cavity (see Figs. 185, 187, 188). The line of fusion between the petrous and squamous parts of the bone is often indicated by a faint, irregular **petro-squamous suture** along the lateral margin of the anterior surface of the petrous temporal.

The most conspicuous feature on the **posterior surface** of the petrous part of the bone is an oblique, oval aperture which leads into the internal auditory meatus. The **internal auditory meatus** is a canal about 10 mm. long that passes laterally and slightly downwards into the bone and ends blindly, except that the bony substance at the **fundus** or far end has a number of small holes in it for the facial nerve and the nerves and vessels of the internal ear (Fig. 1020). Lateral to the meatus and above it, close to the upper border, there is an irregular depression called the **subarcuate fossa**, with one or two small foramina opening into it. It is often faintly marked ; it is seen best in young bones (see Fig. 188, C), where it forms a distinct recess. About half

an inch lateral to the meatus there is the *external aperture of the aqueduct of the vestibule*, often concealed in a narrow curved fissure overhung by a sharp scale of bone. The ridge above it corresponds to the upper half of the posterior semicircular canal.

Ossification.—The temporal bone of man represents the fused periotic, squamosal, and tympanic elements; the squamosal and tympanic are membrane bones, but the periotic is ossified in the cartilaginous auditory capsule. The cartilages of the first and second pharyngeal arches are also intimately associated with its development. The human temporal bone is characterized by the large proportionate size of the squamosal, the comparatively small size of the tympanic, the absence of an auditory bulla, and the large size of the mastoid process.

The **squamous part** is ossified from one centre that appears at the root of the zygoma about the end of the second month.

The **petro-mastoid part** is ossified from four centres, named pro-otic, opisthotic, pterotic, and epiotic. They appear during the fifth month and are more or less fused at the end of the sixth. The *pro-otic* centre appears near the arcuate eminence. It forms the part of the bone medial to that eminence, the roof of the internal auditory meatus, the upper part of the internal ear and part of the medial wall of the tympanum. The *opisthotic* centre appears at the promontory. It forms part of the medial wall of the tympanum, the lower part of the internal ear,

the floor of the internal meatus and part of the walls of the carotid canal. The *pterotic* centre appears in the roof of the tympanum. It forms the tegmen tympani; the part of it in the roof of the canal for the tensor tympani sends down a thin process that forms the lateral wall of the pharyngo-tympanic tube and appears in the squamo-tympanic fissure. The *epiotic* centre (or centres) appears in the base of the petrous part. It gives rise to the bone that encloses the posterior and lateral semicircular canals and forms the mastoid portion.

The **styloid process** is developed from the cranial part of the cartilage of the second pharyngeal arch. It is ossified from two centres. The upper centre (*tympano-hyal*) appears shortly before birth and fuses with the petro-mastoid during the first year. The lower centre (*stylo-hyal*) appears in the cartilage shortly after birth; but the lower part ossifies slowly; it does not fuse with the upper part till after puberty, and may never do so.

The **tympanic part** is ossified from one centre which appears in the third month at the lower margin of the membranous, lateral wall of the tympanum. Ossification proceeds in curved linear directions to form the *tympanic ring*, which is incomplete superiorly, and fuses with the petrous part medially. After birth it extends medially, laterally and downwards to form the tympanic plate.

Structure and Variations.—The temporal bone is remarkable for the hardness and density of its petrous part, which contains the osseous labyrinth, wherein are lodged the delicate organs of hearing and equilibration. The weakest part of the bone corresponds to a line that connects the two meatuses; for they are separated only by the cochlea and tympanum. It is usually in this position that fracture of the bone occurs.

The line of the petro-squamous suture is occasionally grooved for the lodgment of a sinus (petro-squamous); sometimes the posterior end of the groove is continuous with a canal that traverses the upper border of the bone and opens into the transverse groove. Anteriorly the groove may pass into a canal that traverses the root of the zygoma and appears externally above the lateral end of the squamo-tympanic fissure. They are the remains of channels through which the blood passed in the fœtal condition. Single cases have been recorded in which:—(1) the

squamous part was pneumatic, the sinus reaching as high as the parietal bone; (2) the squamous part was separate from the rest of the bone in an adult; (3) the squamous part was divided into two by a transverse suture; (4) the zygoma was separated from the rest of the bone by a suture close to its root; (5) the zygoma was almost completely absent; (6) the carotid canal was rudimentary; (7) there was absence of the internal auditory meatus and the stylo-mastoid foramen and also of the jugular fossa, associated with a large mastoid foramen and partial absence of the transverse groove. In idiots and imbeciles a more pronounced form of post-glenoid tubercle has been noted and associated with regressive changes in the development of the temporal bone. Occasionally the temporal articulates with the frontal, as happens normally in the anthropoid apes.

Sphenoid Bone

The **sphenoid bone** lies in front of the basilar part of the occipital bone and the two temporal bones. It enters into the formation of the cranial, orbital, and nasal cavities, and also the temporal, infratemporal, and pterygo-palatine fossæ. It has a body and three pairs of processes—the greater and lesser wings and the pterygoid processes.

The **body** is more or less cubical, and it is hollow, for it contains the **sphenoidal air-sinuses.** The sinuses are a right and left, separated by a partition. Each sinus communicates by a round aperture with the spheno-ethmoidal recess of the nose (see p. 195). In the adult the **posterior surface** of the body is a sawn surface because it is fused with the basi-occipital. The **superior surface** resembles an oriental saddle (**sella turcica**). The seat is a depression, called the **hypophysial fossa**, that lodges the hypophysis of the brain. The fossa is overhung posteriorly by a sloping plate called the **dorsum sellæ**, the posterior surface of which is continuous with the clivus of the skull. The upper angles of the dorsum sellæ are prominent tubercles called the **posterior clinoid processes.** In front of the hypophysial fossa there is a transverse elevation called the **tuberculum sellæ**, behind the lateral ends of which there are sometimes little spurs of bone called the **middle clinoid processes.** In front of the tuberculum sellæ there is the **optic groove**, which passes laterally into the optic foramina. The flat area in front of the optic groove is called the *jugum sphenoidale*; it is on the same plane as the upper surfaces of the lesser wings, and terminates anteriorly in a ragged edge that articulates with the cribriform plates of the ethmoid.

The lower part of each **side** of the body is fused with the greater wing, and in part also with the root of the pterygoid process. Curving along the side of the body, above its attachment to the greater wing, there is an ʃ-shaped groove, called the **carotid groove**, in which the internal carotid artery lies. Posteriorly, the hinder margin of that groove, formed by the salient lateral edge of the posterior surface of the body, articulates with the apex of the petrous portion of the temporal bone.

The **anterior surface** of the body displays a median ridge, the **crest of the sphenoid**, whose lower, more prominent part is the **rostrum**. The crest articulates with the perpendicular plate of the ethmoid. On each side of the median plane there is a triangular area which forms part of the roof of the nose; in that area there is the opening that leads out of the sphenoidal sinus. The lateral part of the anterior surface, on each side, articulates with the labyrinth of the ethmoid and the orbital process of the palatine bone. The **sphenoidal rostrum** is continued backwards for some distance along the **inferior surface** of the body, where it forms a prominent keel that fits into the recess between the alæ of the vomer. Posteriorly, the inferior surface of the body is rougher, and is covered with the muco-periosteum of the pharynx.

The **sphenoidal conchæ** are a pair of thin bones that are fused with the sphenoid, ethmoid, and palatine bones, and usually are partially destroyed when the skull is disarticulated. They form the anterior surface of the body of the sphenoid and the anterior part of its lower surface, except its crest and rostrum. Each resembles an inverted triangle, and is curved. Its smaller, apical part lies in the floor of the sphenoidal sinus and separates the sinus from the most posterior part of the roof of the nose, and its infero-lateral edge forms the upper margin of the spheno-palatine foramen. The remainder of the triangular plate lies in the anterior wall of the sinus and is divisible into two parts. The lateral part forms the posterior wall of the posterior ethmoidal sinuses and articulates inferiorly with the orbital process of the palatine bone. The medial part is free in the roof of the nose, and in it there is the opening of the sphenoidal sinus.

The sphenoidal conchæ are formed, before birth, around the most posterior part of the cavity of the cartilaginous nasal capsule. That part of each half of the nasal cavity is a recess shut off from the rest of the cavity by membrane inferiorly, but anteriorly it communicates with the cavity by an aperture. In the fifth month, or later, ossification begins in the cartilaginous and membranous boundaries of the recess and converts them into the bony walls of a sphenoidal concha. In the infant, each concha is a hollow, three-sided pyramid. Its cavity is the rudiment of the **sphenoidal sinus**, but it was originally part of the cavity of the nose. It remains in communication with the nose; for the original aperture of communication is in the *base* of the pyramid, which partly is free in the roof of the nose, and partly fits on to the posterior surface of the ethmoid labyrinth and also articulates with the orbital process of the palatine bone. The *apex* articulates with the vaginal process of the medial pterygoid plate. The *infero-lateral wall* forms part of the roof of the nose and the upper boundary of the spheno-palatine foramen. The *superior wall* and the *medial wall* are applied to the antero-inferior aspect of the body of the sphenoid. In the fourth year, the concha fuses with the ethmoid and palatine bones, and its

superior and medial walls are absorbed. But the extension of the rudimentary sinus into the body of the sphenoid, by absorption of its spongy bone, does not begin till the seventh or eighth

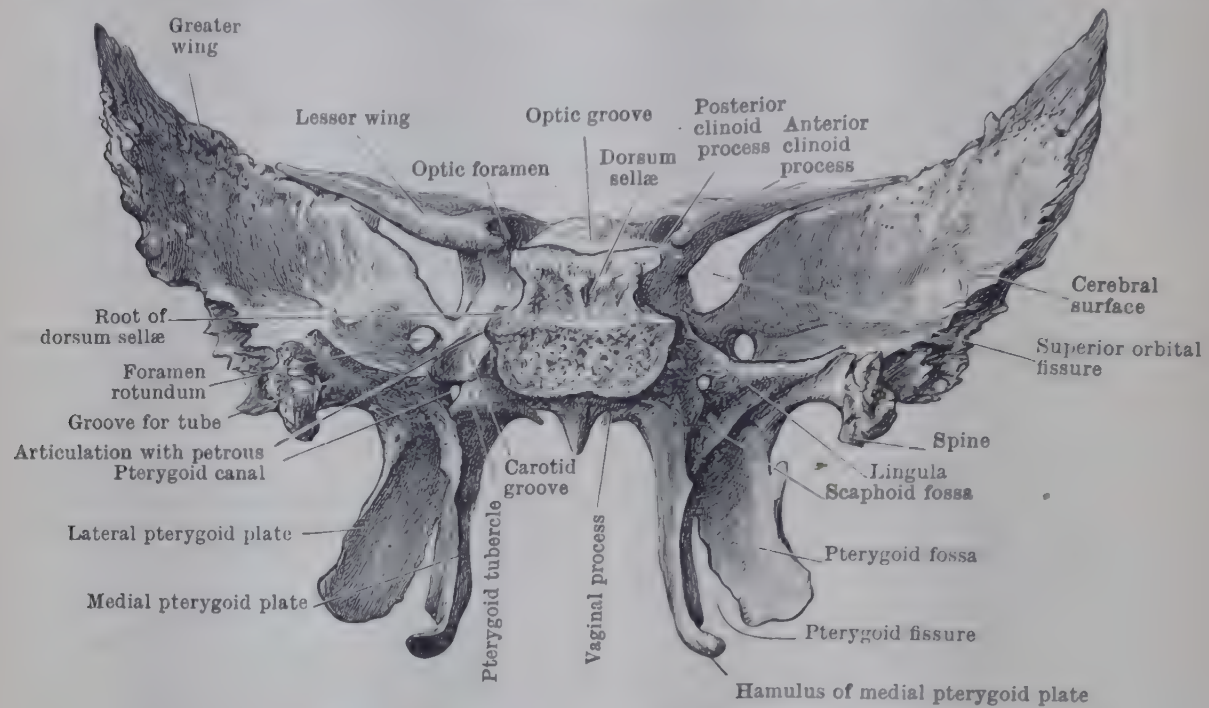

FIG. 189.—SPHENOID BONE SEEN FROM BEHIND.

year; and fusion of the concha with the sphenoid does not take place till between the ninth and twelfth years.

The **lesser wings** are a pair of flattened, triangular plates that project laterally from the anterior and upper part of the body of the bone; each wing is united to the body by two roots—an anterior and a posterior—separated by the **optic foramen.** The posterior root springs from the body just wide of the tuberculum sellæ, separating the carotid groove behind from the optic foramen in front; laterally this root is confluent with the recurved posterior angle of the lesser wing, which projects backwards and is known as the **anterior clinoid process.** The anterior root, broad and compressed, joins the anterior part of the upper surface of the body.

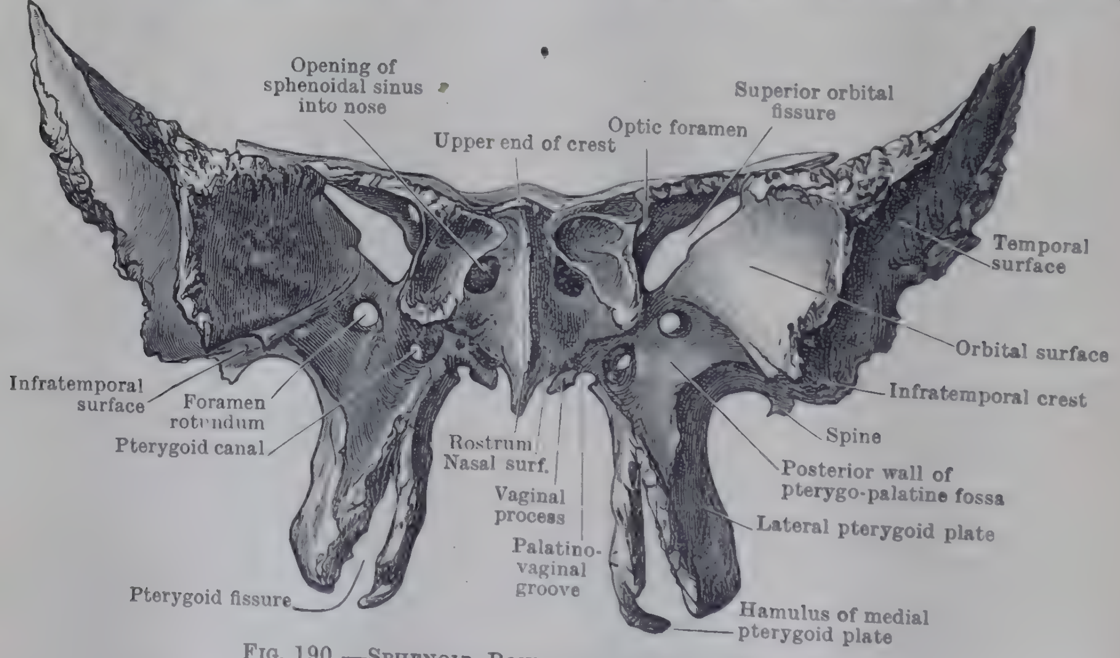

FIG. 190.—SPHENOID BONE SEEN FROM IN FRONT.

Laterally, the pointed end of the wing reaches the region of the pterion and articulates there with the frontal, and may come in contact with the greater wing. The upper surface is smooth and forms part of the floor of the anterior cranial fossa. The lower surface is the most posterior portion of the roof of the orbit, and it is also the upper boundary of the **superior orbital fissure,** which separates the lesser wing from the greater wing. The anterior edge is ragged and articulates with the orbital plate of the frontal bone. The posterior margin, sharp and sickle-shaped, separates the anterior from the middle cranial fossa and ends medially in **the anterior clinoid process.**

Each **greater wing** spreads out from the side of the body of the sphenoid in the floor of the middle cranial fossa and turns upward into the side-wall of the skull. It has three surfaces —an internal or *cerebral*, an *orbital*, and an external, which is divided into a *temporal surface* and an *infratemporal surface.*

The **cerebral surface** is concave and is marked by impressions for cerebral gyri and by grooves for meningeal vessels. Three foramina are seen in it and sometimes four. The **foramen rotundum** is a short horizontal canal that passes forwards below the medial part of the superior orbital fissure. The **foramen ovale** is situated about 10 or 12 mm. behind and lateral to the foramen rotundum. The **foramen spinosum** is the smaller aperture immediately behind and lateral to the foramen ovale. The fourth foramen, which is not always present, is a small hole, called the **sphenoidal emissary foramen,** situated medial to the foramen ovale. The *borders* of the cerebral surface are upper or anterior, medial, and posterior. The *medial border* is fused with the side of the body of the sphenoid. The *posterior border* is divided into two distinct parts that meet together posteriorly in a sharp projecting angle. The medial part is a short distance behind the foramina ovale and spinosum and is oblique in direction; laterally it articulates with the petrous temporal; medially it forms the anterior boundary of the foramen lacerum. There projects backwards from it a spur of bone of variable size, called the **lingula,** which forms the anterior or lateral margin of the commencement of the carotid groove; when the lingula is long enough it forms also the lateral margin of the foramen lacerum. The lateral part of the posterior border is a long, concave, serrated edge that articulates with the squamous temporal. The *upper border* also is divided into parts. The medial part, thin and sharp, forms the lower boundary of the superior orbital fissure; the next part articulates with the frontal bone; and the third part is the extreme upper part of the wing and articulates with the antero-inferior angle of the parietal bone.

The **orbital surface** is smooth, nearly flat, more or less quadrilateral, and forms a great part of the lateral wall of the orbit. Its *posterior border* is the medial part of the upper border of the cerebral surface and forms the lower margin of the superior orbital fissure. The *lower border* is smooth and forms the upper or lateral boundary of a cleft called the inferior orbital fissure; immediately below that border there is an oblique, horizontal groove that forms part of the posterior wall of the pterygo-palatine fossa. The *anterior border* articulates with the zygomatic bone; and the *upper border* articulates with the frontal bone.

The **temporal surface** is separated *posteriorly* from the cerebral surface by the border that articulates with the squamous temporal. *Anteriorly* it is separated from the orbital surface by the sharp crest that articulates with the zygomatic bone and sometimes also with the zygomatic process of the maxilla. *Superiorly* the uppermost part of the surface is separated from the cerebral surface by the short border that articulates with the parietal bone; in front of that it articulates with the frontal bone. The articulation of the greater wing with the frontal bone is by a rough triangular area bounded by the upper margins of the three surfaces of the wing. *Inferiorly* the temporal surface is limited by a rough, horizontal ridge called the **infratemporal crest.**

The **infratemporal surface** is almost at right angles to the temporal surface. The **foramen ovale** and **foramen spinosum** are seen in it near its posterior border, and the occasional *sphenoidal emissary foramen* medial to the foramen ovale. The *posterior border* articulates with the petrous temporal and is grooved lengthwise for the cartilage of the pharyngo-tympanic tube, which lies along the junction of the two bones. *Medially* the surface is fused with the pterygoid process. *Anteriorly* it is bounded by a sharp margin behind the inferior orbital fissure. *Laterally* it is bounded by the infratemporal crest, and behind that it is separated from the cerebral surface by the part of the posterior border that articulates with the lower part of the squamous temporal. That boundary and the posterior border which articulates with the petrous temporal meet at the angle which fits into the angular interval between the squamous and petrous temporal. From the angle a projection called the **spine** of the sphenoid juts downwards.

Each **pterygoid process** springs from the lower part of the side of the body and from the root of the greater wing and passes vertically downwards. Its *lateral* and *medial* plates enclose the **pterygoid fossa** between them; the upper parts of their anterior borders are fused together.

The **lateral pterygoid plate,** thin and expanded, is directed obliquely backwards and laterally—its lower part being often slightly everted. Its posterior edge is sharp, and often has projecting from it one or two spines, one of which (*pterygo-spinous process*) gives attachment to the pterygo-spinous ligament, which stretches to the spine of the sphenoid.

The **medial pterygoid plate** is narrower and rather thicker. It is placed between the pterygoid fossa and the posterior part of the nasal cavity. Its posterior margin is sharp, and ends below as a slender, curved process, called the **pterygoid hamulus,** which, reaching a lower level than the lateral plate, curves backwards and laterally, and has a groove on its lower surface in which the tendon of the tensor palati muscle glides; superiorly, the posterior margin bifurcates to enclose the **scaphoid fossa,** a small, shallow, oval concavity. Below the fossa is a small projection from the posterior margin to support the cartilage of the pharyngo-tympanic tube. At the extreme upper end of the posterior margin of the plate, there is a small, blunt projection called the **pterygoid tubercle.** The **vaginal process** is a thin lamina which passes medially from the upper end of the plate. Near the plate this process is fused with the lower surface of the body of the sphenoid. More medially it is free and is separated from the rostrum by a groove in which the edge of the ala of the vomer fits in the articulated skull, and it articulates with the ala. On the lower surface of the vaginal process, near the medial pterygoid plate, there is a groove which, in an articulated skull, leads forwards into the palatino-vaginal canal.

Above the pterygoid tubercle, and below the lingula, there is a small aperture that leads into

the **pterygoid canal**, which passes forwards through the root of the pterygoid process. In front, at its root, the pterygoid process displays a broad, smooth surface which is confluent above with the root of the greater wing around the foramen rotundum, and forms the posterior wall of the **pterygo-palatine fossa**. Medial to the foramen rotundum, and below it, the anterior opening of the **pterygoid canal** is seen. The lower parts of the pterygoid plates are separated by an angular cleft called the **pterygoid fissure**; this fissure lodges the tubercle of the palatine bone; the edges of the fissure are serrated, and they articulate with the margins of the tubercle.

Ossification.—The sphenoid is ossified partly in cartilage and partly in membrane (p. 213). The body is at first in two parts—pre-sphenoid and post-sphenoid. The **pre-sphenoid** is the part in front of the tuberculum sellæ and is connected with the lesser wings. The **post-sphenoid** is the rest of the body and is connected with the pterygoid processes and the greater wings.

The ossific centres are in pairs, and appear as follows:—

One, at the eighth week, between the foramen ovale and foramen rotundum, for the **greater wing** and the **lateral pterygoid plate**.

One, at the eighth week, in the hypophysial fossa at the side of the cranio-pharyngeal canal, for the main part of the **post-sphenoid**.

One, at the ninth week or later, near the carotid groove, for the side of the post-sphenoid and the **lingula**.

One, at the ninth week, in the **medial pterygoid plate**, for that plate and its hamulus.

One, at the ninth week, immediately lateral to the optic foramen, for the **lesser wing** and its roots and the jugum sphenoidale.

One, at the tenth week, medial to the optic foramen, for the main part of the **pre-sphenoid** (*i.e.*, pre-sphenoid *minus* the jugum and the conchæ).

One (which may be quadruple), in the fifth month or later, for the **sphenoidal concha**.

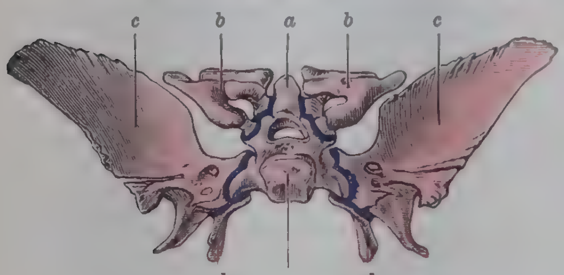

Fig. 191.—Ossification of Sphenoid.

a, Pre-sphenoid; *b*, Lesser wings; *c*, Greater wings; *d*, Medial pterygoid plates; *e*, Post-sphenoid.

The medial pterygoid plate is the first part to be completely ossified; its hamulus is chondrified during the third month immediately before ossification spreads into it. The two pairs of centres for the post-sphenoid are fused by the sixth month; and the post-sphenoid unites with the pre-sphenoid in the seventh month. **At birth** the bone is in three pieces—the greater wing with the pterygoid process on each side, and the body with the lesser wings. They have fused by the end of the first year. During that year ossification spreads medially from the lesser wings to form the jugum sphenoidale. Occasionally two median foramina are seen in young skulls—one on the tuberculum sellæ and one farther forward—due to delayed fusion between the post-sphenoid and the jugum and between the halves of the jugum.

Variations.—The foramen spinosum and the foramen ovale are sometimes incomplete posteriorly. The superior orbital fissure, in rare cases, communicates with the foramen rotundum or with the optic foramen. The optic foramen has been found double—the optic nerve passing through one canal and the ophthalmic artery through the other. Ossification of fibrous bands leads to the formation of anomalous foramina, *e.g.*, the *carotico-clinoid foramen*, between the anterior and middle clinoid processes; the *pterygo-spinous foramen*, enclosed by ossification of the band between the spine and the lateral pterygoid plate; the *porus crotaphitico-buccinatorius*, enclosed by ossification of a ligament below and lateral to the foramen ovale. The lesser superficial petrosal nerve sometimes passes through a minute, unnamed hole near the posterior border of the greater wing. The sphenoidal sinus varies in size; may be absent; and is occasionally multilocular.

Ethmoid Bone

The **ethmoid bone** lies in front of the sphenoid, between the orbits and the orbital plates of the frontal bone; it enters into the formation of the anterior cranial fossa, the orbits, and the nasal cavities. It is extremely light, and consists of a pair of cellular parts called the **ethmoidal labyrinths**, united superiorly to a median **perpendicular plate** by a pair of thin horizontal laminæ which, from their perforated condition, are called the **cribriform plates**.

The study of the ethmoid bone will be easier if one cribriform plate is cut through.

The **perpendicular plate** forms the upper part of the nasal septum and has an irregular pentagonal outline. Its **superior border** projects above the level of the cribriform plates into the cranial cavity to form a crest called the **crista galli**. The crest is thicker than the rest of the plate, and contains either spongy bone or an air-cell. It is highest in front, and its lower part divides anteriorly into a pair of **alæ** which project forwards to articulate with the frontal bone and enclose the **foramen cæcum**. The **posterior border** of the perpendicular plate articulates with the crest of the sphenoid. The **posterior inferior border** in the adult articulates with the vomer, and fuses with it after the fortieth year. The **anterior inferior border** is usually thicker than the others, and unites with the cartilaginous nasal septum. The **anterior superior border** articulates with the nasal spine of the frontal bone and with the median crest of the two

nasal bones. The *surfaces* are fairly smooth, except superiorly, where there are short and shallow grooves that lead to the foramina in the cribriform plate.

Each **cribriform plate** occupies the interval between the orbital plate of the frontal bone and the crista galli; it lies in the roof of the nose and in the floor of the anterior cranial fossa, and it articulates posteriorly with the sphenoid.

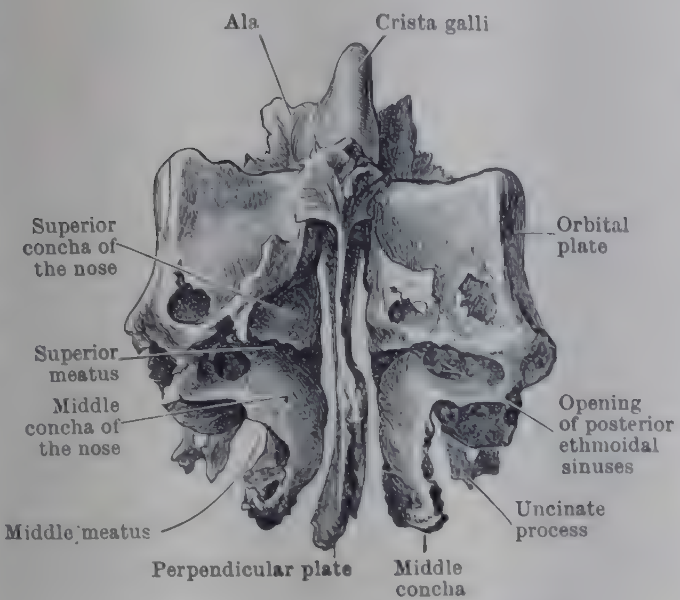

Fig. 192.—Ethmoid seen from Behind.

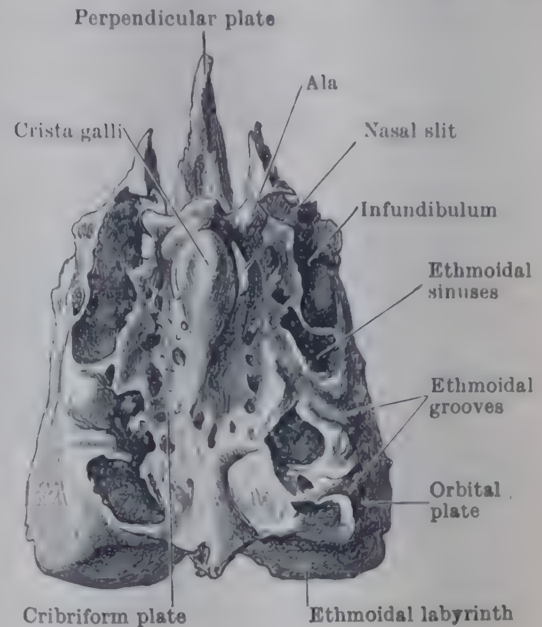

Fig. 193.—Ethmoid seen from Above.

The **ethmoidal labyrinth** is composed of exceedingly thin bone which encloses a large number of air-sinuses; the sinuses are arranged in three groups—an anterior, a middle, and a posterior—the walls of which have been broken in the process of disarticulation.

The *posterior surface* of the labyrinth articulates with the front of the body of the sphenoid and the orbital process of the palatine bone, which close in the posterior sinuses. The *anterior surface* is oblique and is covered by the lacrimal bone and the upper part of the frontal process of the maxilla, which close the anterior sinuses. The *upper surface* is covered by the orbital plate of the frontal bone, which completes the sinuses superiorly; and it is crossed by two grooves which are converted into the **anterior** and **posterior ethmoidal canals** when the orbital plate is in position. *Laterally* the cells are closed in by a thin, oblong lamina, the **orbital plate** of the ethmoid, which forms a part of the medial wall of the orbit. The plate articulates *above* with the orbital plate of the frontal bone; *in front* with the lacrimal bone; *below* with the orbital surface of the maxilla; *behind* with the sphenoid; and at its posterior inferior angle for a variable distance, with the orbital process of the palatine bone.

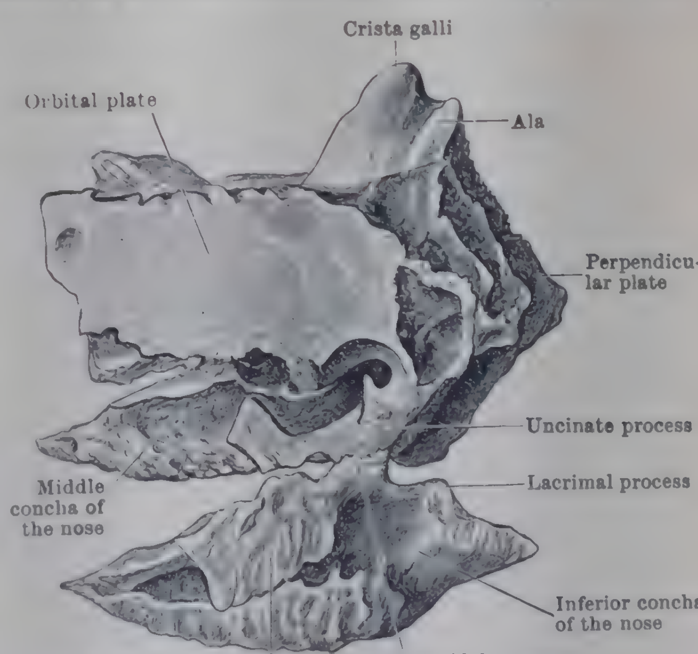

Fig. 194.—Lateral Surface of Ethmoid and Inferior Concha.

On the *medial surface* of the labyrinth the sinuses are closed in by thin, rough bone, but they open into the nose by small apertures on this surface, which is free in the lateral wall of the nasal cavity. The surface is very uneven, and from it two thin, rough, curled plates of bone, called the superior and middle nasal conchæ, project medially into the cavity of the nose and then curve downwards.

The **superior concha** is small and may be a mere ridge. It projects from the posterior half of the surface, less than half an inch below the cribriform plate. The bone above the concha closes in the posterior ethmoidal sinuses, and is finely grooved for olfactory nerves; the grooves begin on the concha and run upwards and forwards to the lateral foramina of the cribriform plate. The space lateral to the concha, and between it and the middle concha, is the **superior meatus** of the nose, and the posterior ethmoidal sinuses open into it. The bone in front of the superior meatus and superior concha closes in middle and anterior ethmoidal sinuses.

The **middle concha** is much deeper than the superior, and is as long as the labyrinth. Its anterior end articulates with the ethmoidal crest of the maxilla, and its posterior end with the ethmoidal crest of the palatine bone. The space lateral to it is the upper part of the **middle meatus** of the nose. The lower members of the middle ethmoidal sinuses bulge into the meatus, forming the **ethmoidal bulla**, a rounded elevation on which the middle sinuses open. The bulla is bounded below and in front by a curved groove or a slit, the **hiatus semilunaris**, into which the anterior sinuses open. The upper or anterior end of the hiatus is continuous with a canal, called the **ethmoidal infundibulum**, which runs upwards and forwards through the anterior part of the labyrinth to open into the frontal sinus. The hiatus is bounded in front and below by a thin bar of bone called the **uncinate process**. The uncinate process springs from the anterior part of the roof of the middle meatus; it curves downwards, backwards and a little laterally, bridging across the opening of the maxillary sinus, to articulate with the ethmoidal process of the inferior concha.

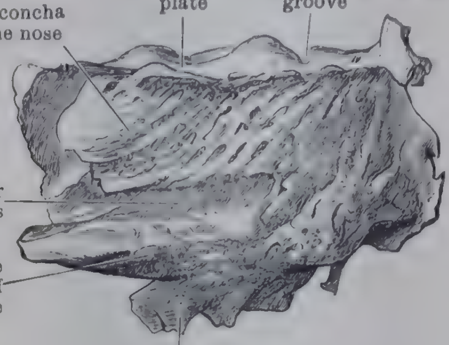

Fig. 195.—Section showing the Nasal Side of Left Labyrinth of Ethmoid.

Ossification takes place in the cartilage of the nasal capsule. In the fourth or fifth month one centre appears, near the orbital plate, for each **labyrinth** (including its conchæ), which is completely ossified at birth; the sinuses appear before birth. At the end of the first year, a pair of centres appear at the root of the crista galli for the **perpendicular plate**, whose ossification is not completed till the fifth or sixth year. The **cribriform plate** is ossified during the second year by extension from the labyrinth and the perpendicular plate; and it fuses with the sphenoid after twenty-five.

Variations.—The orbital plate varies in size and shape. It is narrower from above downwards in the lower races than in the higher—in this respect resembling the condition in the anthropoids. And, as in the gorilla and chimpanzee, it may fail to articulate with the lacrimal, owing to a downgrowth of the frontal which articulates with the orbital surface of the maxilla (orbito-maxillary-frontal suture). It is sometimes divided by a vertical suture into an anterior and a posterior part. The number of the conchæ may be increased from two to four, or may be reduced to one.

Inferior Nasal Conchæ

Each **inferior concha** is an elongated, shell-like lamina of bone that lies along the lower part of the lateral wall of the nasal cavity. It has two surfaces and two borders.

The **superior** or **attached border** is thin and unevenly convex. It is sharp in front and behind, where it articulates with the conchal crests of the maxilla and the palatine bone. Between those two articulations the central part of the upper border rises in the form of a sharp crest; the anterior part of the crest stands up as the **lacrimal process**, which articulates above with the descending process of the lacrimal bone, and also with the edges of the lacrimal groove of the maxilla, thus completing the wall of the naso-lacrimal canal. The posterior end of the crest is raised to form the **ethmoidal process**, an irregular projection which unites with the uncinate process of the ethmoid bone (see Fig. 194). From the middle of the upper border, on its lateral side, a thin irregular plate, the **maxillary process**, spreads downwards and conceals part of the lateral surface. This process unites with the medial surface of the maxilla, partly helping to close the gap that leads into the maxillary sinus and partly hanging down in the sinus between its mucous lining and medial wall. The **inferior** or **free border** is gently curved from before backwards and turned slightly laterally, is rounded and full, is deeply pitted, and is of a slightly cellular character. The **anterior** and **posterior ends** of the bone are thin and sharp.

Fig. 196.—Medial Surface of Right Inferior Concha.

The **medial surface** is uneven and convex and bulges into the nasal cavity; it is rough and pitted, and is marked by some fine, scattered, and longitudinally directed vascular grooves. The **lateral surface** is concave and forms the medial boundary of the inferior meatus of the nose. It is smooth in front, where it corresponds to the opening of the naso-lacrimal canal; posteriorly and towards its inferior border it is irregular and pitted.

A case in which the inferior conchæ were absent has been recorded.

Ossification.—The inferior concha is ossified in the cartilage of the lateral wall of the nasal capsule from one centre which appears about the fifth month of intra-uterine life.

Lacrimal Bones

The **lacrimal bone**—a thin scale of bone about the size of a finger-nail—forms part of the medial orbital wall behind the frontal process of the maxilla. It is irregularly quadrangular, and has two surfaces—a medial and a lateral—and four borders.

The posterior part of the **medial surface** is uneven and cellular; it closes in some anterior ethmoidal sinuses and the ethmoidal infundibulum. The anterior part is smaller and smoother, and is separated from the posterior part by a shallow groove; it forms a small part of the lateral wall of the nose behind the frontal process of the maxilla and above the inferior concha. The **lateral surface** looks into the orbit, and is divided by a vertical ridge opposite the groove on the medial surface. This **crest** ends inferiorly as a hook-like process called the **lacrimal hamulus.** The hamulus curves forwards round the postero-lateral edge of the naso-lacrimal notch of the maxilla, and thus forms the postero-lateral boundary of the opening into the naso-lacrimal canal. The area behind the crest is nearly flat, and forms the part of the medial wall of the orbit in front of the orbital plate of the ethmoid. The area in front of the crest is narrower and is concave, forming the floor of the **lacrimal groove**, which combines with the lacrimal groove on the frontal process of the maxilla to form the fossa for the lacrimal sac. The floor of the lacrimal groove is prolonged downwards beyond the main part of the bone as the **descending process**, which forms the medial boundary of the opening of the naso-lacrimal canal.

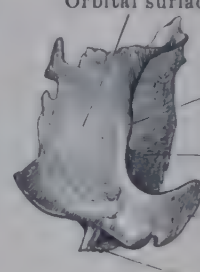

FIG. 197.—RIGHT LACRIMAL BONE (Orbital Surface).

The **inferior border** articulates with the orbital surface of the maxilla, and, anteriorly, by the descending process, with the lacrimal process of the inferior concha. The **anterior border** articulates with the frontal process of the maxilla; the **superior border** with the frontal bone; the **posterior border** with the orbital plate of the ethmoid.

Ossification.—The lacrimal is ossified from one centre which appears in the third month of intra-uterine life in the membrane that covers the cartilaginous nasal capsule.

Variations.—The lacrimal bone is occasionally absent. In some skulls it is divided into two or more parts. The hamulus may be small; but in rare cases it extends forwards to the orbital margin, and shares in the formation of the face, as in lemurs.

Vomer

The **vomer** is placed in the posterior part of the nasal septum. It has four borders and two surfaces. The **superior border** is easily recognized, because it is split into a pair of everted lips or **alæ**. It articulates with the inferior surface of the body of the sphenoid, whose rostrum fits in between the alæ. Each **ala** is wedged in between the sphenoidal process of the palatine bone and the vaginal process of the medial pterygoid plate. The **posterior border** is a free, sharp, slightly curved edge, and forms the posterior margin of the nasal septum. The **inferior border** articulates with the nasal crest formed by the maxillæ and the palatine bones. The **anterior edge** is the longest; it slopes obliquely from above downwards and forwards. Its upper half articulates with the perpendicular plate of the ethmoid and is fused with it after middle age; its lower half is grooved to receive the septal cartilage of the nose. The **anterior end** of the bone is a truncated angle which articulates with the posterior border of the prominent, anterior part of the nasal crest of the maxillæ, and sends downwards a pointed process which passes between the incisive canals. The **surfaces** of the bone are smooth, except for a few vascular grooves; one groove, usually more distinct than the others, runs obliquely downwards and forwards and lodges the long spheno-palatine nerve.

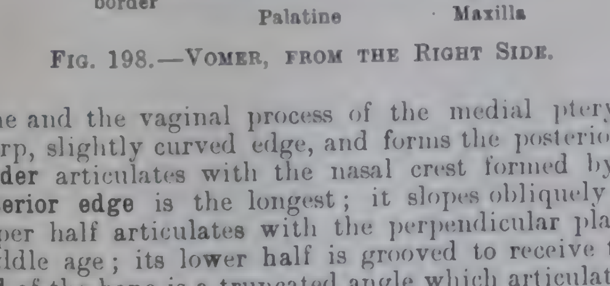

FIG. 198.—VOMER, FROM THE RIGHT SIDE.

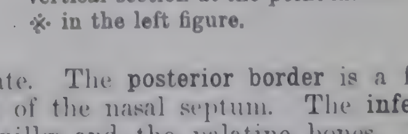

FIG. 199.

VOMER AT BIRTH, consisting of two Osseous Laminæ united inferiorly. The figure to the right represents a vertical section at the point marked * in the left figure.

Ossification.—The vomer begins to ossify at the eighth week of intra-uterine life from a pair of centres that appear in the membrane on the postero-inferior part of the cartilaginous septum of the nose. They form a pair of plates of bone separated by cartilage. During the third month the plates unite along their lower edges, and their fusion is not much further advanced at birth. As growth goes on, the cartilage is absorbed, and fusion of the laminæ takes place from below

upwards and is almost complete at puberty; but, even in the adult, the bilaminar origin is indicated by the alæ and by the groove on the anterior border. The anterior end is partly ossified in cartilage by extension of the ossifying process into the paraseptal cartilages (p. 213).

Structure and Variations.—The bone is composed of two compact layers fused together, except at the grooves for the rostrum of the sphenoid and the septal cartilage, and also along a line where a canal runs horizontally from behind forwards in the substance of the bone. The canal is named the **spheno-vomerine canal**; it transmits the nutrient vessels, which enter the bone through a minute aperture at the posterior end of the groove between the alæ.

Owing to imperfect ossification there may be a deficiency in the bone—filled up during life with cartilage. The depth of the groove along the anterior border varies considerably; sometimes the two lamellæ are separated by a considerable cavity; and occasionally the sphenoidal sinus sends a small extension forwards between the lamellæ.

Nasal Bones

The **nasal bones** lie between the frontal processes of the maxillæ in the bridge of the nose. Each bone is elongated and quadrangular and is slightly constricted above its middle. The **outer surface** is convex from side to side, and slightly concavo-convex from above downwards. Near its centre there is usually the opening of a vascular canal. The **inner surface** or mucous surface forms part of the roof and side-wall of the cavity of the external nose. It is smooth and concave, and it is triangular in outline. On its posterior part the anterior ethmoidal nerve makes a narrow, nearly vertical groove. The **medial border** articulates with its fellow of the other side. Inferiorly it is thin. Superiorly it widens out into a triangular area. The posterior edges of these triangular areas of the right and left bones are raised to form a narrow median **nasal crest**, which forms a small part of the nasal septum and articulates, from above downwards, with the nasal spine of the frontal bone, the perpendicular ethmoidal plate, and the septal cartilage. The **lateral border**, usually the longest, is serrated and bevelled, and articulates with the anterior edge of the frontal process of the maxilla. The **superior border** is a toothed surface which articulates with the frontal bone at the nasal notch. It rests, posteriorly, on the root of the nasal spine. The **inferior border** is thin and sharp; it is connected with the lateral cartilage of the nose, and is often deeply notched near its medial extremity.

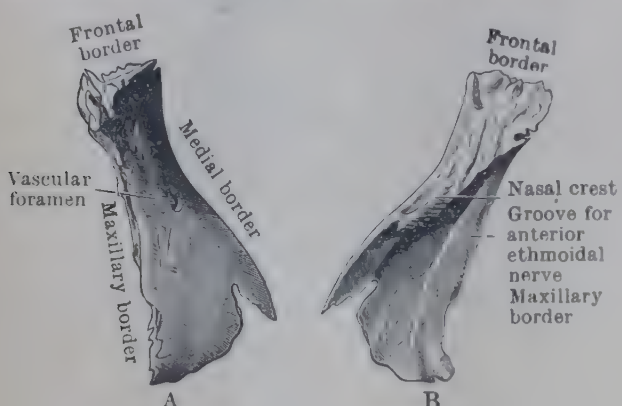

FIG. 200.—RIGHT NASAL BONE.
A, Outer aspect; B, Inner aspect.

Ossification.—The nasal bones are each developed from a single centre which appears about the end of the second month in the membrane that covers the cartilaginous nasal capsule.

Structure and Variations.—The nasal bone is made of dense compact tissue, and it is strengthened by the formation of the nasal crest.

The nasal bones vary greatly in different people as well as in different races. As a rule they are large and prominent in the White races, and are small, flat, and depressed in Mongolians and Negroes. Absence has been recorded; and division into two or more parts; and one case of unusual extension downwards. Obliteration of the internasal suture is uncommon; it is stated to occur more frequently in negroes, and it is the usual condition in adult apes.

Maxillæ

The two **maxillæ** form the upper jaw. Each has a **body** and four **processes**—**zygomatic, frontal, alveolar,** and **palatine.**

The **body** is pyramidal, and contains the **maxillary sinus** (p. 197). It has four surfaces—anterior, posterior, orbital, and nasal.

The **anterior surface** is concavo-convex. *Superiorly* it is limited, from behind forwards (or latero-medially), by the root of the zygomatic process, the **infra-orbital margin**, and the root of the frontal process. *Anteriorly* it is limited by a sharp, curved edge that bounds the wide concavity of the nasal notch, and ends below in a pointed process. This process unites with the similar projection of the other maxilla to form the **anterior nasal spine**, a sharp spur situated at the upper end of the intermaxillary suture. *Inferiorly* the surface is confluent with the alveolar process, which is ridged by the sockets of the teeth. The largest ridge is the canine eminence produced by the socket of the canine tooth. The shallow depression medial to the eminence overlies the upper parts of the incisor sockets. The wide depression that extends from the eminence to the zygomatic process is called the **canine fossa**; immediately above it, near the infra-orbital margin, is the **infra-orbital foramen**. *Posteriorly* the surface is limited by

the zygomatic process and a blunt ridge that descends from the process and fades away at the first or the second molar socket.

The **posterior surface** is rounded and full. It forms the anterior walls of the infratemporal and pterygo-palatine fossæ. *Laterally* it is separated from the anterior surface by the zygomatic process and the ridge. *Medially* it is separated from the nasal surface by an uneven, vertical margin. *Inferiorly* it ends as the **maxillary tuberosity**, which is a rough, low prominence behind the last molar socket; above the tuberosity there are the openings of the two **posterior dental canals**, which convey the vessels and nerves downwards and forwards to the molar and premolar teeth. *Superiorly* the surface is limited by a rounded border that forms the anterior boundary of the inferior orbital fissure in the articulated skull.

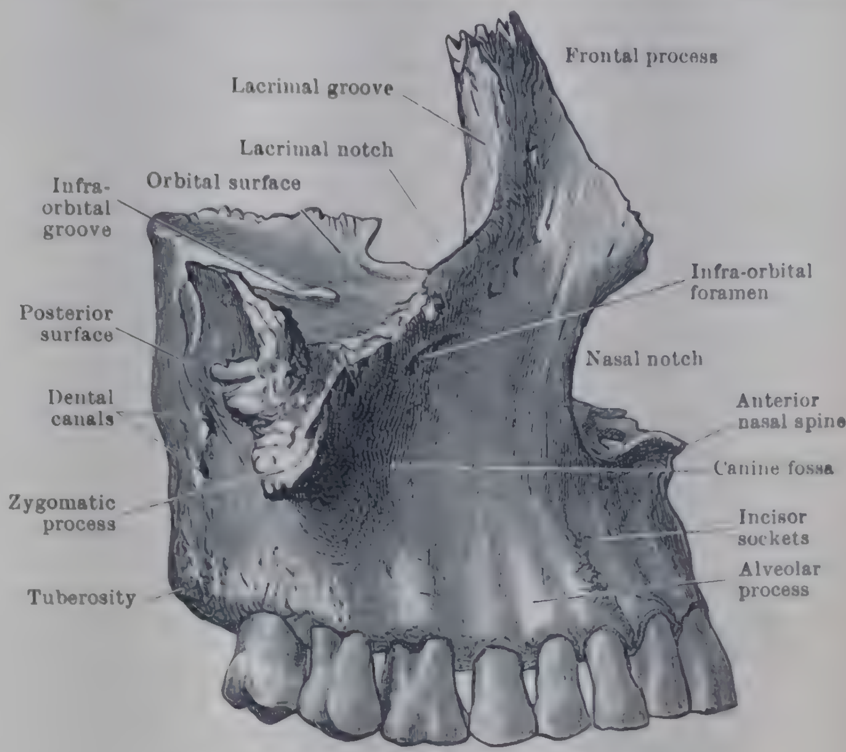

FIG. 201.—RIGHT MAXILLA (Lateral View).

The **orbital surface** is smooth and flat, and is triangular in outline. It forms the greater part of the floor of the orbit. From behind forwards, the surface is traversed by the **infra-orbital groove** and **canal**. The canal ends as the infra-orbital foramen; and, if it is laid open, a small aperture is seen leading into the **anterior dental canal**, which conveys the vessels and nerve to the canine and incisor teeth. The surface is limited *posteriorly* by the margin of the inferior orbital fissure, and *anteriorly* by the root of the zygomatic process and the infra-orbital margin. *Medially* it is limited by a sharp margin whose anterior part bounds the **naso-lacrimal notch**, while the rest articulates, from before backwards, with the lacrimal bone, the orbital plate of the ethmoid, and the orbital process of the palatine bone.

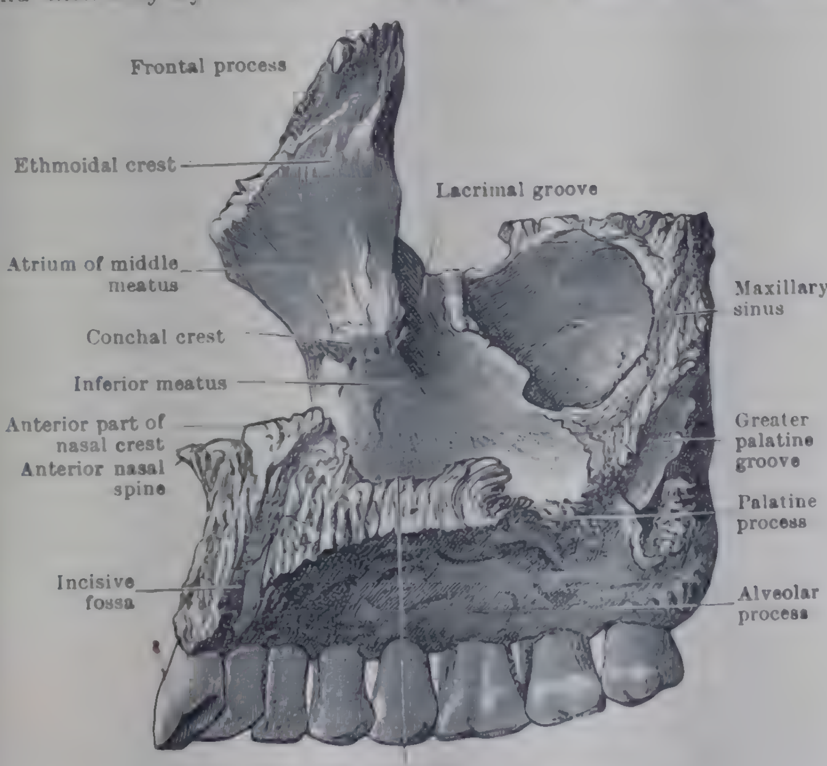

FIG. 202.—RIGHT MAXILLA (Medial Aspect).

The **nasal surface** forms part of the lateral wall of the cavity of the nose. It is limited *superiorly* by the medial margin of the orbital surface and the root of the frontal process, *posteriorly* by the medial margin of the posterior surface, *anteriorly* by the margin of the nasal notch, and *inferiorly* by the attachment of the palatine process. Above that attachment, there is a wide smooth area that forms the anterior and larger part of the lateral wall of the inferior meatus of the nose. Above and behind that area there is the large opening into the maxillary sinus; in the articulated skull the opening is to a large extent closed by the lacrimal, the ethmoid, the inferior concha, and the palatine bone. Behind the opening and also below it, there is a rough area for articulation with the perpendicular plate of the palatine bone; that area is traversed from above downwards and forwards by an oblique groove which, when the palatine bone is in place, is converted into the greater palatine canal. In front of the opening there is a wide, vertical lacrimal groove, which is converted into the naso-lacrimal canal when the lacrimal and inferior

concha are in place. In front of the groove, at the junction of the body and the frontal process, there is a low, horizontal **conchal crest**, which articulates with the inferior concha.

The **frontal process** is a long, wide, thin plate that stands up from the junction of the nasal, facial, and orbital surfaces. It lies in the side-wall of the cavity of the nose and forms a great part of the skeleton of the external nose. Its *upper end* is serrated and articulates with the maxillary process of the frontal bone. The upper part of the *anterior border* is rough or grooved for articulation with the nasal bone; the lower part is sharp and bounds the upper part of the nasal notch. The *posterior border* is a thin edge that articulates with the lacrimal. The *lateral surface* is divided lengthwise into two parts by a smooth ridge, the **lacrimal crest**, which forms the medial margin of the orbital opening and is continuous with the infra-orbital margin. The part of the surface in front of the crest lies in the side of the external nose and is confluent inferiorly with the anterior surface of the body; one or two vascular foramina may be seen on it. The part behind the crest is narrower, and it forms the most anterior part of the medial wall of the orbit; it is the floor of a vertical groove which is continuous with the lacrimal groove of the body, and, combined with the groove of the lacrimal bone, it forms the **fossa for the lacrimal sac.** The uppermost part of the *medial surface* is rough for articulation with the front of the ethmoid labyrinth, and it closes in some of the anterior ethmoidal sinuses. Below the rough area there is an ill-defined, nearly horizontal **ethmoidal crest**. The posterior part of that crest articulates with the anterior end of the middle concha; in the unmacerated head its anterior part produces a slight elevation called the **agger nasi**. The rest of the surface is the wide, smooth area between the ethmoidal and conchal crests, and forms the side-wall of the atrium of the middle meatus.

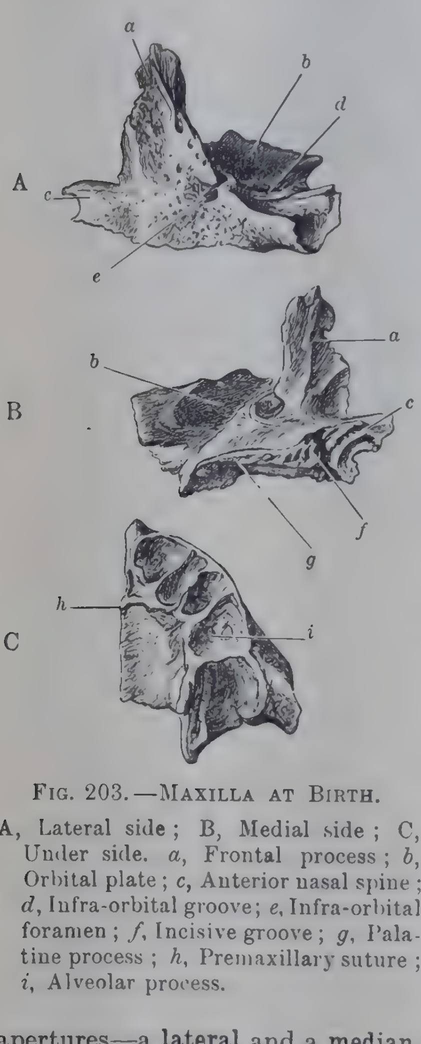

Fig. 203.—Maxilla at Birth.

A, Lateral side; B, Medial side; C, Under side. *a*, Frontal process; *b*, Orbital plate; *c*, Anterior nasal spine; *d*, Infra-orbital groove; *e*, Infra-orbital foramen; *f*, Incisive groove; *g*, Palatine process; *h*, Premaxillary suture; *i*, Alveolar process.

The **palatine process** is a horizontal plate attached to the medial side of the bone, at the junction of the body and alveolar process, from the incisor sockets to the second molar socket. It is much thinner behind than in front and has two surfaces and three borders. The *upper surface* is smooth and is slightly concave from side to side; it forms the anterior two-thirds of the floor of the nasal cavity. The *lower surface* is in the roof of the mouth, forming the anterior two-thirds of its own half of the bony palate (Fig. 156); it is rough, and is pitted for the palatine mucous glands; near its lateral margin there is an ill-defined groove (or maybe two) for the greater palatine vessels and nerve. The *lateral border* is the attached border and is curved. The *posterior border* is a notched, sharp, nearly horizontal edge that articulates with the horizontal plate of the palatine bone. The *medial border* is rough and articulates with its fellow in the median line of the palate. It is raised up as a lip which, with its fellow, forms the **nasal crest** The lower edge of the vomer fits in between the two lips of the posterior part of the crest. The anterior part is raised still higher; it articulates with the subvomerine cartilages superiorly, and with the anterior end of the vomer posteriorly, while anteriorly it is continuous with the anterior nasal spine. Inferiorly, behind the incisor sockets, the articulating margins of the two palatine processes are grooved to form the sides of a small funnel-shaped pit called the **incisive fossa** The **incisive canal**, one on each side, begins in the floor of the nose at the side of the nasal crest and divides to open into the fossa by two small apertures—a **lateral** and a **median incisive foramen**.

The **alveolar process** is thick and curved. It projects downwards from the body. With its fellow of the opposite side it forms the *alveolar arch*, in which the roots of the teeth are embedded; when the adult dentition is complete, each alveolar process has sockets for eight teeth. Two small vascular foramina are usually visible on the lingual surface behind the incisor sockets. When any or all of the teeth are shed the walls of the sockets are absorbed, and the alveolar process may be reduced to the level of the plane of the palatine process. Posteriorly the alveolar process ends in the **maxillary tuberosity**.

The **zygomatic process** is short and thick. It projects from the junction of the anterior, posterior, and orbital surfaces. Its *anterior* and *posterior surfaces* are separated from each other by a rounded, concave ridge that fades away at the socket of either the first or the second molar tooth. The *upper surface* is oblique and rough, and articulates with the zygomatic bone.

The **premaxillæ**, in most vertebrates, are a pair of independent bones that lie in front of the maxillæ. In Man and Apes they are the parts of the maxillæ that lie in front of the incisive fossa and carry the incisor teeth. But the premaxillary part is ossified separately, and, though the greater part of it fuses in intra-uterine life with the rest of the maxilla, yet, up to middle age, their independent origin is indicated by a faint suture that extends sinuously from the hinder part of the incisive fossa to the interval between the canine and lateral incisor sockets.

Ossification.—The **maxilla proper** is ossified in membrane in the wall of the oral cavity

from one centre which appears in the sixth week above the germ of the canine tooth. Ossification spreads rapidly in different directions to form the body of the bone and its processes. The infra-orbital nerve is at first placed considerably above the orbital surface of the maxilla, and comes in contact with it only in the second month, when a groove is formed on the bone; the groove is converted into the infra-orbital canal and foramen by the uprising and folding medialwards of its lateral boundary. In the early stages the alveolar part lies close below the infra-orbital groove; later, they are separated by the maxillary sinus, which first makes its appearance as a shallow fossa on the medial side of the bone about the fourth month of intra-uterine life.

The **premaxilla** is ossified from at least two centres. The first appears above the incisor tooth germs in the sixth week; from it, most of the premaxilla is ossified and also the anterior part of the frontal process; the bone formed from it fuses with the maxilla proper, beginning at the alveolar part almost at once. The second centre appears at the twelfth week and soon fuses with the rest; it forms the medial wall of the incisive canal. It may be that there are two main centres and that they fuse almost at once, but sometimes never fuse. For in some cases of lateral cleft palate the line of cleavage does not pass between the germs of the canine tooth and lateral incisor tooth (*i.e.*, the cleft is not between the maxilla proper and the premaxilla), but passes between the germs of the two incisors, or even through the germ of the lateral incisor—accounting for the extra incisor sometimes found on the lateral side of the cleft.

Variations.—There may be a vertical suture in the infra-orbital margin above the infra-orbital foramen. The infra-orbital canal may be an open groove. A spine that projects upwards from the lower part of the nasal notch has been recorded. A case has been described in which the premaxillæ and the incisor teeth were absent. A *torus palatinus* is not uncommon—*i.e.*, a ridge along the median suture of the hard palate. The lacrimal groove may be constricted towards its centre. A part of the maxillary sinus may be constricted off anteriorly and, owing to its relation to the naso-lacrimal canal, is called the *lacrimal recess.* Almost complete septa in the maxillary sinus have been recorded.

Palatine Bones

Each **palatine bone** is ∟-shaped with two main parts—a **horizontal** and a **perpendicular plate.** At their junction posteriorly there is an irregular projection called the **tubercle.** Two irregular projections, named the **sphenoidal** and **orbital processes**, stand up from the upper edge of the perpendicular plate and are separated by an interval called the **spheno-palatine notch.**

The **horizontal plate** is thin and square, having two surfaces and four borders. Its *upper surface* is smooth, is slightly concave from side to side, and forms the floor of the posterior part of the nasal cavity. Its *lower surface* is rougher, and forms the posterior third of the bony

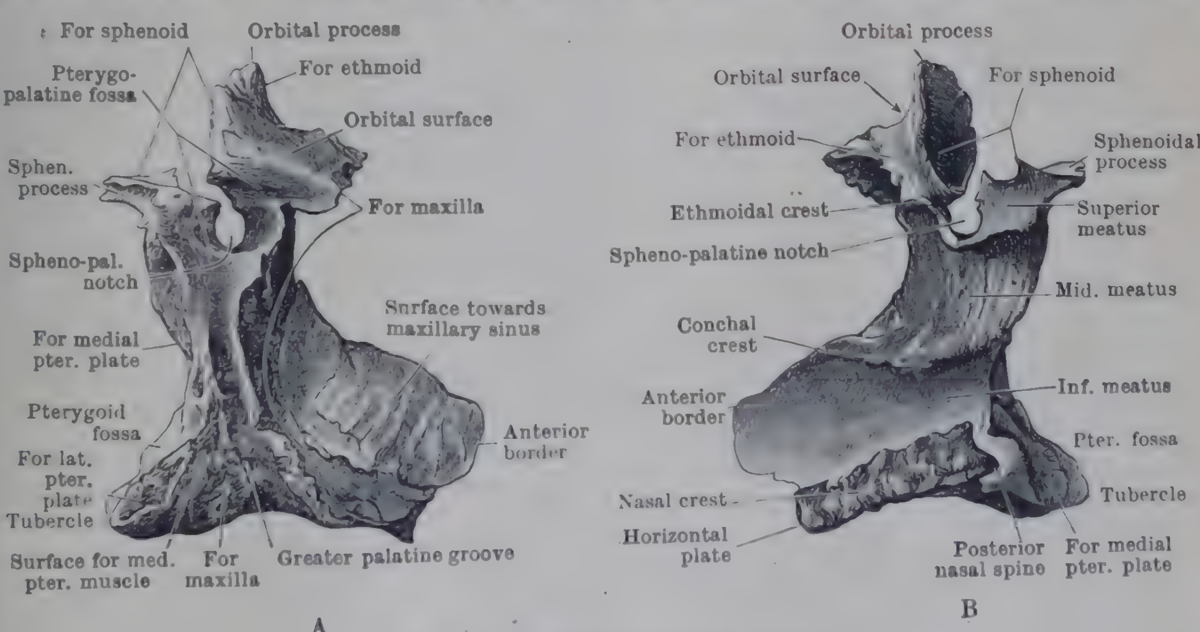

FIG. 204.—RIGHT PALATINE BONE.

A: As seen from the Lateral Side. B: As seen from the Medial Side.

palate; near its posterior edge there is a sharp, transverse ridge called the **palatine crest.** The *anterior border* is rough, and articulates with the palatine process of the maxilla. The *posterior margin* is free and concave; at the median plane it meets its fellow, and the two together send backwards a pointed **posterior nasal spine.** The *medial border* is thick and rough, and articulates with its fellow; the two margins send up a median ridge called the **nasal crest**; it is continuous in front with the nasal crest of the maxilla, and the posterior part of the inferior border of the vomer fits in between its two lips. The *lateral border* joins the perpendicular plate at a right angle, and is grooved to form the medial margin of the **greater palatine foramen.**

The **perpendicular plate** also is thin and has two surfaces and four borders. It is longer than the horizontal part and is much wider inferiorly. Its *medial surface* is crossed horizontally, about its middle, by the **conchal crest**, which articulates with the posterior part of the inferior concha; above and below the crest, the surface forms part of the lateral wall of the middle and inferior meatuses of the nose. Near the upper end of the surface there is another horizontal ridge, called the **ethmoidal crest**, which articulates with the posterior part of the middle concha. The *lateral surface*, for the most part, is applied to the medial side of the maxilla and helps to close the opening into the maxillary sinus; but the upper, posterior part—below the sphenoidal process and the spheno-palatine notch—is free, and forms the medial wall of the pterygo-palatine fossa. From that free area, the **greater palatine groove** runs downwards and forwards to the lower end of the plate. When the bone is in place, the groove, with the corresponding groove on the maxilla, forms the greater palatine canal, which leads from the pterygo-palatine fossa to the greater palatine foramen. The *anterior border* is a thin edge, of irregular outline, which articulates above with the ethmoid, with the posterior edge of the maxillary process of the inferior conchal bone about its middle, and below with the maxilla. The *posterior border* is thin above, where it articulates with the anterior part of the medial pterygoid plate, but expands below into the tubercle. The *lower border* is fused with the lateral edge of the horizontal plate. The *upper border* supports the **orbital** and **sphenoidal processes**; the notch between them is converted into the **spheno-palatine foramen** by the articulation of the palatine bone with the body of the sphenoid.

The **tubercle** is directed backwards and laterally from the junction between the perpendicular and horizontal plates. Its *posterior surface* presents a smooth, vertical groove bounded by two rough furrows that unite above in a ⋀-shaped manner. The furrows articulate with the anterior parts of the lower portions of the two pterygoid plates, and the groove fits into the pterygoid fissure to form the floor of the lower part of the pterygoid fossa. The *lateral surface* of the tubercle is confluent with the lateral surface of the perpendicular plate; its anterior part is rough for articulation with the maxilla; its posterior part is a smooth, narrow triangle that fits into the interval between the tuberosity of the maxilla and the lateral pterygoid plate in the medial wall of the infratemporal fossa. The **lesser palatine canals** descend through the tubercle to open on its lower surface as the **lesser palatine foramina**.

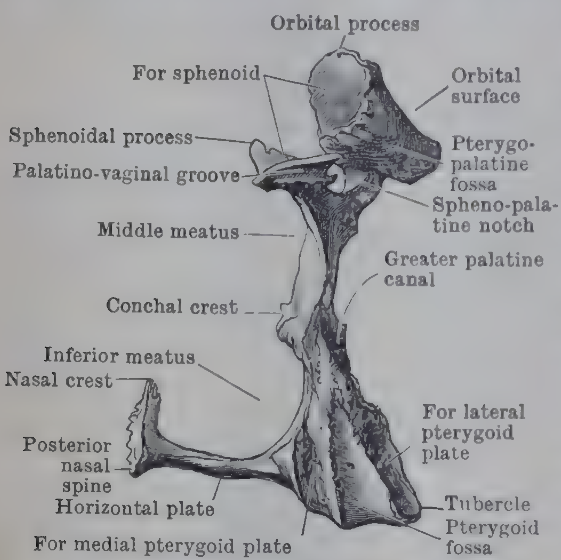

Fig. 205.—Right Palatine Bone.
As seen from behind.

The **orbital process**, shaped like a hollow cube, surmounts the anterior part of the perpendicular plate The mouth of the cube is applied to the body of the sphenoid and usually opens into its cavity; the anterior part of the cube articulates with the medial end of the border between the orbital and posterior surfaces of the maxilla. Of the remaining four surfaces, one, directed forwards and medially, articulates with the ethmoid. The others are non-articular: the *superior* forms the posterior part of the floor of the orbit; the *lateral* is directed towards the pterygo-palatine fossa; whilst the *inferior*, which is confluent with the medial surface of the perpendicular plate, is of variable width, and overhangs the superior meatus of the nose.

The **sphenoidal process**, much smaller than the orbital, curves upwards, medially, and backwards from the posterior part of the summit of the perpendicular plate. Its *upper surface*, which is grooved, articulates with the anterior part of the lower surface of the body of the sphenoid and the root of the medial pterygoid plate, thereby converting the groove into the **palatino-vaginal canal.** Its *lateral surface* forms part of the medial wall of the pterygo-palatine fossa. Its *medial surface* is in the side-wall of the superior meatus of the nose; its medial edge is in contact with the ala of the vomer.

Ossification.—The palatine bone ossifies from one centre which appears during the eighth week in the membrane in the side-wall of the nasal cavity. The orbital process may be ossified from an independent centre. Until the third year the antero-posterior width is greater than the vertical height, which increases as the maxillary sinus enlarges.

Structure and Variations.—The greater part of the palatine bone is composed of two thin plates of compact substance, which may be separated, in the horizontal plate, by an extension of the maxillary sinus. The lower part of the greater palatine canal may be completely bounded by the palatine bone. The orbital process varies greatly in size, and is not always pneumatic; occasionally it unites with the sphenoidal process and converts the spheno-palatine notch into a foramen, which may be divided into two by a bridge of bone.

Zygomatic Bones

Each **zygomatic bone** lies below and lateral to the orbit in the most prominent part of the cheek, and hence it is often called the *cheek-bone*. It forms the lateral border of the orbit and helps to separate it from the temporal fossa and the upper part of the infratemporal fossa; below, it rests upon and is united to the maxilla; behind, it enters into the formation of the zygomatic arch. The zygomatic bone is described as having three *surfaces*, named the *lateral*, the *orbital*, and the *temporal*, two processes, named the *frontal* and the *temporal*, and a *marginal tubercle*.

The **lateral surface** is the largest surface; it is slightly convex and rather uneven; above its most elevated part there is a small aperture called the **zygomatico-facial foramen**, which is often double. The lower border of the surface is free and rough, and is continuous with the lower edge of the zygomatic process of the maxilla. The upper border is smooth and

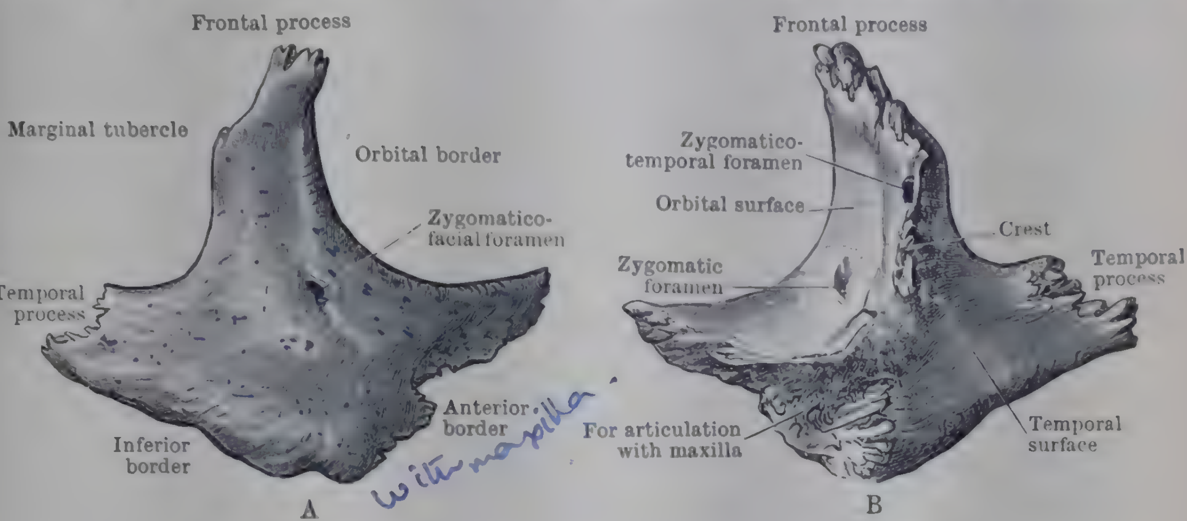

FIG. 206.—RIGHT ZYGOMATIC BONE. A, Lateral Side; B, Medial Side.

forms a great part of the infra-orbital margin. The anterior border is oblique and is united to the zygomatic process of the maxilla. The posterior border is continuous with the two processes. The **temporal process** projects backwards and articulates by an oblique, serrated extremity with the zygomatic process of the temporal bone. The **frontal process** is a large process that projects upwards; its medial margin is smooth and forms the greater part of the lateral border of the orbit; its lateral or posterior margin meets the upper border of the temporal process almost at a right angle. About half-way up that margin there is usually a prominence ~~called~~ the **marginal tubercle**. The upper end of the frontal process articulates with the zygomatic process of the frontal bone; and from its deep surface a wide, thin crest projects backwards in the lateral wall of the orbit, between the orbit and the temporal fossa, and articulates by its sharp, posterior edge with the greater wing of the sphenoid. That crest is continuous inferiorly with a small shelf of bone which projects backwards from the infra-orbital margin into the floor of the orbit and articulates with the maxilla. The crest and the shelf form the **orbital surface** of the bone; their free margins may be separated by a small, smooth notch that forms the anterior end of the inferior orbital fissure; at a varying point on the orbital surface there is an aperture, called the **zygomatic foramen**, which may be double.

The **temporal surface** is a large, concave surface which looks towards the temporal and infratemporal fossæ and includes the deep aspects of the temporal and frontal processes. On that part formed by the frontal process there is a small hole called the **zygomatico-temporal foramen**.

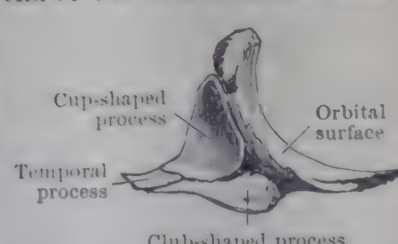

FIG. 207.—MEDIAL SURFACE OF ZYGOMATIC BONE AT BIRTH.

Besides the named surfaces there is a wide, rough, triangular area which articulates with the zygomatic process of the maxilla.

Ossification.—The zygomatic bone ossifies in membrane from one centre which appears between the eighth and the tenth week. There may be more than one centre, for the bone is sometimes divided in the adult. At birth there are narrow grooves or fissures on the temporal surface, produced by the overlapping edges of a cup-shaped and a club-shaped thickening of the bone; in some cases these grooves persist in the adult.

Structure and Variations.—In structure the zygomatic bone is compact, with little spongy tissue. Together with the zygomatic process of the temporal bone it forms the buttress which supports the maxilla and the lateral wall of the orbit. Additional strength is imparted to the bone by the angular mode of union of its orbital and facial parts.

The zygomatic bone is sometimes divided by a horizontal or a vertical suture. Partial separation of the upper and lower parts by a process from the maxilla has been recorded; and in one case an extension of the maxilla completely separated the two parts and articulated with the

zygoma. Cases have been noted where, owing to deficiency in the zygomatic bone, the zygomatic arch has been incomplete; and a case of absence of the zygomatic arch has been recorded.

Sutural Bones

Sutural bones are isolated bones of variable size and shape occasionally met with in the sutures and at the fontanelles. They were once called Wormian bones after the Danish anatomist *Ole Worm*. They are ossified from independent centres and usually include the whole thickness of the cranial wall, but they may involve only the outer or the inner table. They are most frequent at the lambda and in the lambdoid suture (Fig. 153). They are common at the pterion where they are called *epipteric bones*, and by their fusion with one or other of the adjacent bones they may lead to the occurrence of a fronto-squamosal suture. They have been seen in the sagittal suture, and sometimes in the interfrontal suture of metopic skulls. They are occasionally met with at the asterion and more rarely at the obelion. They are infrequent in the face, but they have been noted around the lacrimal bone, and also at the lateral end of the inferior orbital fissure, where one may form an independent nodule wedged in between the greater wing of the sphenoid, the zygomatic bone, and the maxilla.

The **mandible** and the **hyoid bone** are described on pp. 200, 206

BONES OF THE UPPER LIMB

The parts of the **upper limb** are the shoulder, the upper arm, the forearm, and the hand (see Fig. 129, p. 119).

The **shoulder** is not a sharply defined region; it includes not only the familiar prominence at the proximal end of the arm, but also (1) the *scapular region* (the parts around the shoulder-blade); (2) the *pectoral region* (the parts which overlie the upper part of the front of the chest); and (3) the *axilla* or armpit. The bones of the shoulder are the **scapula** or shoulder-blade and the **clavicle** or collar-bone. These two constitute what is called the *shoulder-girdle*: they articulate with each other at the *acromio-clavicular joint*. The clavicle articulates with the upper end of the sternum or breastbone, forming with it the *sterno-clavicular joint*; the scapula does not articulate with any part of the axial skeleton, being connected with it only by muscles.

The **upper arm** (brachium) extends from the shoulder to the elbow. The bone of the upper arm is the **humerus**; it articulates with the scapula to form the *shoulder joint*.

The **forearm** (ante-brachium) is continuous with the upper arm at the *elbow* (cubitus); there the humerus articulates with the two bones of the forearm to form the *elbow joint*. The bones of the forearm are the **radius** and the **ulna**; they articulate with each other at their proximal and distal ends, forming *radio-ulnar joints*.

The **hand** (manus) has three parts: (1) the wrist; (2) the hand proper, one surface of which is the palm and the other surface is the "back of the hand"; (3) the five digits.

The bones of the **wrist** (carpus) are eight small bones named collectively the **carpal bones**, and each has its own name besides. They are arranged in two rows—a proximal and a distal—four bones in each row. Three of the bones of the proximal row articulate with the radius and with a fibro-cartilaginous *articular disc* to form the *radio-carpal joint* or *wrist joint*, where the hand joins the forearm. Each carpal bone articulates with the adjoining carpal bones, forming *intercarpal joints*. Note that the "wrist" of every-day speech is the distal part of the forearm; the anatomical *wrist* is lower, and it is not marked off from the rest of the hand on the surface.

The bones of the **hand proper** (metacarpus) are the five **metacarpal bones**—one to each digit. They are named **first** metacarpal, **second** metacarpal, etc., beginning with the one that corresponds to the thumb. The metacarpal bones articulate with the distal row of carpal bones, forming *carpo-metacarpal joints*; and they articulate with one another at their proximal ends, forming *intermetacarpal joints*; their distal ends are the rounded prominences known as the first row of *knuckles*.

Each of the **digits** is named: the thumb or *pollex*; the forefinger or *index*; the middle finger or *digitus medius*; the ring-finger or *digitus annularis*; the little finger or *digitus minimus*. The bones of the digits are called **phalanges.** The thumb has two phalanges, named the **proximal** phalanx and the **distal** phalanx. Each finger has three phalanges: **proximal, middle,** and **distal.** The distal phalanx is sometimes called the *ungual phalanx*, because the *nail* (unguis) is associated with it. The proximal phalanx of each digit articulates with the distal end of its metacarpal bone to form a *metacarpo-phalangeal joint.* The ends of the middle phalanx articulate with the other two, forming *interphalangeal joints.*

Scapula

The **scapula** is a thin, wide, triangular bone [σκαπάνη (scapanē) = a digging tool] that lies obliquely in the upper part of the back and in the posterior wall of the axilla, opposite the second to the seventh ribs. It is classed as a 'flat' bone and has a main part or **body** and three processes,[1] named the **spine**, the **acromion**, and the **coracoid process**. At one of its angles the body is greatly thickened and is coated with articular cartilage. The thickened angle is the **head**, and the part contiguous to the head is the **neck**. The spine is the large triangular plate attached to the posterior surface of the body; the acromion is the flattened piece of bone which is continuous with the spine at the angle between its two unattached borders; and the coracoid process is the thick, bent piece of bone that projects from the upper part of the head and neck.

The **body** is the blade proper; it is thin and even translucent in places, and is triangular in outline—having two surfaces, three borders, and three angles.

The **borders** of the scapula are named *superior*, *medial*, and *lateral*.

The **superior border** is the shortest of the three. At its lateral end, close to the root of the coracoid process, there is a notch called the *suprascapular notch* which may be wide and shallow, or narrow and deep; it is bridged across by a fibrous band called the *suprascapular ligament*. In some scapulæ the ligament is ossified, and the notch is thus converted into a foramen.

The **medial border** is the longest of the three, and it looks medially and backwards towards the spines of the vertebræ. When the shoulder is at rest the border lies two or three finger-breadths from these spines and can be both felt and seen in a thin person. It is divided into three parts:—a small part opposite the spine of the scapula, a part above that and a part below, the lowest part being by far the longest.

The **lateral border** looks in a lateral direction and forwards, and lies in the posterior wall of the axilla, where it may be indistinctly felt. The part of it immediately below the head is thick and rough and is called the *infraglenoid tubercle*; the rest of it is thin, though rough.

The **angles** of the scapula are named *superior*, *inferior*, and *lateral*.

The **superior angle** is the one between the superior and medial borders; it is so thickly covered with muscles that it can scarcely be felt.

The medial and lateral borders meet at the **inferior angle**, the lowest part of the scapula. It is covered thinly with muscle, is easily felt and is used as a landmark for spines of vertebræ. When the arm is hanging at rest, it is at the level of the spine of the *seventh* thoracic vertebra.

The **lateral angle** is between the lateral and superior borders. It is only nominally an angle, for it is truncated and thickened to form the **head**. The lateral surface of the head is slightly hollowed to form what is called the **glenoid cavity**; it is smooth, articular, and pear-shaped in outline; it is directed forwards and slightly upwards as well as laterally, and it articulates with the head of the humerus to form the shoulder joint [γλήνη (glēnē) = a socket]. The small rough area at the upper margin of the glenoid cavity is called the *supraglenoid tubercle.*

The **surfaces** of the scapula are named *costal* and *dorsal*.

The **costal surface** looks towards the ribs and the greater part of it is concave;

[1] Definitions of terms are given on pp. 3 and 111.

the concavity is known as the **subscapular fossa**, and is deepest opposite the spine. At the medial and lower angles there are usually flat, triangular areas marked off by ridges from the rest of the surface, and these two areas are connected by a narrow, raised strip alongside the medial border; the areas and the strip are for the insertion of a large muscle, the *serratus anterior*. All the rest of the costal surface (except a small part near the neck, Fig. 211) gives origin to the *subscapularis* muscle and low ridges that run from the medial margin towards the neck give attachment to tendinous fibres in the substance of the subscapularis. A wide, blunt, smooth ridge begins at the neck, runs downwards near the lateral margin and fades away near the inferior angle. If the scapula is held up against the light, this will be seen to be the thickest part of the blade; and it is the bar-like lever on which the serratus anterior acts when it moves the scapula.

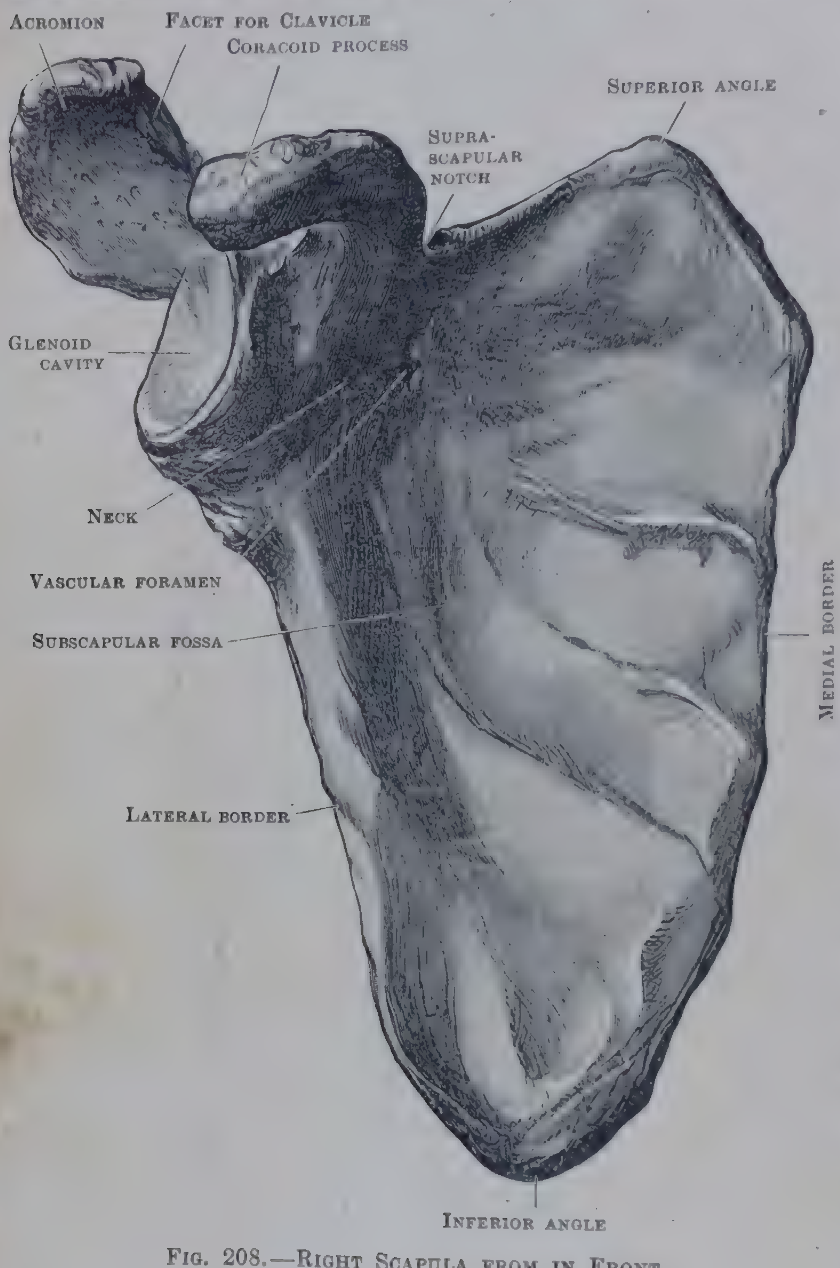

Fig. 208.—Right Scapula from in Front.

The **dorsal surface** is divided into two unequal parts by the spine; the two parts are not in the same plane, for the scapula is bent at the attachment of the spine. The smaller, supraspinous part and the upper surface of the spine form the boundaries of the **supraspinous fossa.** On the larger, infraspinous part there is a raised oval area alongside the lower part of the lateral margin; this area gives origin to the *teres major* muscle. Above that area there is a raised narrow strip that reaches up to the head of the bone; the *teres minor* muscle arises from the strip; and, crossing it, there is a narrow, shallow groove produced by the circumflex scapular artery; occasionally there are two grooves, and they correspond to branches of the artery. The remainder of the lower part of the dorsal surface forms one wall of the **infraspinous fossa**, while the the lower surface of the spine is the other wall.

The **spine of the scapula** is a triangular plate of bone attached by one of its borders to the dorsum of the scapula. Another border of the spine looks in a lateral direction towards the shoulder joint; it is smooth and rounded, and the wide notch that separates it from the neck and head of the scapula is the **spino-glenoid notch**. The notch is bridged by a weak fibrous band called the *spino-glenoid ligament.* The third border is the **crest of the spine.** It is subcutaneous and can be felt easily in all its length in the living person. It has fairly sharp *upper* and *lower lips* or edges; and the lower lip shows a low, wide *tubercle* or enlargement towards

PLATE IX.—RADIOGRAPH OF SHOULDER REGION OF MAN AGED 29.

For alterations in the relative positions of the Humerus and the Scapula during movements of the Upper Limb, see Plate XXXII, p. 347.

PLATE X

PLATE X.—RADIOGRAPH OF SHOULDER REGION OF YOUTH AGED 18 TO SHOW THE RELATION OF THE DIAPHYSIS OF THE HUMERUS TO THE CAP-LIKE EPIPHYSIS OF THE HEAD AND TUBEROSITIES.

Note also the acromial epiphysis and the scale-epiphysis on the coracoid process.

[Facing p.

its medial end. At the medial margin of the blade the lips of the crest spread apart to enclose a small, smooth, triangular area which one can easily feel in the living person by pressing the finger along the crest; it is at the level of the spine of the *third* thoracic vertebra, and is used as a landmark.

The **acromion** is broad and flattened; it is continuous with the spine at the angle where the crest and the lateral border of the spine meet; it extends in a lateral direction and forwards and overhangs the shoulder joint above and behind. It is easily felt at the top of the shoulder, its upper surface being subcutaneous and continuous with the crest of the spine [ἄκρον (acron) = highest point; ὦμος (ōmos) = shoulder (with upper arm)]. Its lateral border is long and is sharply bent to become continuous with the lower lip of the crest. The bend, called the **acromial angle**, is easily found in the living person, and is used as a point from which measurements may be taken and as a guide to the back of the shoulder joint which lies directly below and in front of it. The medial border of the acromion is short and is continuous with the upper lip of the crest. Its anterior and larger part is occupied by an oval facet, facing slightly upwards as well as medially, for articulation with the lateral end of the clavicle at the *acromio-clavicular joint*.

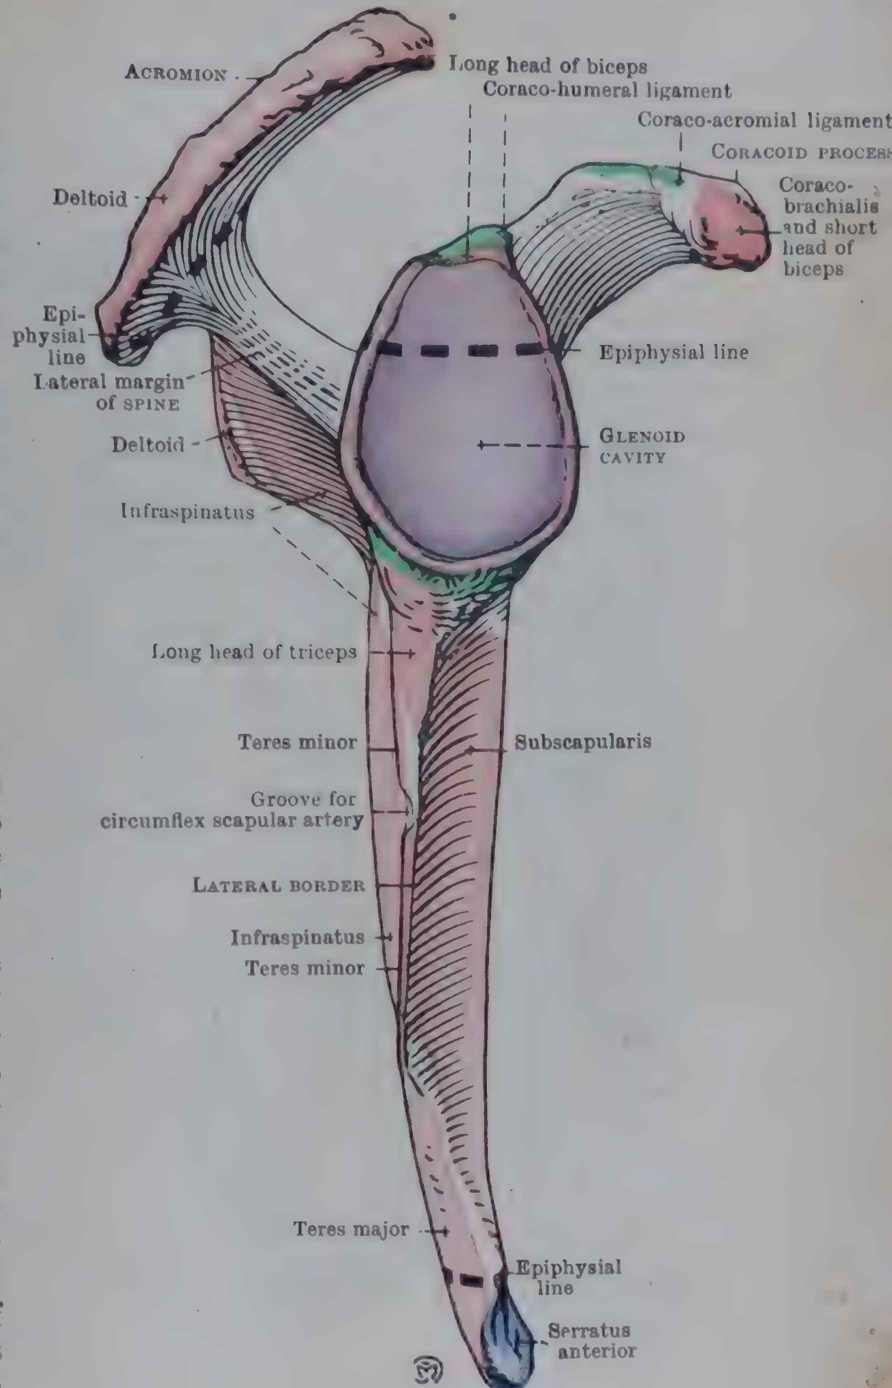

FIG. 209.—LATERAL VIEW OF RIGHT SCAPULA.

The **coracoid process** is the stout, blunt process that projects from the upper margin of the neck and head of the scapula. In shape it has some resemblance to the bill of a bird [κόραξ (corax) = a raven or crow], and it is divisible into a root and a coracoid process proper.

The **root** projects upwards and forwards from the neck and head and is flattened from before backwards—its anterior and posterior surfaces being continuous with the front and the back of the neck. Its medial border is the lateral margin of the suprascapular notch, and its lateral border is immediately above the glenoid cavity.

The **coracoid process proper** is fused with the top of the root and is almost horizontal. When the scapula is in its right position in the skeleton, with its

glenoid cavity looking forwards as well as sidewards, the coracoid process extends forwards and only slightly in a lateral direction. It overhangs the shoulder joint above and in front. Its **borders** are *lateral* and *medial*. The lateral border is connected with the tip of the acromion by the strong, flat, triangular *coraco-acromial ligament*; the two processes and this ligament form a wide **coraco-acromial arch**, which overhangs the shoulder joint and protects it. The **surfaces** of the coracoid

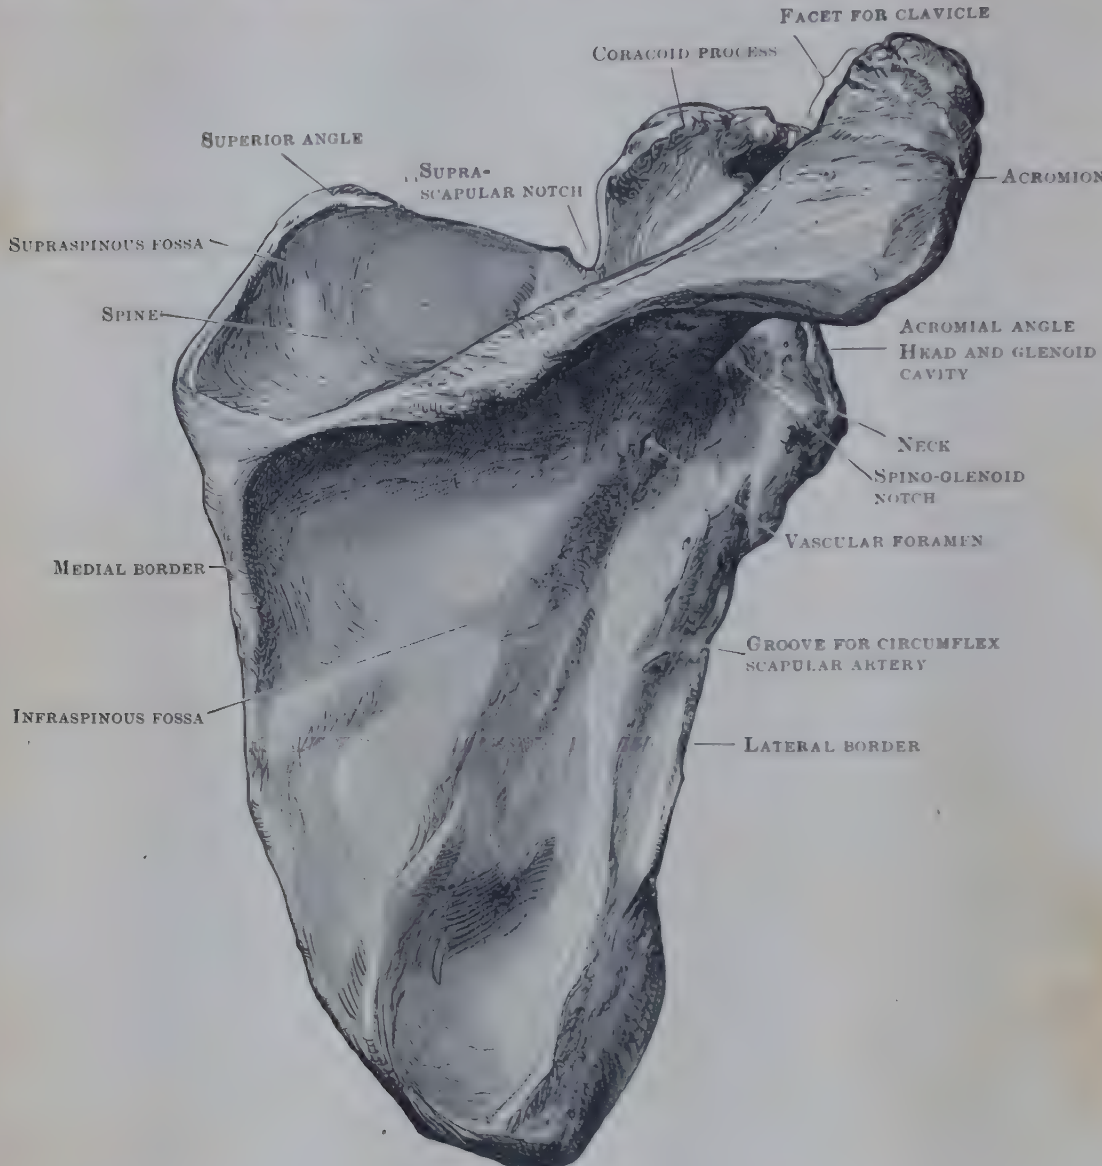

Fig. 210.—Dorsal Surface of Right Scapula.

process are *upper* and *lower*. The posterior part of the upper surface is roughened for the attachment of a thick, strong *coraco-clavicular ligament*, which binds it to the clavicle. The **tip of the coracoid process** is a landmark in the root of the upper limb. It is felt, rather indistinctly, as a hard, resisting object in the hollow on the front of the shoulder about an inch below the clavicle.

Nutrient foramina, by which arteries enter the bone and veins leave it, are scattered here and there, and are largest near the attached margin of the spine.

Attachments.—The **upper margin** of the scapula gives attachment to only one small muscle, namely, the inferior belly of the omo-hyoid, which arises from the suprascapular ligament and the adjoining part of the upper margin. The **medial border** gives insertion to three muscles: (1) the levator scapulæ, opposite the supraspinous fossa; (2) the rhomboideus minor, opposite the spine; and (3) the rhomboideus major, opposite the infraspinous fossa.

The **costal surface** gives attachment to (1) the serratus anterior, which is inserted into the small areas at the upper and lower angles and into the narrow strip along the medial border,

and (2) the subscapularis, which arises from the whole costal surface except the parts for the insertion of the serratus anterior and a part near the neck; a *bursa* protrudes from the capsule of the shoulder joint and separates the subscapularis from the neck and from the root of the coracoid process, and these parts of the bone are smooth.

The **glenoid cavity** gives attachment by its circumference to a fibrous ring called the labrum glenoidale. The capsular ligament of the shoulder is attached to the rim of the cavity outside

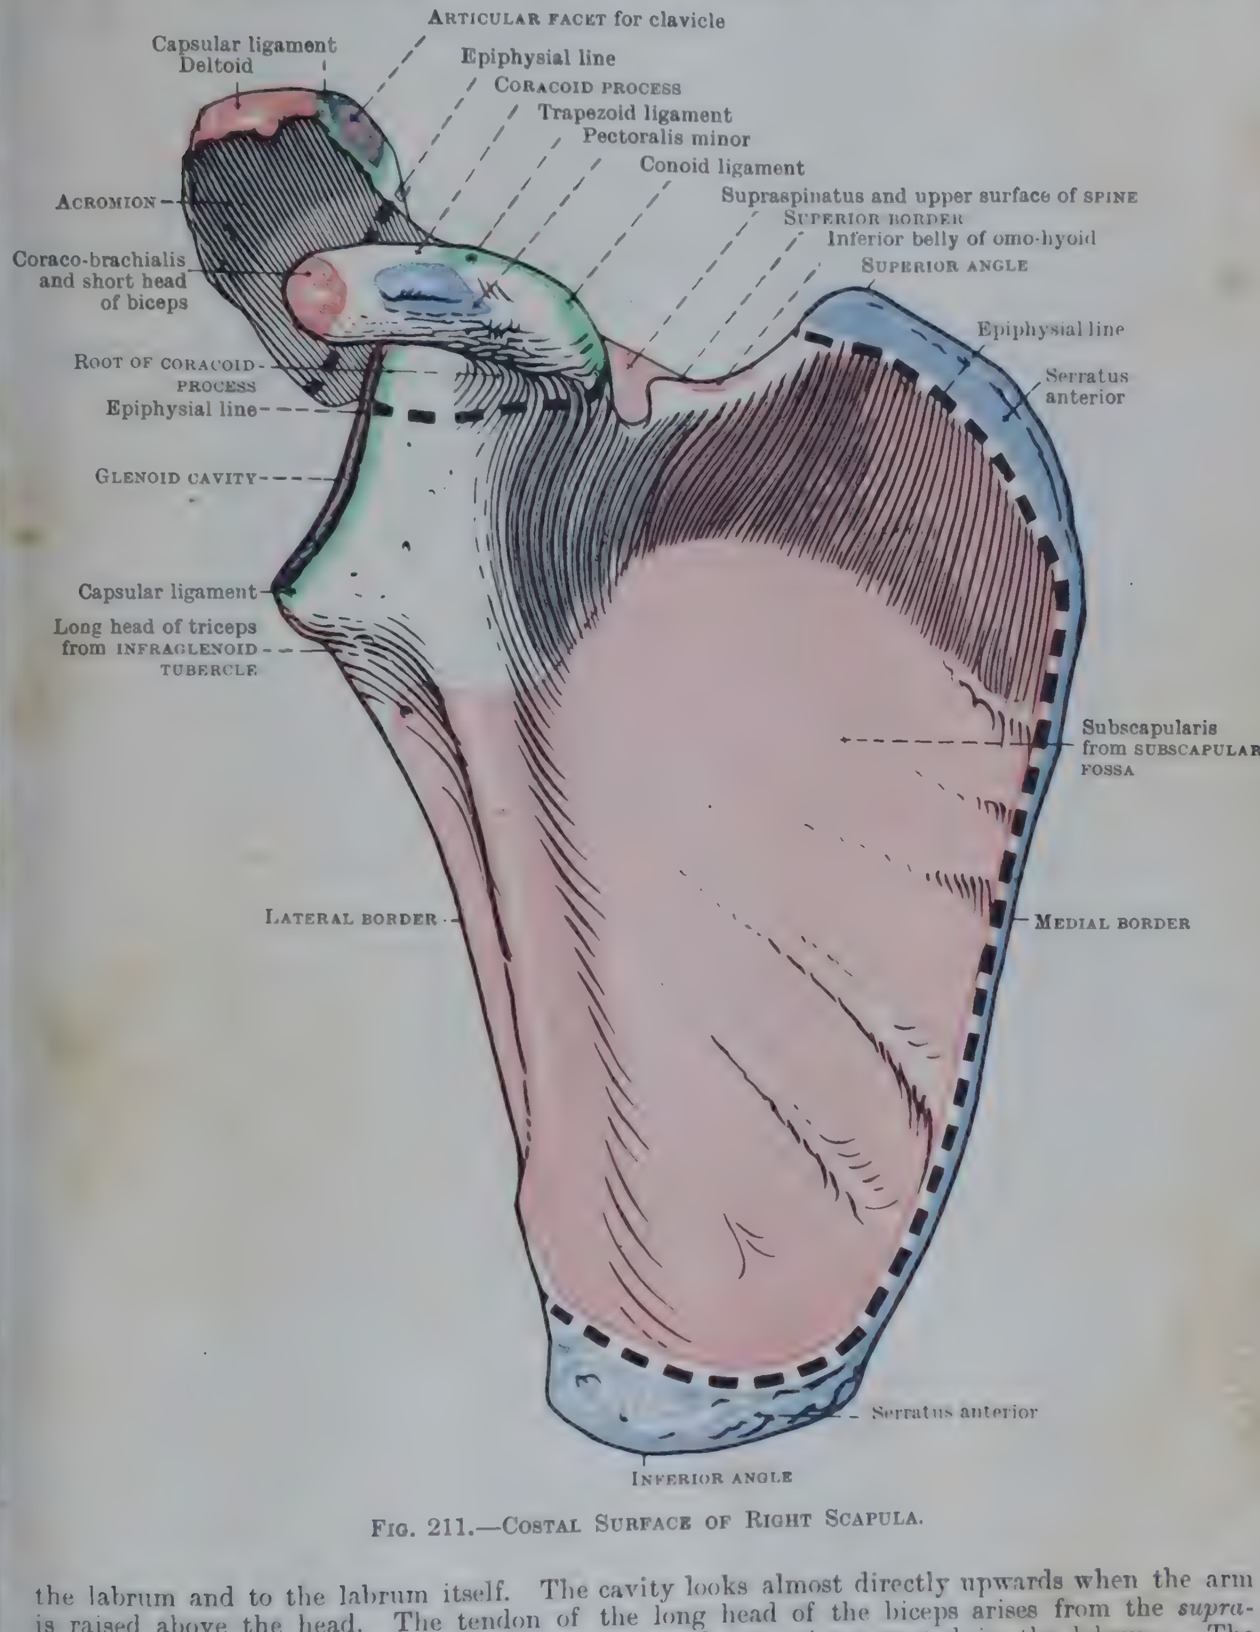

FIG. 211.—COSTAL SURFACE OF RIGHT SCAPULA.

the labrum and to the labrum itself. The cavity looks almost directly upwards when the arm is raised above the head. The tendon of the long head of the biceps arises from the *supraglenoid tubercle*, and some of the fibres of the tendon are incorporated in the labrum. The tendon of the long head of the triceps arises from the *infraglenoid tubercle*, and that is the only muscle attached to the **lateral border**.

On the **dorsal surface** the teres major muscle arises from the oval or *triangular elevated area* near the inferior angle, and the latissimus dorsi muscle receives a small slip of origin from the lowest part of that area; the teres minor arises from the *elongated elevated area* that extends upwards to the head; the infraspinatus muscle arises from the walls of the **infraspinous fossa**, except near the neck. The supraspinatus arises from the walls of the **supraspinous fossa**, except a part near the neck; as it passes over the shoulder joint towards its insertion into

the humerus it is separated from the smooth, lower surface of the acromion by the *subacromial bursa.*

The *upper* and *lower surfaces* of the **spine** help to bound the supra- and infraspinous fossæ and give origin to some fibres of the supraspinatus and infraspinatus. The spino-glenoid ligament stretches from the *lateral margin* of the spine to the back of the **neck** of the scapula. The whole of the *lower lip* of the **crest** and the *lateral margin* of the **acromion** give origin to fibres of the deltoid muscle. The circumference of the *facet* on the medial margin of the acromion

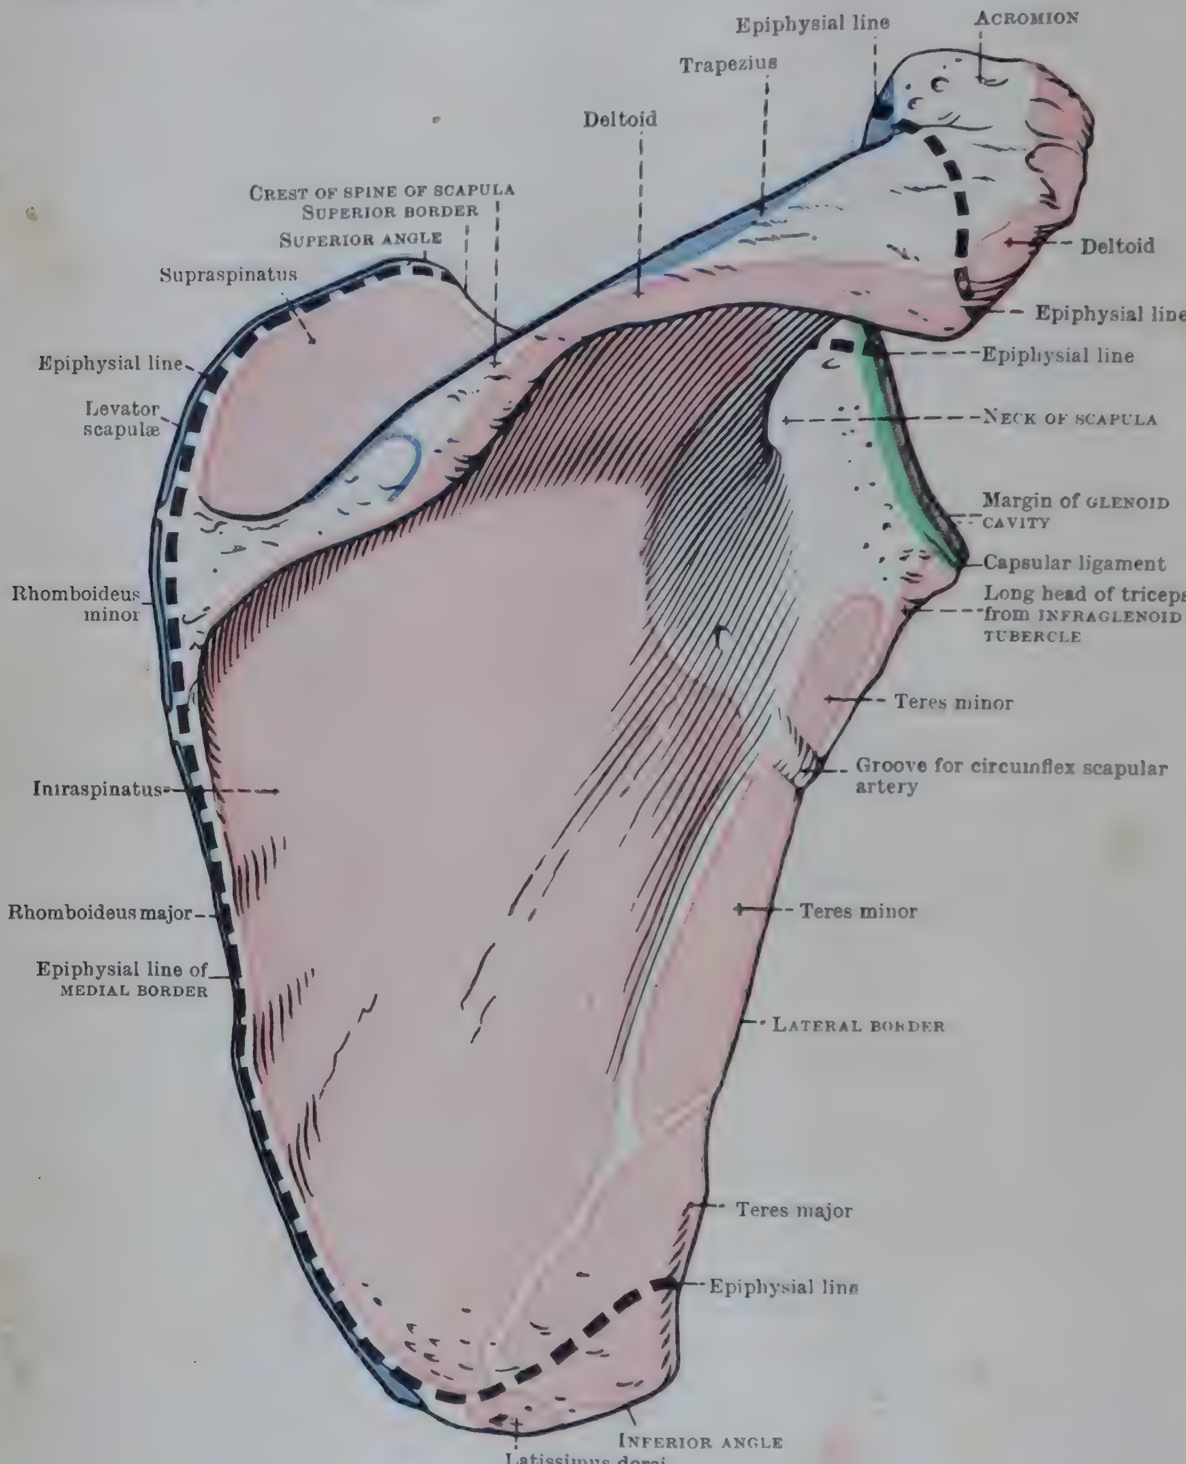

Fig. 212.—Dorsal Surface of Right Scapula.

gives attachment to the capsule of the acromio-clavicular joint. The coraco-acromial ligament is attached to the *tip* of the acromion in front of the facet. Fibres of the trapezius muscle are inserted into the small part of the *medial margin* behind the facet, and into nearly the whole length of the *upper lip* of the **crest** and the **tubercle** on the *lower lip* of the crest; and a tendinous part of the trapezius, before reaching its insertion, plays over the smooth area where the spine joins the medial border, and it is separated from that area by a small *bursa.*

The **coracoid process** gives attachment to numerous structures. The coraco-humeral ligament is attached to the *lateral margin* of its **root**, and the suprascapular ligament to the *medial margin.* The coraco-brachialis muscle and the tendon of the short head of the biceps muscle arise conjointly from the *tip* of the **process proper**; the coraco-acromial ligament is attached

to its *lateral margin*; the clavi-pectoral fascia to the posterior part of the *medial margin*; the pectoralis minor muscle is inserted into the anterior part of the *medial margin* and the adjoining part of the *upper surface*, and its attachment is sometimes marked by a ridge or a tubercle. The coraco-clavicular ligament is attached to the posterior part of the *upper surface*. The *lower surface* does not give attachment to any structure; it is smooth and is in relation with the subscapular *bursa* and muscle.

Ossification.—The **primary** centre appears at the eighth week of intra-uterine life. At birth the acromion, the coracoid process, the glenoid cavity, the inferior angle, and the medial border are still cartilaginous.

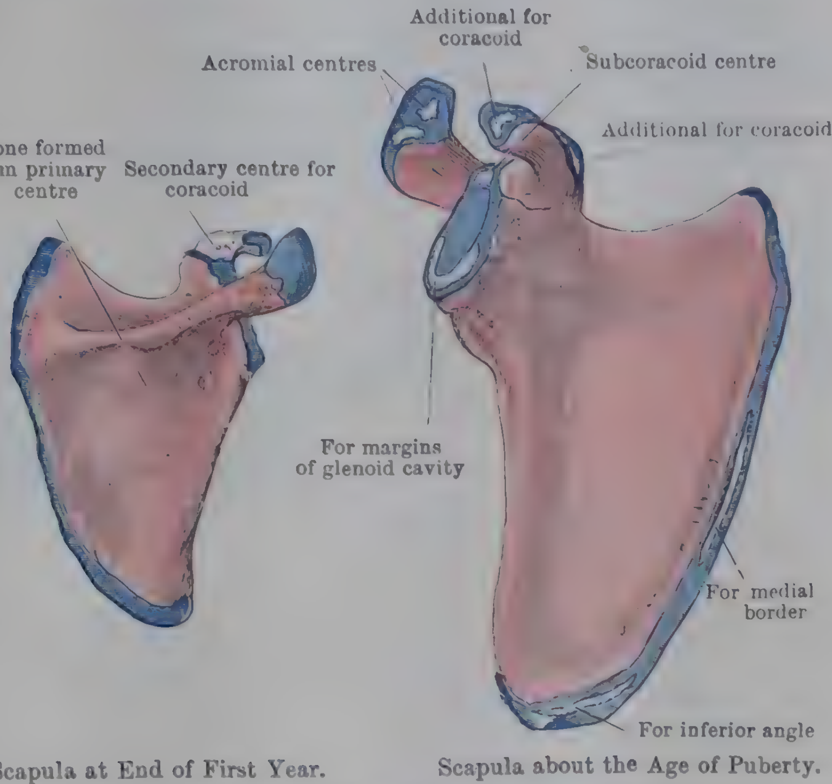

Fig. 213.—Ossification of Scapula.

Occasionally the epiphysis formed from the two acromial centres fails to fuse with the rest of the bone, and the greater part of *the acromion is* **throughout life a separable bone** united to the rest of the bone by a cartilaginous or a synovial joint; the joint appears like a line of fracture

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial line to Capsule of Neighbouring Joint.

in a radiograph; the condition is usually alike on the two sides. The centre for the coracoid process may be regarded morphologically as a primary centre and is sometimes present at birth; sometimes one or two additional centres appear on its surface after puberty and form small scaly epiphyses which join about the twentieth year.

Structure and Variations.—Two plates of compact bone separated by spongy tissue in the thicker parts and fused together in the thinner parts. In old people the bone may be absorbed in parts, but the periosteum remains. The coracoid process may be separate, but much more seldom than the acromion. In an infant the scapula is relatively wide.

Clavicle

The **clavicle** is an elongated, curved bone [*clavicula*, diminutive of *clavis* = a key, or of *clavus* = nail or bolt]. It lies nearly horizontally in front of the upper part of the thorax at the root of the neck, stretching from the upper end of the sternum or breastbone to the acromion of the scapula and bracing the upper limb back so that the arm can swing to and fro clear of the trunk; it can be felt through the skin from end to end. It is a long bone and has a **shaft** and two slightly expanded **ends**. The **lateral third** of the bone is flattened from above downwards, and the lateral end can therefore be distinguished from the medial end at once; the lower surface of the lateral third is rougher than the upper surface, and therefore one can determine at a glance which is the *upper surface* and which is the *lower*. The bone

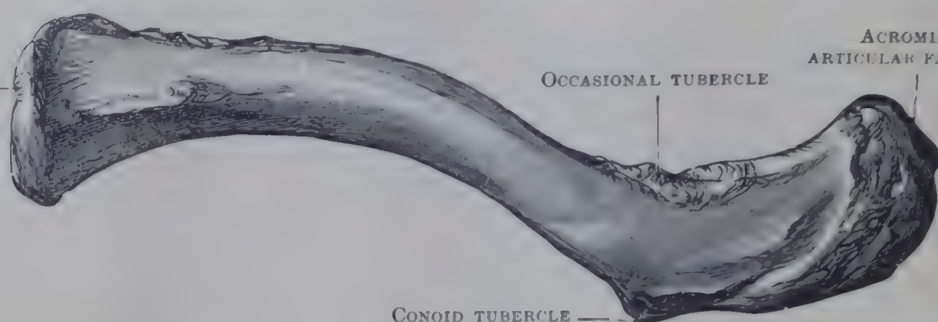

FIG. 214.—RIGHT CLAVICLE SEEN FROM ABOVE.

as a whole has a double curve like the *italic* letter *f*: the **medial half or two-thirds** of the bone is convex forwards, as may be felt and seen in the living person, and the lateral half or third is concave forwards; the *anterior* and *posterior surfaces* of the bone are therefore easily identified.

The **acromial end** of the clavicle articulates with the medial margin of the acromion and is occupied by an oval *articular facet*. The margins of the facet are often raised or 'lipped', and the ridge at the upper margin may assist one in finding the acromio-clavicular joint in the living person. Its articulation with the acromion is not direct, for an *articular disc* of fibro-cartilage intervenes between the two bones. The articular surface is oblique, looking downwards as well as laterally; when the bones are dislocated the clavicle therefore overrides the acromion, and it is difficult to keep it in place once dislocated.

The **sternal end** is thick. It articulates with the clavicular notch on the upper

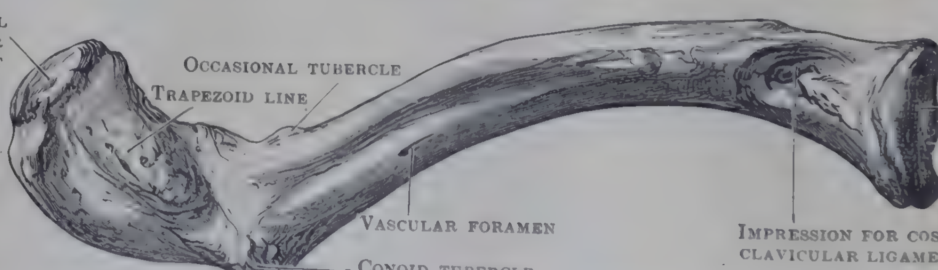

FIG. 215.—RIGHT CLAVICLE SEEN FROM BELOW.

end of the sternum and with the cartilage of the first rib at the side of the sternum, and the joint is called the *sterno-clavicular joint*. The end of the clavicle is larger than the clavicular notch on the sternum and its upper part can be felt above the level of the sternum; the *articular facet* occupies the lower three-fourths of the end of the clavicle and curves also on to the inferior surface for articulation with the first costal cartilage. In some clavicles the facet has been destroyed during maceration. An *articular disc* separates the clavicle from actual contact with the sternum, though not from the first costal cartilage.

The **shaft** of the clavicle is divided, for descriptive purposes, into a lateral third and a medial two-thirds.

The **lateral third** has two surfaces, *upper* and *lower*, and two borders, *anterior* and *posterior*. The **anterior border** is rough and concave; the **posterior border** is smooth and convex. The **superior surface** is subcutaneous and is usually smooth, but it may be rough near the borders, because the muscles attached to the borders sometimes extend their attachments on to the surface. The **inferior surface** is rough. At the posterior border there is a blunt, rounded **conoid tubercle**; a broad, rough ridge, the **trapezoid ridge**, extends from the tubercle towards the lateral end of the clavicle. The lateral third of the clavicle lies above the coracoid process of the scapula and is attached to it by a strong, *coraco-clavicular ligament*. The ligament is in two parts named from their shape *conoid* and *trapezoid*, and they give the names to the tubercle and the ridge to which they are attached.

The **medial two-thirds** of the clavicle has four surfaces—anterior, posterior, superior, and inferior—separated by borders for which names are not necessary.

The **anterior surface** is the convex surface; laterally it narrows down to become continuous with the anterior border of the lateral third. Nearly all of it is occupied by an impression for the origin of part of the *pectoralis major* muscle. The **posterior surface** is the concave surface; it is smooth and is continuous with

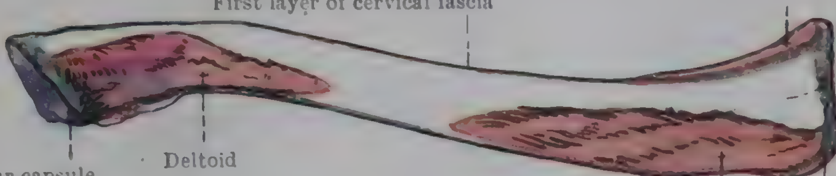

FIG. 216.—ANTERIOR ASPECT OF RIGHT CLAVICLE.

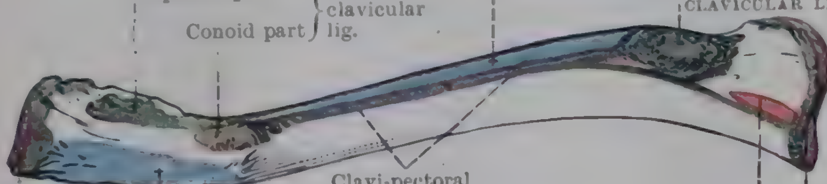

FIG. 217.—POSTERIOR ASPECT OF RIGHT CLAVICLE.

the posterior border of the lateral third. The **upper surface** is continuous with the upper surface of the lateral third, and is usually smooth and flat; it may be so narrow that it is a mere ridge, or it may seem to be part of the anterior surface.

Close to the medial end of the **lower surface** there is a rough impression of variable size and character which may be an elevation or a depression. It gives attachment to the *costo-clavicular ligament*, a strong fibrous band which binds the clavicle to the first rib. The lateral part of the lower surface of the medial two-thirds is occupied by a shallow groove which extends as far as the conoid tubercle and gives insertion to a small muscle called the *subclavius*. The rest of the surface may be of appreciable width, but it is often narrowed to a mere border.

The **nutrient foramen** is on the posterior surface near the junction of the lateral third with the medial two-thirds, and it is directed towards the lateral end.

The clavicle varies a great deal in different people, and a poorly developed bone may have ill-defined surfaces in its medial two-thirds.

The clavicle is horizontal or nearly so when the body is in the upright position. But it slants upwards from medial to lateral end when the body is recumbent; for, in that position, the shoulder-blades are moved upwards, and the lateral ends of the clavicles move with them. In a radiograph of a recumbent person the shadow of the clavicle is therefore very oblique. It is oblique also in radiographs taken when

the arm is held away from the side; for, in the movement of raising the arm, the scapula rotates, and the acromion, with the lateral end of the clavicle, is raised.

Attachments.—The capsule of the acromio-clavicular joint is attached to the margins of the *facet* on the **lateral extremity**. Part of the trapezius is inserted into the *posterior border* of the **lateral third**; part of the deltoid arises from the *anterior border*, on which there is occasionally a small, rough tubercle; the conoid and trapezoid ligaments are attached to the **conoid tubercle** and the **trapezoid ridge**.

The capsular ligament of the sterno-clavicular joint is attached to the margins of the *facet* at

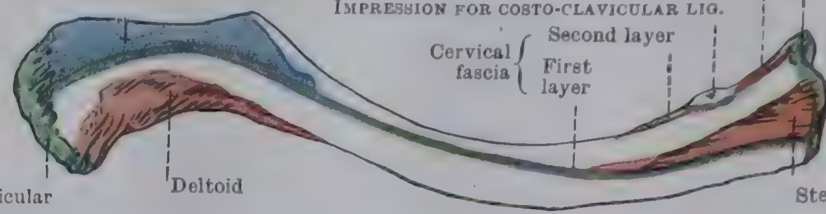

FIG. 218.—SUPERIOR ASPECT OF RIGHT CLAVICLE.

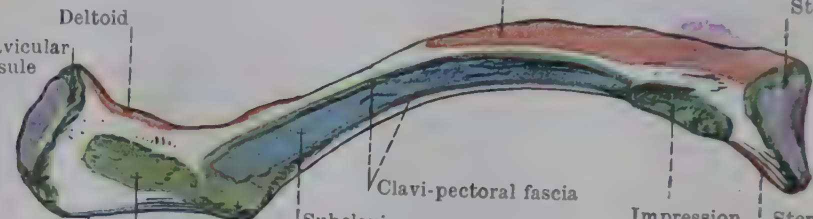

FIG. 219.—INFERIOR ASPECT OF RIGHT CLAVICLE.

the **medial end**; the capsular ligament, the articular disc and the interclavicular ligament are attached to the rough *area above the facet*. The costo-clavicular ligament is attached to the impression on the lower surface. The subclavius muscle is inserted into the floor of the *elongated groove* on the lower surface of the shaft; the clavi-pectoral fascia, which splits to enclose the subclavius, is attached to the *margins of the groove*. Part of the pectoralis major muscle arises from the *anterior surface* of the **medial two-thirds**. Part of the sterno-mastoid muscle arises from the *upper surface* of the medial third. Fibres of the sterno-hyoid muscle (and sometimes sterno-thyroid) arise from the *posterior surface* near the medial end.

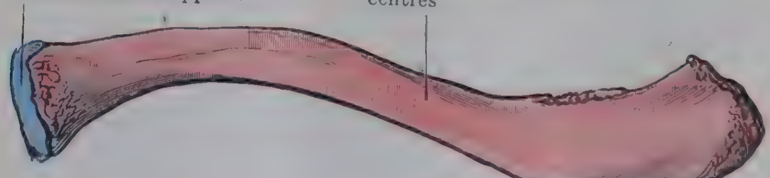

FIG. 220.—OSSIFICATION OF CLAVICLE.

Ossification.—The clavicle is the first bone in the body to begin to ossify, and it is peculiar in its mode of ossification. Two **primary** centres appear in the fifth week of intra-uterine life in two separate portions of mesodermal tissue which are at the pro-cartilage stage. When the tissue between those two portions also becomes pro-cartilage, the two centres coalesce to form one; ossification spreads from this centre into the cartilage that appears at the ends of the bone-rudiment, and almost the whole bone is ossified from it.

Secondary Centre.	Appears at	Epiphysis fuses at	Epiphysial Line is inside
For medial end	20th year	25	Capsule of sterno-clavicular joint.

Structure and Variations.—The clavicle, though a long bone, has no medullary cavity. It consists of spongy tissue surrounded by a shell of compact bone which is thickest in the middle. The nutrient artery is a branch of the suprascapular. There may be two nutrient foramina,

and one of them may be on the lower surface. The right clavicle is often longer, stronger, and more curved than the left.

The clavicle in women is shorter, smoother, and more slender than in men, and the curvatures are less marked; its acromial end is at a lower level than the sternal end, while in men the ends are at the same level or the acromial end is the higher. Occasionally the clavicle is perforated by one of the supraclavicular nerves. In rare cases the clavicle is incompletely developed or is absent. A freely movable medial end and a bifurcated lateral part have been recorded. A small epiphysis may appear at the acromial end about 20, and it unites rapidly.

Humerus

The **humerus** is the bone of the upper arm; its length is about one-fifth of the height of the person; though nearly all thickly covered with muscles it can be felt by deep palpation in all its length. It is a long bone with a **shaft** and **two ends**.

It is necessary first to distinguish the ends and ascertain the general direction of its surfaces. The **upper** end is the thick, rounded end, while the lower end is compressed from before backwards; there is a wide, deep hollow on the **back** of the lower end; the smooth, hemispherical part of the upper end looks in a **medial** direction.

The **upper end** includes the head, the anatomical neck, the greater and lesser tuberosities, and part of the bicipital groove.

The **head** is the large, convex, smooth articular part. It looks in a medial direction and also upwards, and, when the arm is hanging naturally by the side, it looks backwards as well. It articulates with the glenoid cavity of the scapula and may be indistinctly felt by the fingers pushed well up into the axilla.

The **lesser tuberosity** is the well-marked prominence on the front of the upper end; the part of it nearest the head has an impression, usually smooth, for the insertion of the tendon of the subscapularis. The lesser tuberosity can be felt in the front of the shoulder immediately lateral to the coracoid process (and may be mistaken for it) when the arm is hanging comfortably by the side, but at a

FIG. 221.—FRONT OF RIGHT HUMERUS.

little distance from that process when the limb is rotated so that the palm of the hand looks forwards.

The **greater tuberosity** is the prominence on the lateral side of the upper end. Though larger than the lesser tuberosity it is not so clearly defined, for its lateral surface shades off into the lateral side of the shaft. Its upper surface and its posterior surface have smooth impressions for the insertion of muscles. The greater tuberosity forms the "point of the shoulder", *i.e.*, its most projecting lateral part, and it may be felt there a little below the lateral margin of the acromion.

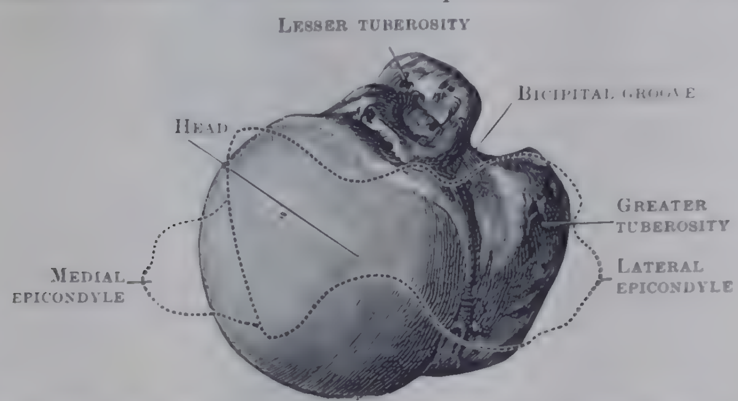

Fig. 222.—Proximal Aspect of Right Humerus (with the outline of lower end in relation to it in dotted line).

The **bicipital groove** is the clean-cut groove between the two tuberosities, and it is prolonged slightly spirally (Fig. 221) for two inches or more on to the shaft, where it is not so sharply defined. The tendon of the long head of the biceps, after it emerges from the shoulder joint, lies in the groove.

The **anatomical neck** is the narrow strip that encircles the margins of the head; its upper part is the narrow and shallow depression that separates the head from the tuberosities.

The **surgical neck** is the region immediately below the head and tuberosities—where the upper end joins the shaft. It does not have sharp limits, and may be reckoned as about a finger's breadth in extent all round the bone. The name is given because the bone is often fractured there.

The **lower end** includes the capitulum, the trochlea, the radial, coronoid and olecranon fossæ, and the lateral and medial epicondyles.

The **capitulum** is the smooth, rounded knob placed near the lateral part of the lower end. It is situated partly on the front and partly below, but not at all on the back. It articulates with the head of the radius.

The **radial fossa** is the shallow depression on the front of the bone immediately above the capitulum; the margin of the head of the radius comes into close relation with it when the forearm is fully bent.

The **trochlea** is the wide, smooth, pulley-shaped surface at the medial side of the capitulum [τροχιλία (trochilia) = the sheave of a pulley]. It is situated on both the front and back and distal aspect. It winds slightly spirally from front to back, and its medial lip stands out as a prominent rim. It articulates with the ulna at the trochlear notch, *i.e.*, the wide concavity on the front of the upper end of the ulna. The axis of rotation of the joint is set slightly obliquely, so that the forearm is not quite in line with the upper arm when the limb is held with the palm facing forwards.

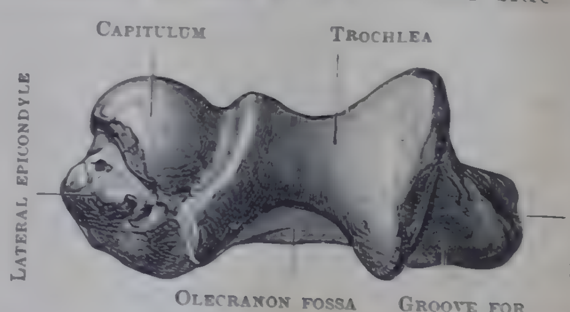

Fig. 223.—Distal Aspect of Right Humerus.

The **coronoid fossa** is the depression on the front, immediately above the trochlea. It is related to the coronoid process of the ulna when the forearm is fully flexed.

The **olecranon fossa** is the large depression in a corresponding position on the back; the olecranon of the ulna fits into it when the forearm is straightened out. The bony substance between the coronoid and olecranon fossæ is very thin.

The **medial epicondyle** is the prominent projection on the medial side of the lower end. It is easily felt at the medial side of the elbow and can be gripped between finger and thumb. Its anterior surface has impressions for the origin

of muscles; its posterior surface is smooth and has a shallow groove which lodges the *ulnar nerve* as it passes from the upper arm into the forearm; the nerve can be felt and rolled between the finger and the bone.

The line or ridge (often poorly marked) that extends from the epicondyle on to the shaft for two or three inches is called the **medial supracondylar ridge**.

The **lateral epicondyle** is the projection on the lateral side of the lower end; it is not nearly so prominent as the medial epicondyle. Its anterior surface is small and is occupied by an impression for the origin of muscles. Its posterior surface is broad and smooth and subcutaneous; it can be felt on the back of the arm immediately above the lateral part of the elbow joint—that part of the joint being recognizable as a transverse depression.

The strong ridge which extends on to the shaft from the lateral epicondyle is the **lateral supracondylar ridge**; it is easily felt when the elbow joint is in the bent position and the muscles are relaxed.

When the upper limb is placed so that the palm looks forwards, the various parts of the humerus are in the position indicated in the description given; but when the limb hangs comfortably by the side with the palm looking towards the thigh, the directions in which the parts look are altered—for example, the lateral epicondyle is felt on the antero-lateral aspect of the limb, and the medial epicondyle on the postero-medial aspect.

The **shaft** is more or less cylindrical in its upper half, but is rather compressed from before backwards in its lower part; it is described as having three borders and three surfaces. The **borders** are anterior, medial, and lateral; the **surfaces** are posterior, antero-lateral, and antero-medial.

The **anterior border** begins at the anterior margin of the greater tuberosity, runs along the front of the bone, and ends near the radial and coronoid fossæ; its upper third is the lateral lip of the bicipital groove.

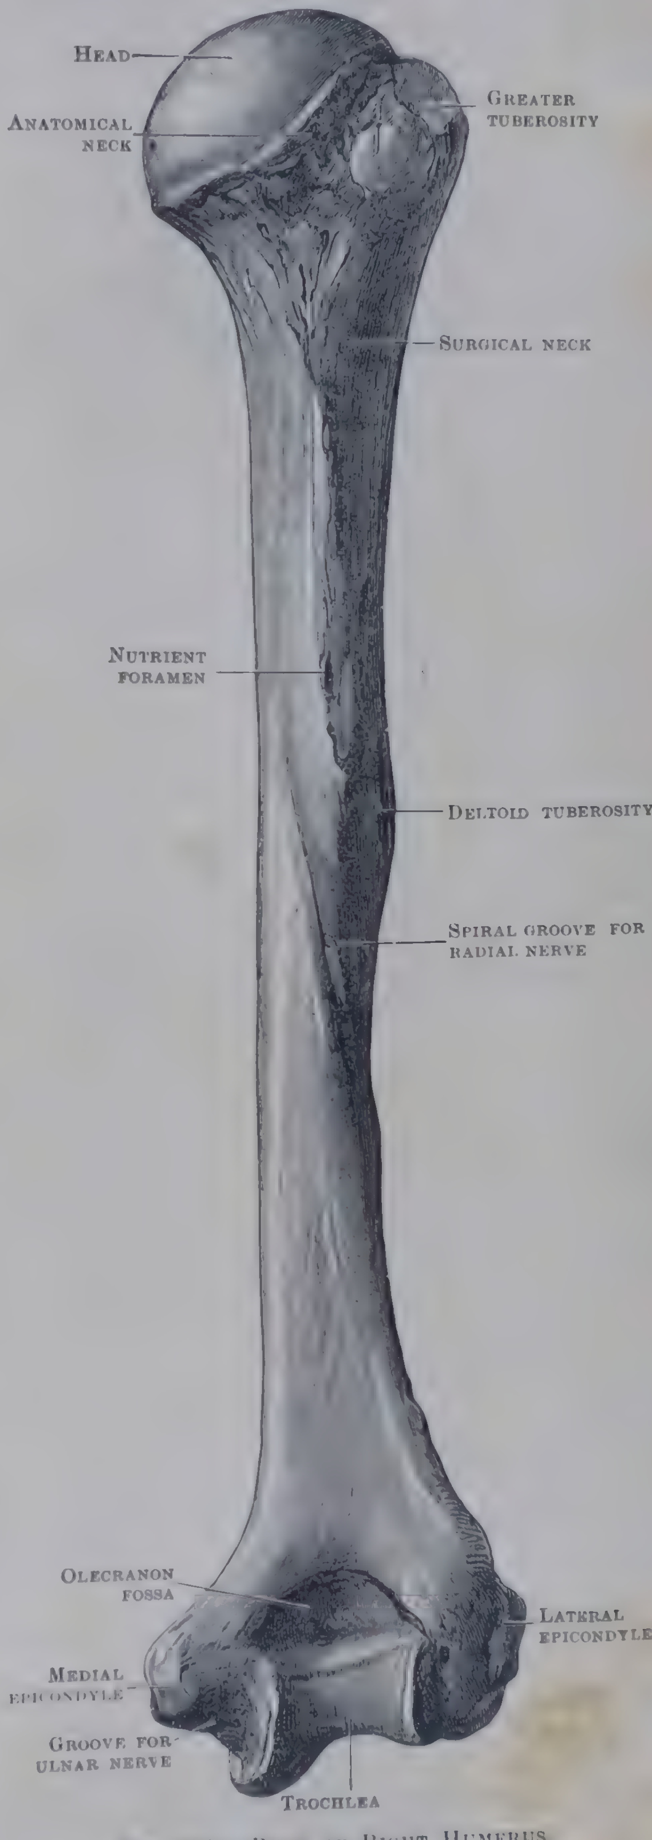

FIG. 224.—BACK OF RIGHT HUMERUS.

The **medial border** begins at the lesser tuberosity and ends at the medial epicondyle. It is not nearly so well marked as the anterior border. Its upper

third is the medial lip of the bicipital groove; its lower third is the medial supracondylar ridge; in bones in which muscular markings are well seen its middle part is roughened for the insertion of the coraco-brachialis muscle.

The **lateral border** begins at the posterior surface of the greater tuberosity and ends at the lateral epicondyle. Its lower third is the lateral supracondylar ridge;

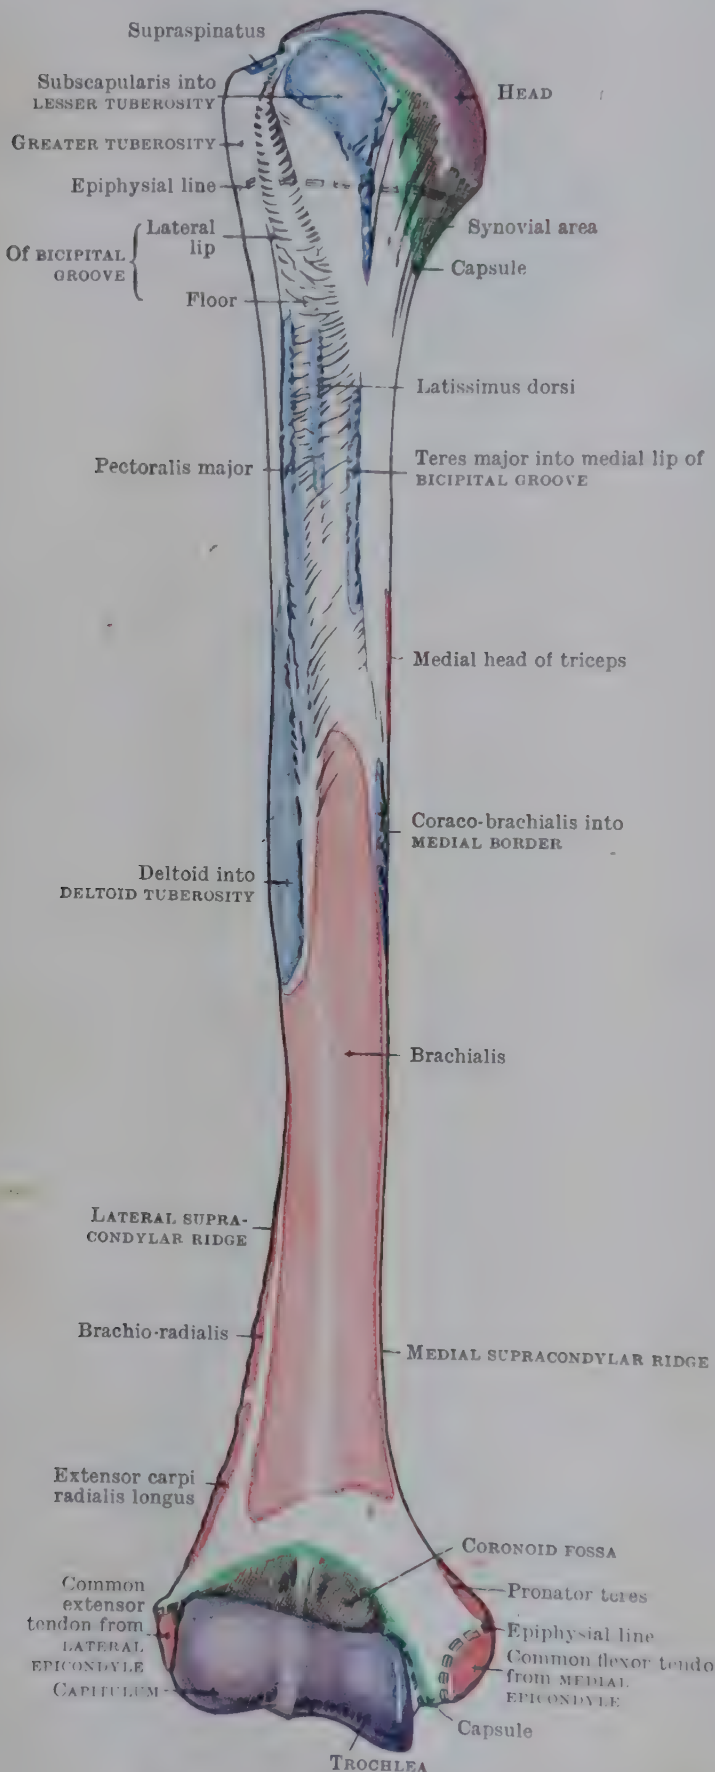

FIG. 225.—FRONT OF RIGHT HUMERUS.

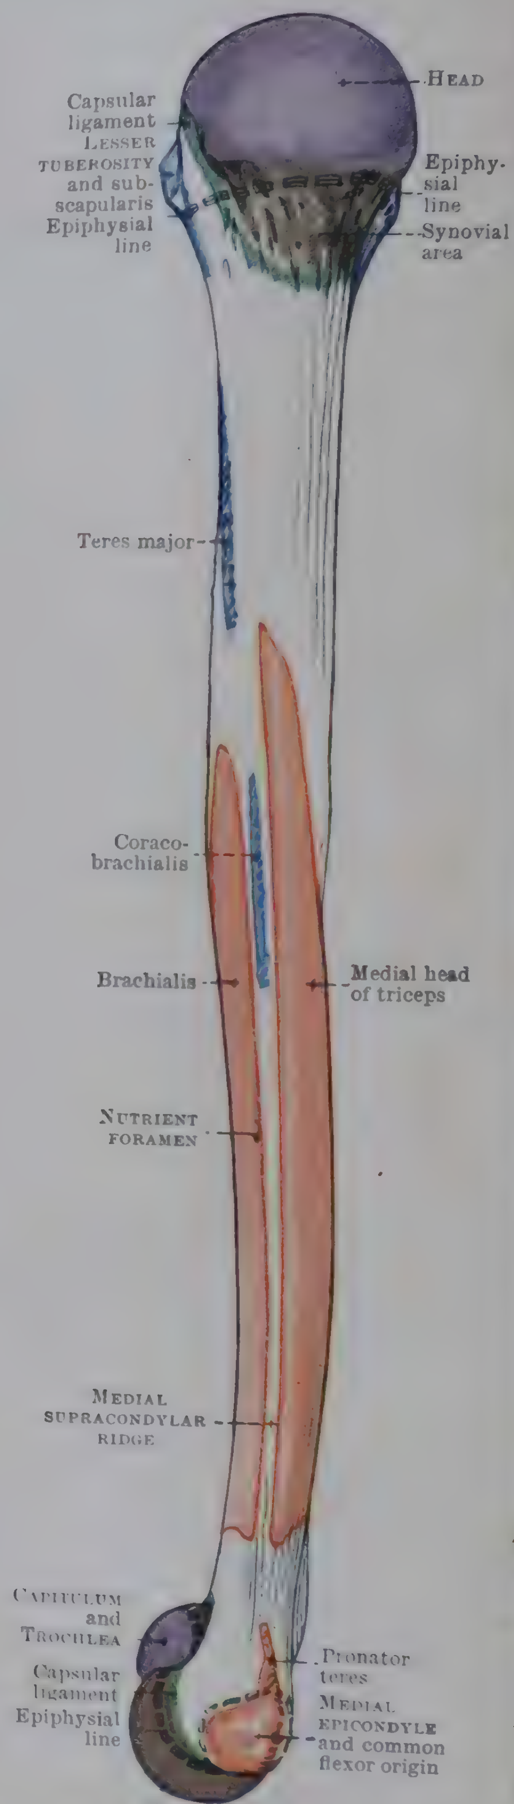

FIG. 226.—MEDIAL ASPECT OF RIGHT HUMERUS.

its upper third is an indistinct ridge that descends from the back of the greater tuberosity; it is interrupted in its middle third by a broad, shallow groove which extends obliquely across it. The groove is named the **spiral groove**; it begins on the back of the bone and is directed downwards and forwards on to the front;

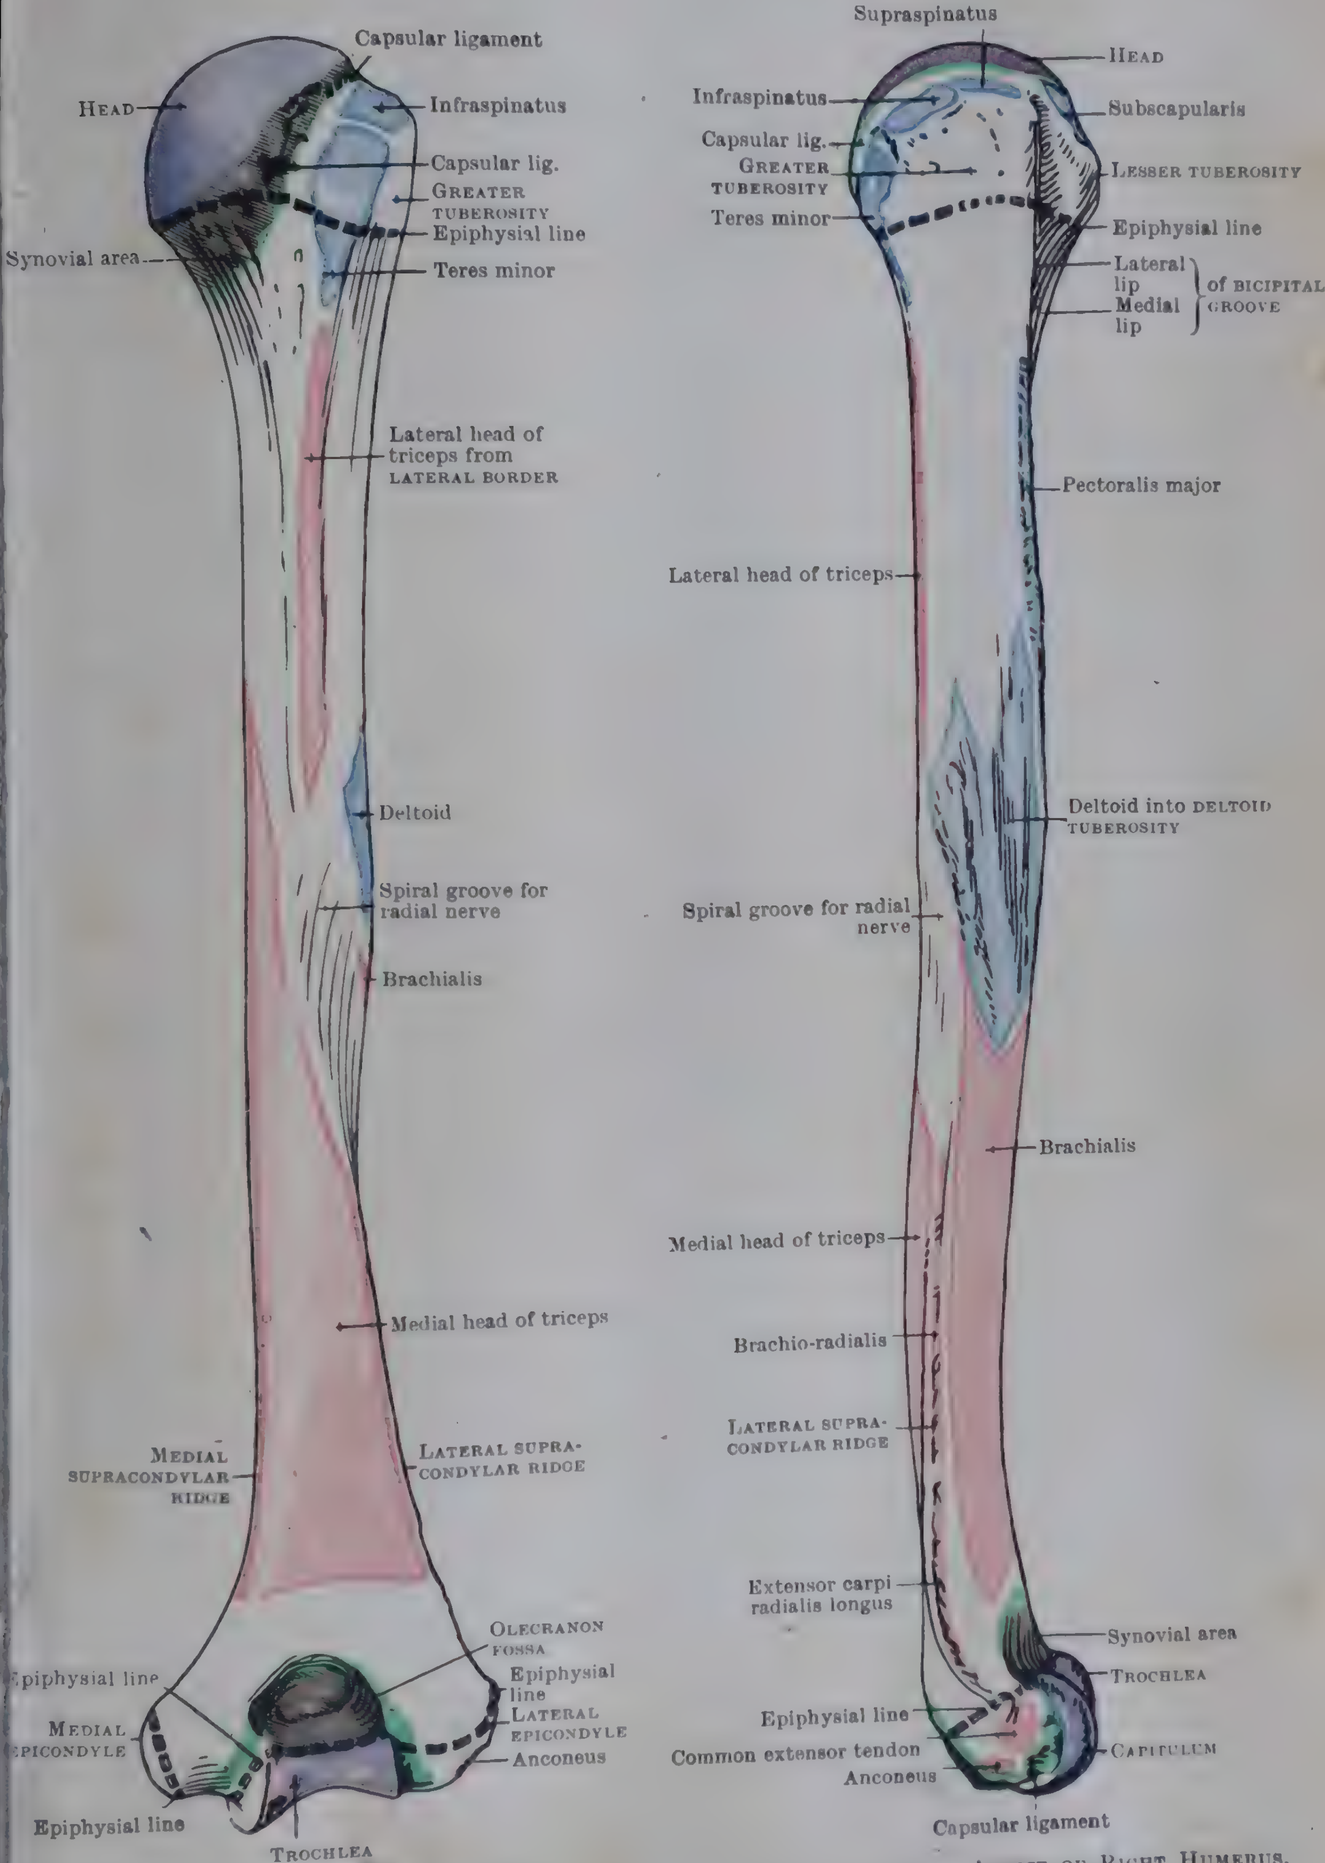

FIG. 227.—BACK OF RIGHT HUMERUS.

FIG. 228.—LATERAL ASPECT OF RIGHT HUMERUS.

the radial nerve, winding round the humerus, lies in it along its posterior or lower margin.

The **posterior surface** is the area between the lateral and medial borders.

The **antero-lateral surface** is the area between the anterior and lateral borders. Its proximal part is continuous with the lateral surface of the greater tuberosity. About its middle it is occupied by a rough, V-shaped **deltoid tuberosity**—so named because the deltoid muscle is inserted into it. The anterior margin of the V is part of the anterior border of the humerus, and its posterior margin is one of the boundaries of the spiral groove, for that groove is immediately behind and below the tuberosity. The tuberosity can usually be made out in the living person by deep pressure on the middle of the lateral side of the upper arm.

The **antero-medial surface** is the area between the anterior and medial borders. Its upper part is narrow, for it is merely the floor of that part of the bicipital groove which extends on to the shaft.

The lower halves of the antero-lateral and antero-medial surfaces are often spoken of together as the lower half of the anterior aspect of the humerus, in order to simplify the description of the brachialis muscle, which arises from the whole of that region.

The principal **nutrient foramen** is almost always situated immediately in front of the medial border—not far from its middle—and is directed towards the lower end. Sometimes it is in the upper part of the spiral groove; and there may be a foramen in both places.

Attachments.—The capsular ligament of the shoulder joint is attached to the **anatomical neck** above and in front and behind, but is attached to the bone nearly a finger's breadth below the head on the medial side, and the part of the medial side of the bone immediately below the head is therefore covered with synovial membrane; the coraco-humeral ligament is attached to the anatomical neck at the anterior and upper part of the greater tuberosity. The supraspinatus is inserted into the anterior impression on the top of the **greater tuberosity**, the infra-spinatus into the impression behind that, the teres minor into the impression on the back and into a strip below that for half an inch; the subscapularis into the **lesser tuberosity** and into the surface below for half an inch. The transverse ligament of the humerus is attached to *both tubercles*, and bridges across the upper end of the **bicipital groove**, holding the tendon of the long head of the biceps in place; farther down—on the shaft—the pectoralis major is inserted into the *lateral lip* of the groove, the teres major into the *medial lip*, and the latissimus dorsi into *its floor*; the tendon of the long head of the biceps lies in the groove, ensheathed in synovial membrane which is prolonged from the synovial lining of the shoulder joint and envelops the tendon and lines the groove; deep to that sheath a little artery, a branch of the anterior circumflex, runs upwards in the groove to the joint.

The common extensor tendon (*i.e.*, the combined tendons of origin of the extensores carpi radialis brevis, digitorum, digiti minimi and carpi ulnaris) arises from the *front* of the **lateral epicondyle**; the lateral ligament of the elbow is attached to its *distal margin*; and the tendon of the anconeus arises immediately behind the attachment of the ligament, leaving the posterior surface smooth. The common flexor tendon (the combined tendons of origin of the flexores carpi radialis, palmaris longus, digitorum sublimis and carpi ulnaris) arises from the impressions on the lower part of the *front* of the **medial epicondyle**, the pronator teres from the flatter, upper part and the adjoining lower end of the supracondylar ridge; the medial ligament of the elbow is attached to the *distal margin* of the epicondyle. The anterior ligament of the elbow is attached to the *upper margins* of the **radial** and **coronoid fossæ** and to the front of the epicondyles near the capitulum and trochlea. The posterior ligament is attached to the *floor* of the **olecranon fossa**, to its margins on each side, and to the backs of the epicondyles close to the margins of the trochlea.

The deltoid is inserted into the **deltoid tuberosity**; the coraco-brachialis into the middle of **the medial border**. The medial intermuscular septum is attached to the *edge* of the **medial supracondylar ridge**; the lateral intermuscular septum to the *edge* of the **lateral supracondylar ridge**; the brachio-radialis arises from the upper two-thirds of the *anterior aspect* of the lateral ridge, and the extensor carpi radialis longus from its lower third. The lateral head of the triceps arises from the *upper third* of the **lateral border**; the medial head from the *whole width* of the **posterior surface** below the spiral groove; the brachialis from the distal half or two-thirds of the **anterior aspect** of the shaft.

Ossification (Pls. XIII, XIV, XV, pp. 260, 261, 268).—The **primary** centre appears at the eighth week of intra-uterine life. At birth only the ends are cartilaginous.

The centres for the head and the tuberosities coalesce in the sixth year to form **one** epiphysis, which fits like a cap on the end of the diaphysis. Radiographs show a separate centre for the greater tuberosity in only 50 per cent of cases (Paterson, 1929), and **seldom show one for the** lesser tuberosity; and though the overlap of shadows may account for their apparent absence in some cases, yet it may be that the tuberosities are often ossified by extensions from the head. The centres for the capitulum and the trochlea coalesce to form **one** epiphysis at 15 in boys and 13

in girls. The lateral epicondyle usually joins the shaft independently (Paterson), but it may fuse with the capitulum before doing so; and in 30 per cent of cases it appears to have no separate centre but to be ossified by extension from the capitulum.

For medial epicondyle	M. 8–9 F. 5 6	M. 18–21. F. 14–15	Outside.

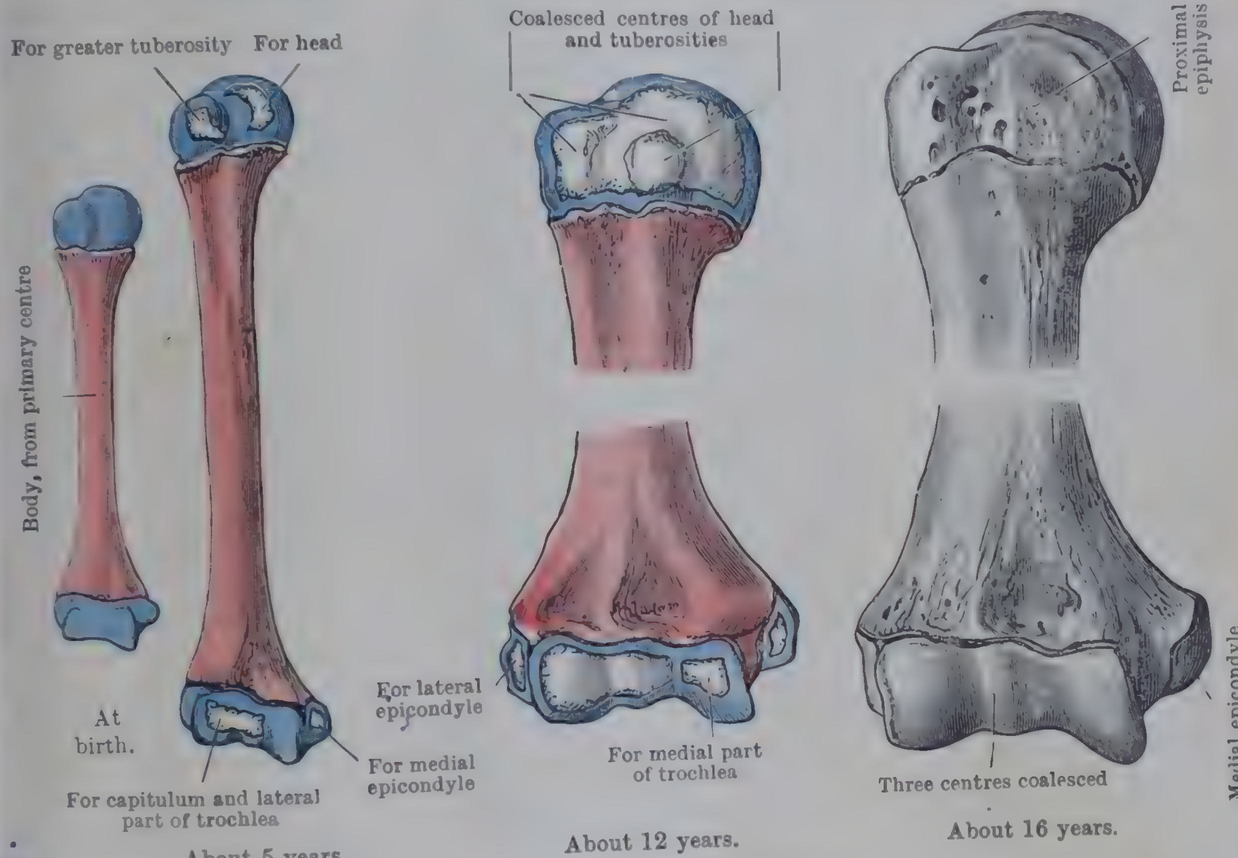

Fig. 229.—Ossification of Humerus.

Structure and Variations.—The structure is that of a typical long bone; the walls of the medullary cavity are thickest immediately below the middle of the bone. *Vascular foramina* are most numerous at the upper end—where most of the growth takes place. The chief nutrient canal runs a course of over two inches before it reaches the medullary cavity.

In women the head is relatively smaller than in men. Occasionally—more often in lower races—the bone above the trochlea is perforated. In rare cases a small projection (*supracondylar process*) is found about two inches above the medial epicondyle, with which it is connected by a fibrous band; the median nerve and brachial vessels—taking an unusual course—pass under cover of the band. The humerus normally appears twisted, so that while the articular surface at the upper end looks mainly in a medial direction, the articular surfaces at the lower end look backwards and forwards; the twist is more marked in adults than in children and fœtuses, in men than in women, and in modern Europeans than in more primitive races or in prehistoric Europeans.

Ligament of Struthers.

Ulna

The **ulna** is the medial and longer bone of the forearm [from ὠλένη (ōlenē) = forearm or elbow]. It is easily felt on the back of the forearm in its whole length.

It is a long bone, about one-sixth of the body-length, and it has a **shaft** and **two ends.**

The **upper** end is the larger end, and it has two large projections that give it a resemblance to a spanner. The wide, deep concavity between these two projections is directed **forwards.** The lateral side can be distinguished from the medial because the **lateral** border of the shaft is the sharpest and most outstanding of the three borders.

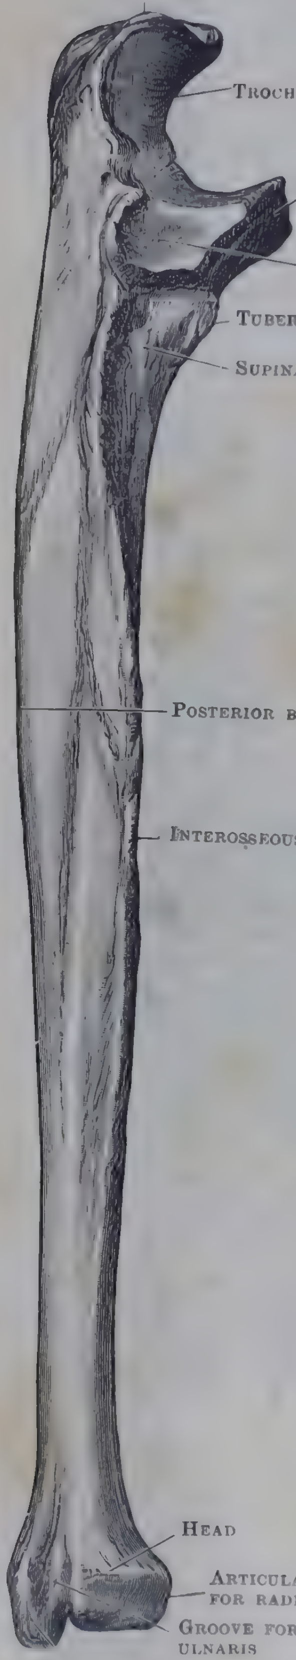

FIG. 230.—LATERAL SIDE OF RIGHT ULNA.

The **upper end** includes the olecranon, the coronoid process, the trochlear notch, the radial notch, and the tuberosity of the ulna.

The **olecranon** is the larger of the two projections and is the uppermost part of the ulna [*ὠλένη*—see p. 255; *κρανίον* (cranion) = head]; it is the prominence felt at the back of the elbow and is the part which rests on the table when one leans on the elbow. It is in line with the shaft, and, though stout and strong, it is sometimes broken off. It has superior, anterior, and posterior surfaces, and lateral and medial borders or surfaces. The **posterior** surface is smooth and subcutaneous and is nearly triangular in outline, with the apex pointing downwards. The **anterior** surface is smooth and coated with articular cartilage. The **superior surface** is the very end of the bone, and the tendon of the triceps muscle is inserted into its posterior part. The **lateral** and **medial** borders are thick and are rough for the attachment of ligaments and muscles.

The **coronoid process** is the projection that juts forward from the upper part of the shaft and has a fancied resemblance to the beak of a bird [*κορώνη* (corōnē) = a sea-crow]. Its *upper* surface is smooth and coated with articular cartilage; its *anterior* surface is rough for the insertion of the brachialis muscle; on its *medial* side there is a rounded tubercle for the attachment of part of the medial ligament of the elbow joint; the tubercle can be felt about a thumb's breadth below the medial epicondyle of the humerus, and the ulnar nerve, as it passes into the forearm, can be felt and rolled over the tubercle by the finger.

The **radial notch** is the shallow, smooth hollow on the lateral surface of the coronoid process; its floor is coated with articular cartilage and articulates with the side of the head of the radius. Immediately below the notch—on the shaft—there is a rough, shallow, triangular hollow with its base at the notch; it is named the *supinator fossa*, and its posterior margin, which is often a strong ridge, is named the *supinator crest*, for the supinator muscle arises from both the crest and the floor of the fossa.

PLATE XI

PLATE XI.—POSTERIOR RADIOGRAPH OF ELBOW OF YOUNG WOMAN AGED 19.

For lateral radiographs of the same elbow, see Plate XII. Cf. also Plate XIII, p. 260 and Plate XIV, Fig. 1.

PLATE XII

FIG. 1.—LATERAL RADIOGRAPH OF THE SAME ELBOW AS IN PLATE XI (YOUNG WOMAN AGED 19), FULLY EXTENDED.

Note the tip of the Olecranon in the olecranon fossa of the Humerus.

FIG. 2.—LATERAL RADIOGRAPH OF THE SAME ELBOW, SEMI-FLEXED.

Compare with Fig. 1, and note the relative positions of Epicondyle and Olecranon.

Cf. also Plate XIV, Fig. 2, p. 261.

The **trochlear notch** is the wide concavity between the coronoid process and the olecranon. The trochlea of the humerus fits into it and articulates with both olecranon and coronoid process. The articular surfaces are the reverse of a pulley, being elevated in the middle and sloping to the sides—the medial slope is more pronounced. If the humerus and the ulna are placed together properly, the olecranon fits into the olecranon fossa when the bones are in line, *i.e.*, when the forearm is extended. The coronoid process comes into relation with the coronoid fossa when the two bones make an acute angle, *i.e.*, when the forearm is fully flexed. Where the olecranon and the coronoid process join each other the trochlear notch has little rough patches at its sides; these patches may meet, forming a rough strip across the floor of the notch, separating the front of the olecranon from the upper surface of the coronoid process.

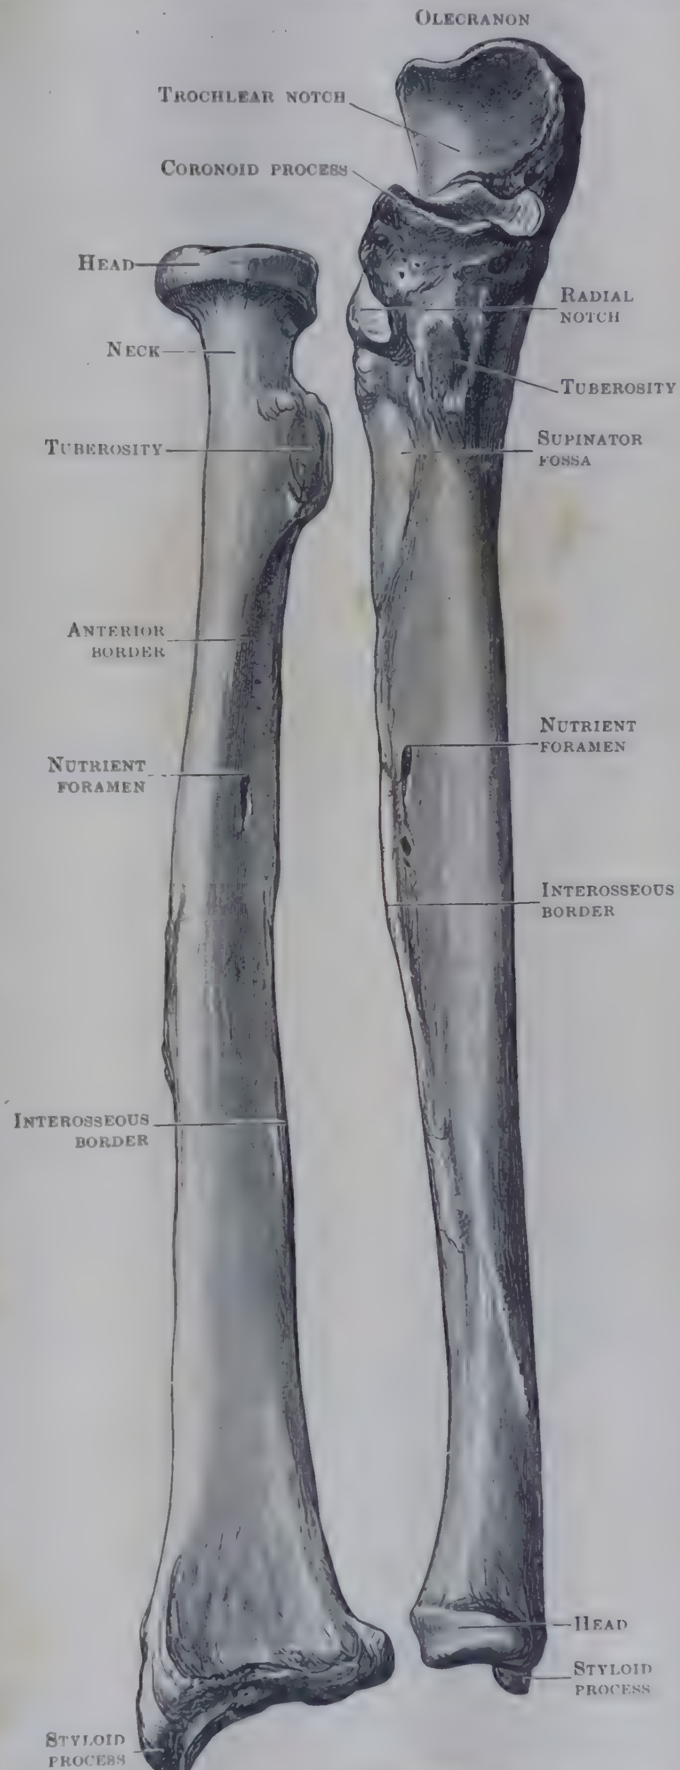

Fig. 231.—Front of Right Radius and Ulna.

The **tuberosity** of the ulna is a rough mark at the distal end of the anterior surface of the coronoid process and is continuous with that surface; but it is on the shaft rather than on the upper end.

The **lower end** of the ulna is small, and it includes the head and the styloid process.

The **head** is the larger, rounded part. Note that in the ulna the part called the *head* is at the *lower* end. When the hand is held with the palm looking downwards, the head of the ulna can be seen as a knob on the back of the forearm immediately above the wrist on the ulnar side (in line with the little finger). The *front* and *lateral side* of the head are smooth and convex, and articulate with the lower end of the radius—the radius articulating with the lateral side when the limb is in *supination* (the thumb pointing away from the body) and with the front in *pronation* (when the thumb points medially) — see p. 264. The *lower surface* also is smooth; it articulates not with a bone but with a triangular plate of fibro-cartilage, called the *articular disc*, which separates the head from the bones of the wrist.

The **styloid process** is the small, conical projection that juts downwards towards

the wrist from the postero-medial part of the lower end. Between the base of the styloid process and the lower surface of the head there is a small, rough patch to which the apex of the articular disc is attached. On the *back of the bone*, between the styloid process and the head, there is a well-marked **groove** which lodges the tendon of the *extensor carpi ulnaris* muscle.

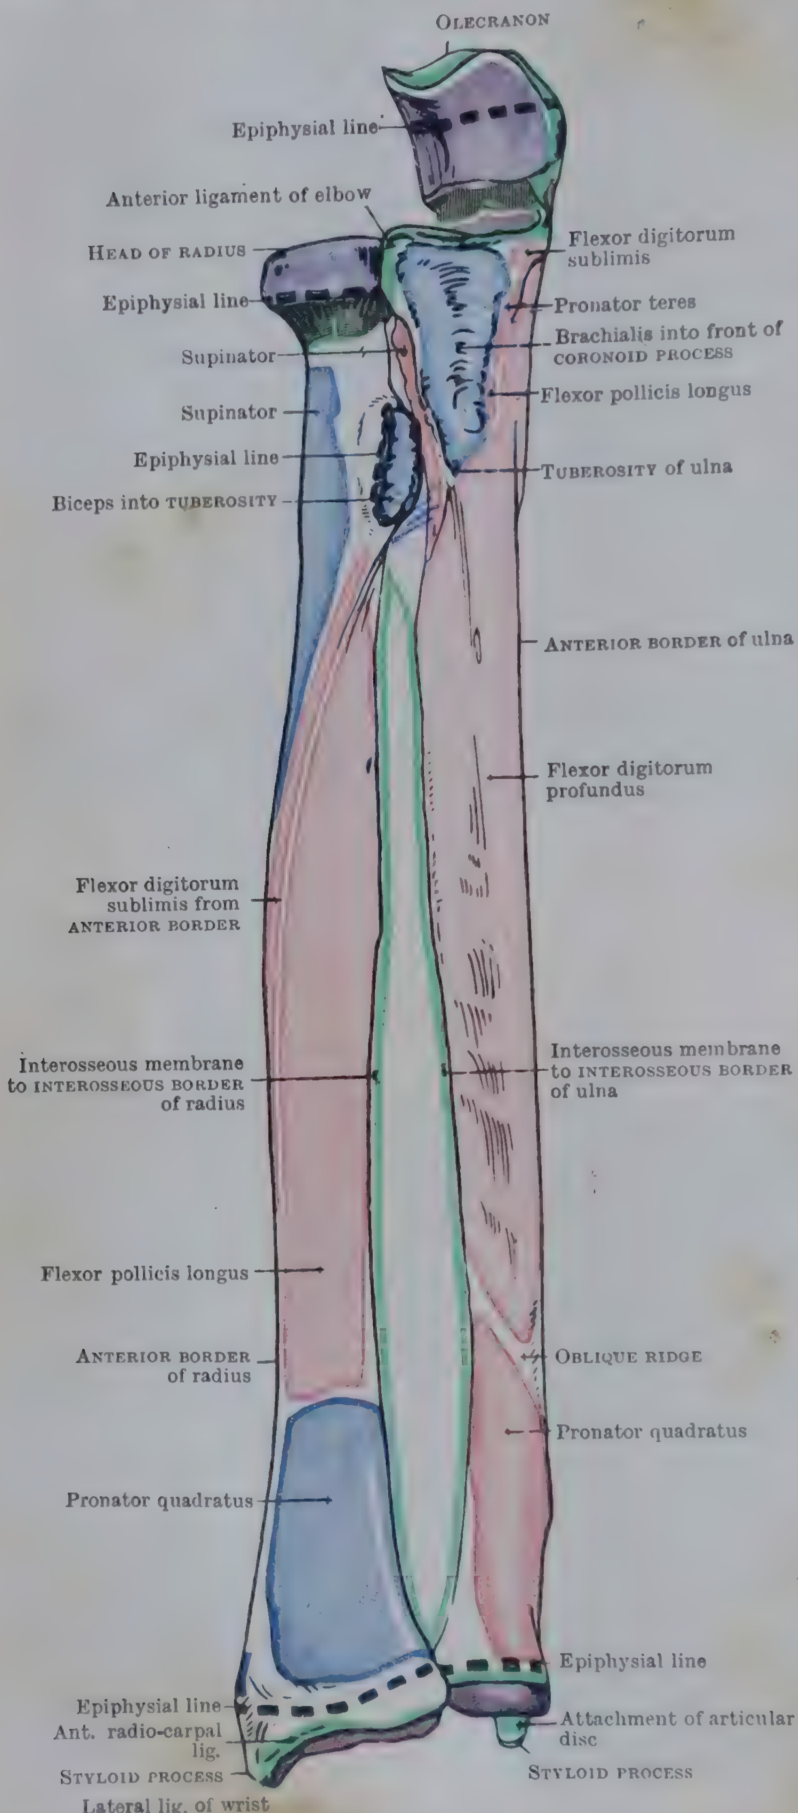

FIG. 232.—FRONT OF RIGHT RADIUS AND ULNA.

When the hand is in the position in which the palm looks towards the shoulder (the elbow being bent), the styloid process, along with the tendon of the extensor carpi ulnaris, can be felt as a ridge on the ulnar border of the back of the forearm, but the head of the ulna is scarcely palpable. When the hand is held palm downwards, the head of the ulna appears as a round knob at the ulnar border of the back of the forearm, and the styloid process is then felt on the ulnar surface of the limb. The apparent differences in position are not due to movements of the ulna, but to movements of the lower end of the radius round the head of the ulna (see p. 264).

The **shaft** of the ulna diminishes in thickness from above downwards. It has three **borders**, named anterior, posterior, and interosseous, and three **surfaces**, named posterior, anterior, and medial.

The **anterior border** is smooth and rounded. It begins at the tuberosity and ends at or near the root of the styloid process. The **posterior border** begins at the lower angle of the back of the olecranon, extends sinuously along the shaft, and fades away near the distal end. It is felt as a sharp, subcutaneous ridge on the back of the forearm. The **interosseous border** is a sharp, salient ridge on the lateral side. It is so named because a strong,

wide fibrous sheet, the *interosseous membrane*, stretches across from it to the radius. It begins at the lower angle of the supinator fossa, becomes very prominent in the middle of the bone, and fades away near the lower end.

The **anterior surface** is between the anterior and interosseous borders; and the tuberosity of the ulna is situated at its upper end. It is usually hollowed out longitudinally in its upper two-thirds or more, and the lower end of the hollow is limited by an oblique ridge from which a part of the pronator quadratus muscle arises. The ridge begins about two inches above the lower end and winds spirally towards the root of the styloid process. The **posterior surface** is between the posterior and interosseous borders. In a well-marked bone an oblique ridge runs from the back of the radial notch to a point on the posterior border about an inch below the lower end of the back of the olecranon. The anconeus muscle is inserted into the area above the ridge. Below the ridge a vertical line maps off a long, flat strip between itself and the posterior border. The strip gives no attachment to any muscle, but the extensor carpi ulnaris lies on it; nearly all the rest of the posterior surface is mapped out by faint oblique ridges into areas for the origin of muscles. The **medial surface** is the smooth, slightly convex surface between the anterior and posterior borders. Its upper part is covered with muscle, but its lower third is subcutaneous and therefore easily felt.

The **nutrient foramen** is on the anterior surface about the junction of the upper and middle thirds, and it is directed towards the upper end.

Attachments.—The tendon of the triceps is inserted into the posterior part of the *superior surface* of the **olecranon**; the posterior ligament of the elbow joint is attached to the anterior edge of the surface; and a small *bursa* lies between them on the intervening part. The posterior ligament is attached also to the *lateral surface*, and the anconeus is inserted into that surface behind the ligament; the posterior band of the medial ligament of the elbow joint is attached to the *medial surface*, and fibres of the flexor carpi ulnaris and of the flexor digitorum profundus arise from it behind the ligament.

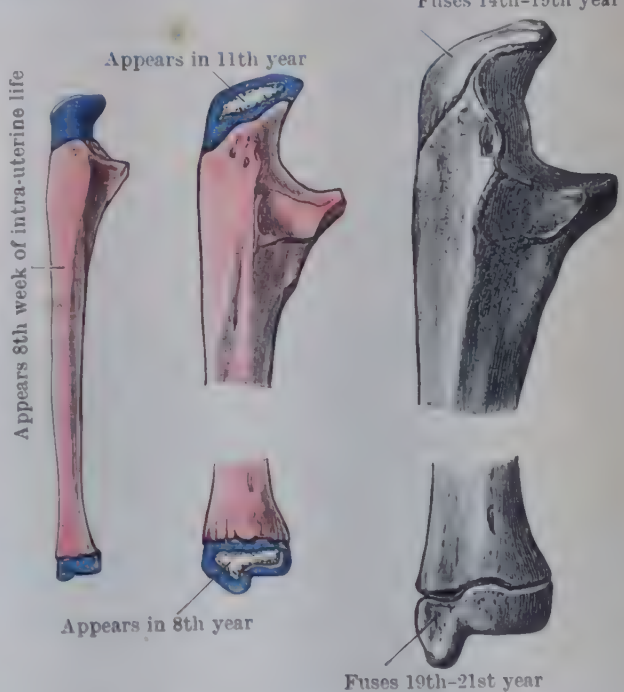

Fig. 233. Ossification of Ulna.

The anterior band of the medial ligament is attached to the *tubercle* on the *medial border* of the **coronoid process**; some fibres of the flexor digitorum sublimis arise from it; slips of the pronator teres and flexor pollicis longus arise from the ridge which descends from the tubercle, and fibres of the flexor profundus from the hollow behind that ridge; the anterior ligament of the elbow joint is attached to the *anterior margin* of the process, and the brachialis is inserted into the *anterior surface* and also into the **tuberosity** immediately below. The annular ligament which surrounds the head of the radius is attached to the *anterior* and *posterior margins* of the **radial notch**, and the quadrate ligament to its *lower margin*.

The capsule of the inferior radio-ulnar joint is attached to the *front* and *back* of the **head**: a septum of the extensor retinaculum to the radial border of the **groove** on the back; the medial ligament of the wrist joint to the tip of the **styloid process**, and the apex of the articular disc to the small, rough mark between its root and the head.

On the **shaft**, the oblique cord, as well as part of the brachialis, is attached to the **tuberosity**. The supinator arises from the **supinator crest** and **fossa**. The interosseous membrane is attached to the **interosseous border**. The flexor carpi ulnaris arises by a wide aponeurosis from the upper three-fourths of the *posterior border*, besides having a small origin from the ~~lateral~~ med surface of the olecranon. By means of the same aponeurosis part of the extensor carpi ulnaris arises from the middle third of the posterior border. The anconeus is inserted into the upper part of the *posterior surface*; parts of the abductor pollicis longus, extensor pollicis longus, and extensor indicis arise from the lateral part of the posterior surface—in that order from above downwards. The pronator quadratus arises from the lower fourth of the *anterior surface* (including the ridge above that fourth); the flexor digitorum profundus arises from the upper two-thirds or three-fourths of the *anterior* and *medial surfaces*—extending up to the medial surfaces of the coronoid process and olecranon.

Ossification (Pls. XIII, XIV; XV, p. 268; XVIII, p. 273).—The **primary centre** appears at the eighth week of intra-uterine life, and from it the shaft, the coronoid process, and nearly the whole of the olecranon are ossified, though at birth a great part of the olecranon—as well as the lower end—is cartilaginous.

Secondary Centre.	Appears at	Epiphysis joins at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For lower end	8th year	**M.** 21. **F.** 19-20	Outside.
For top of olecranon	11th ,,	{ **M.** 18-19 / **F.** 14-15	Outside; anterior part sometimes inside (Fig. 232).

The olecranon may have an additional centre, or more than one, in its body; and its epiphysis varies in size.—See Figs. 232, 233.

Structure and Variations.—The structure resembles that of the humerus and other long bones. The medullary canal extends from the root of the coronoid process to the distal fifth of the bone, and its posterior wall is the thicker. The weakest parts are at the junction of the olecranon and the coronoid process, and the junction of the middle and lower thirds of the shaft.

In rare cases the ulna is incompletely developed or is absent. In one recorded case the olecranon was a separate bone.

Radius

The **radius** resembles the spoke of a wheel—hence its name. It is the lateral and shorter bone of the forearm, and can be felt in all its length, though deep pressure is necessary at its middle. It is a long bone with a **shaft** and **two ends.**

The **upper** end is the smaller end. The lower end is slightly bent forwards, and its **anterior** surface is broad, slightly concave, and fairly smooth; from the **lateral side** of the lower end a short, pointed process projects downwards.

The **upper end** includes the head, the neck, and the tuberosity.

The **head** is a circular disc, cupped on its upper surface, and that surface is smooth and articulates with the capitulum of the humerus. The circumference of the head is smooth; it articulates with the radial notch of the ulna and with the inner surface of a fibrous band, called the *annular ligament* of the radius, which encircles five-sixths of the head of the radius and is attached by its ends to the anterior and posterior margins of the radial notch of the ulna; the ligament and the notch, together, make a complete ring within which the head of the radius rotates during the movements of supination and pronation (p. 264). The head of the radius can be felt, through the ligament, on the back of the limb towards the lateral side, immediately below the lateral epicondyle of the humerus.

The **neck** is the cylindrical, slightly constricted part that supports the head.

The **tuberosity** of the radius is the broad, low prominence on the medial side immediately below the neck. The tendon of the biceps is inserted into it.

When the humerus and radius are fitted together properly the upper surface of the head of the radius articulates with the capitulum at its lower part when the elbow is extended (straightened), with its anterior part when the elbow is flexed to a right angle. Its edge comes into relation with the radial fossa of the humerus in extreme flexion. The trochlear notch of the ulna partially encircles and hinges on the trochlea; the ulna is therefore the more important constituent of the elbow joint, and the stability of the joint depends on it—the radius offering no bar to dislocation. The grip of the ulna is least secure when the forearm is extended in line with the arm; the ulna can then slip backwards off the humerus. But the olecranon is a positive bar to forward dislocation until the forearm is becoming acutely flexed.

The **lower end** of the radius has five surfaces and a styloid process. The surfaces are anterior, posterior, medial, lateral, and distal or carpal.

FIG. 1.—POSTERIOR RADIOGRAPH OF ELBOW OF BOY AGED 7.
(Dr. J. Duncan White.)

Note that the centre for the capitulum of the Humerus forms part of the trochlea, and that the other trochlear centre and the lateral epicondyle centre have not yet appeared. For further development of the epiphyses, see Fig. 2.

FIG. 2.—POSTERIOR RADIOGRAPH OF ELBOW OF BOY AGED 12, SHOWING ALL EPIPHYSIAL CENTRES.

The three centres for (1) capitulum and lateral part of trochlea, (2) medial part of trochlea, and (3) lateral epicondyle, unite to form a single epiphysis.
Note the olecranon epiphysis above the part of the olecranon that overlaps the Humerus. For earlier stage of development of the epiphyses, see Fig. 1.

[Facing p. 260

PLATE XIV

Fig. 1.—Posterior Radiograph of Elbow of Girl aged 12, showing Epiphyses of Medial Epicondyle of Humerus and Head of Radius not yet united.

Fig. 2.—Lateral Radiograph of the same Elbow (Girl aged 12), slightly flexed.
Note the uniting Epiphyses of Head of Radius and Olecranon of Ulna.

[Facing p

The **anterior surface** is broad and slightly concave; at its lower margin there is a broad, rough ridge that can be felt on the front of the forearm about an inch above the ball of the thumb; it indicates the position of the distal epiphysial line, and it is also a guide to the position of the wrist joint, which is immediately distal to it.

The **posterior surface** is more uneven, being occupied by grooves and ridges. The most prominent ridge is about the middle of the surface; it is called the **dorsal tubercle** and can usually be felt in the living limb. On the lateral side of the tubercle there is a shallow groove, more than half an inch wide, on which two thick tendons lie; they are the tendons of the extensor carpi radialis longus and brevis muscles, and when the closed fist is bent slightly backwards they can be seen as they pass off the radius on to the back of the wrist. On the medial side of the tubercle there is a narrow, oblique, clean-cut groove for the tendon of the extensor pollicis longus, which can be seen reaching almost to the thumb-nail when the thumb is outstretched. The rest of the surface—the part medial to the narrow groove—is a wide, shallow groove that lodges the tendons of the extensor digitorum and extensor indicis (Fig. 234).

The **lateral surface** is less than half an inch wide; it is occupied by a shallow groove for the tendons of the abductor pollicis longus and extensor pollicis brevis, and it is separated from the anterior surface by a sharp ridge that is easily felt in the living limb.

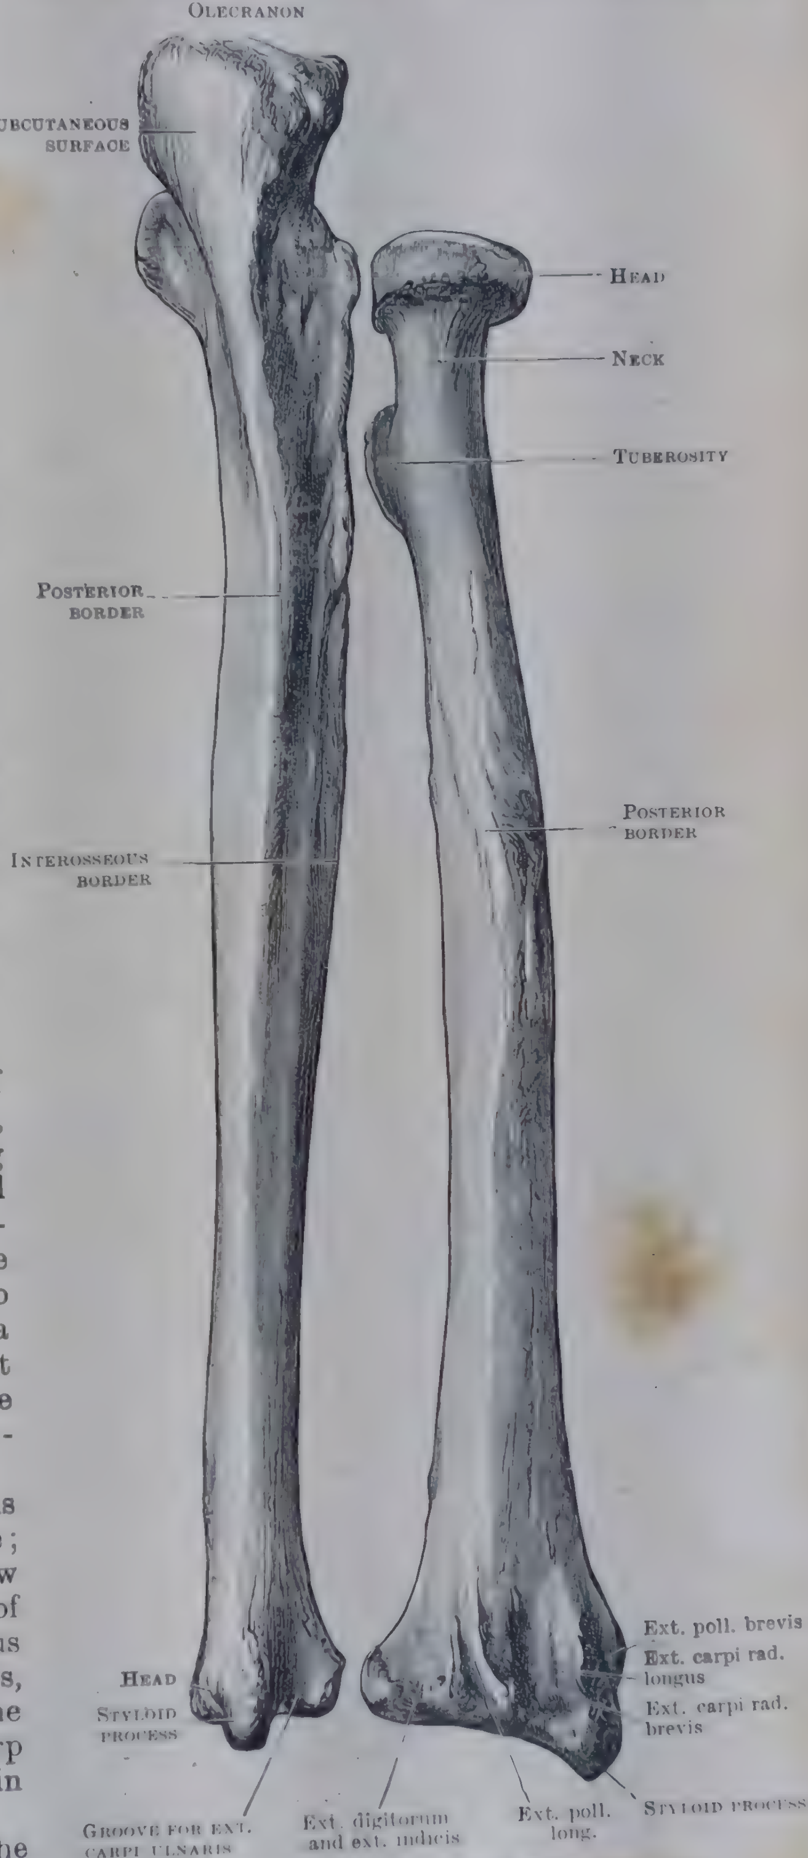

Fig. 234.—Back of Right Radius and Ulna.

The lateral part of the lower end of the radius is prolonged downwards as the short, thick **styloid process**. When the thumb is outstretched a hollow is seen on the radial side of the wrist, called by the French the *anatomical snuff-box*

(tabatière anatomique); its posterior boundary is the tendon of the extensor pollicis longus; anteriorly the tendons of the abductor pollicis longus and extensor pollicis brevis lie together and make a ridge between the front of the wrist and its lateral surface; the styloid process is the bone felt in the proximal part of the floor of the hollow. Its position should be compared with that of the styloid process of the ulna; the radial styloid process is at a lower level than that of the ulna. In the common variety of fracture of the lower end of the radius that relationship may be reversed.

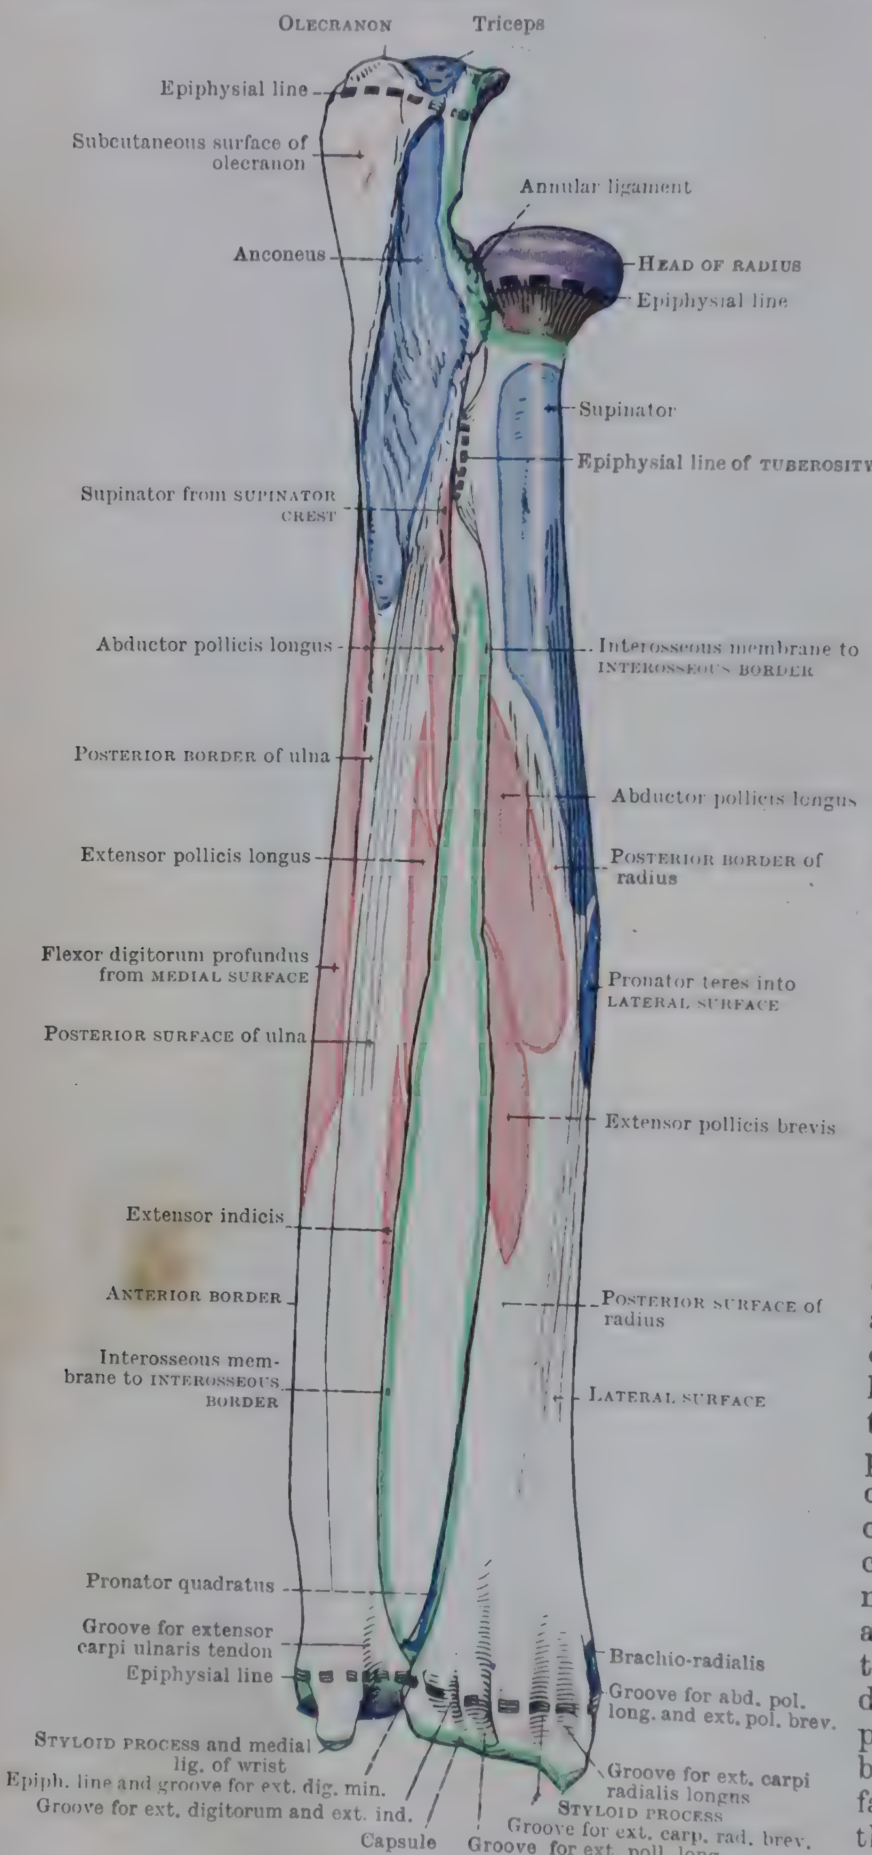

FIG. 235.—BACK OF RIGHT RADIUS AND ULNA.

The **medial surface** is small, smooth and concave and forms the **ulnar notch**. It articulates with the head of the ulna and rotates round it during the rotary movements of the forearm and hand (pronation and supination).

The *distal* or **carpal surface** is concave and smooth, and articulates with bones of the wrist or carpus. It is divided into two areas: a medial area nearly quadrilateral, and a lateral area nearly triangular, the apical part of which extends on to the styloid process. Between the carpal surface and the medial surface there is a sharp edge to which the base of the articular disc is attached. The posterior and lateral boundaries of the surface reach lower down than the others, and in a fall on the hand the posterior and lateral part of the lower end may be chipped off. A break in the lower third of the shaft is, however, more likely with consequent displacement of the lower end of the bone.

Since the anterior surface is concave from above downwards and the posterior surface is slightly convex, the lower end of the bone curves forwards. A broken bone must be 'set' so as to restore the proper shape and to avoid straightening the bone, a fault which would alter the position of the wrist joint and the pull of the tendons.

The **shaft** increases in girth from above downwards, but it is most often broken near the lower end; it has three borders and three surfaces. The **borders** are anterior, posterior, and interosseous; the **surfaces** are posterior, anterior, and lateral.

The **interosseous border** is on the medial side and is the sharpest and most definite of the three; the interosseous membrane is attached to it. It begins near the tuberosity and towards its lower end it divides into two ridges which diverge slightly to become continuous with the margins of the ulnar notch. The **anterior border** begins at the tuberosity and ends at the ridge between the anterior and lateral surfaces of the lower end of the bone. Its upper part is well marked and oblique; its lower part is rounded and indistinct (Fig. 231). The **posterior border** is distinct in the middle third of the bone (Fig. 234); the upper part is an indistinct line that leads from the middle third obliquely towards the back of the tuberosity; the lower part—a smooth, indistinct ridge—runs from the middle third to the dorsal tubercle on the distal end.

The **anterior** and **posterior surfaces** separate the interosseous border from the anterior and posterior borders. The **lateral surface** is between the anterior and posterior borders and is roughened at its middle for the insertion of the pronator teres muscle. Its upper part encroaches greatly on the front and back of the bone owing to the obliquity of the upper parts of the anterior and posterior borders; the lower part of the surface also encroaches on the back, so as to be continuous with the lateral surface of the lower end and with the lateral part of the back.

The **nutrient foramen** is on the anterior surface about the junction of its upper and middle thirds, and it is directed towards the upper end.

Attachments.—The lower margin of the annular ligament and the lateral margin of the quadrate ligament are attached round the **neck**—*loosely*, so as not to interfere with the rotatory movements of the radius. The posterior part of the **tuberosity** is roughened for the insertion of the tendon of the biceps, but the anterior part is smooth for the *bursa* that separates it from that tendon.

At the **lower end**, the anterior radio-carpal ligament is attached to the distal margin of the *anterior surface*; the lateral ligament to the **styloid process**; the posterior ligament to the distal edge of the *posterior surface*; the capsule of the inferior radio-ulnar joint to the anterior and posterior margins of the **ulnar notch**; the base of the articular disc to the border between the notch and the *carpal surface*; the lateral end of the extensor retinaculum to the *sharp border* between the lateral and anterior surfaces, and its septa to the ridges that bound the grooves on the *posterior surface*; the tendon of the brachio-radialis is inserted into the upper part of the *lateral surface*.

At Birth. About 12 years. About 16 years.

Fig. 236.—Ossification of Radius.

On the **shaft**, the oblique cord is attached to the bone immediately below the tuberosity; the interosseous membrane to the **interosseous border** and to the hinder of the two ridges into which the lower end of the border divides. Part of the flexor digitorum sublimis arises from the upper half of the *anterior border*, and the flexor pollicis longus from the upper three-fourths of the *anterior surface*; the pronator quadratus is inserted into the lower fourth of the anterior border and anterior surface, into the anterior surface of the lower end, and into the narrow triangular area above the ulnar notch. The pronator teres is inserted into the rough mark on the middle of the *lateral surface*; the supinator into the upper third, including its encroachments on the front and back. Parts of the abductor pollicis longus and extensor pollicis brevis arise from the *posterior surface*—the abductor immediately above the middle of the bone, and the extensor immediately below.

The radius has a slight double curve—convex in a medial direction in its upper quarter, and in a lateral direction in the lower three-quarters. The biceps and the pronator teres are inserted into the maximum points of the curves, and their value as supinator and pronator (p. 367) respectively, is thus increased. The medial side of the head is deeper and flatter from above downwards than the rest of its circumference. The lower part of the lateral surface of the shaft does not give attachment to any muscle; but it is overlain by the tendons of the brachio-radialis and the radial extensors of the carpus. Occasionally there is a small tubercle on the posterior lip of the groove on the lateral side of the lower end; this is for the attachment of the most lateral septum of the extensor retinaculum. The slight ridge between the two areas on the carpal surface is best marked at its ends where there may be slight notches on the anterior and posterior margins of the carpal surface.

Ossification (Pls. XIII–XV, pp. 260, 268; XVIII, p. 273).—The **primary centre** appears at the eighth week of intra-uterine life. At birth only the lower end, the head, and the tuberosity are cartilaginous.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For lower end	**M.** 1-1½ yr. **F.** 1	**M.** 21. **F.** 19-20	Outside.
For head	**M.** 6-7. **F.** 5-6	**M.** 18-19. **F.** 14-15	Inside.
For tuberosity (occasional)	Puberty	Shortly after puberty	Outside.

Structure and Variations.—The medullary canal reaches the neck but does not reach the lower part of the shaft; its walls are thick compared with the size of the bone; the thickness is especially marked along the interosseous border—imparting rigidity to the curve of the bone. The neck is the most slender part of the bone, but the commonest seat of fracture is near the lower end, for that part of the bone bears the impact of a fall on the hand. The nutrient canal traverses the bone for half an inch before it reaches the medullary cavity.

Absence of the radius has been recorded more than once, and in some of these cases the thumb also was absent.

Supination and Pronation

The terms supination and pronation refer to position and movements of the forearm and hand. The **supine position** is that in which the two bones of the forearm are parallel and the thumb is directed away from the side of the body; in that position the palm of the hand looks forwards when the limb hangs by the side, upwards when the elbow is flexed to a right angle [*supinus* = lying on the back], and backwards when the elbow is acutely flexed. The **prone position** is that in which the thumb is directed towards the side of the body [*pronus* = inclined downwards—here referring to the palm when the elbow is flexed to a right angle.]

When the forearm and hand are placed, say, on a table with the palm facing upwards they are in the *supine* position. If the humerus is kept steady and the forearm is turned to make the palm face downwards, it assumes the *prone* position. In full **supination** the radius and ulna lie parallel. As the forearm is pronated the upper end of the radius revolves within the annular ligament; the lower end is carried round the head of the ulna, and the shaft is rotated and carried obliquely across the ulna. The ulna remains practically stationary. In full **pronation** the radius and ulna are crossed and the hand has been carried medially with the radius and turned until the thumb is situated medially. Description of the radius and ulna is much simplified when the bones are parallel and for this reason full supination is used as the normal *anatomical position*. A normal comfortable position of the forearm is nearly midway between pronation and supination. The slight supination which is usual when the limb hangs naturally is masked by a medial rotation of the humerus. Evidence of this can be had by noting the position of the epicondyles of the humerus. Supination is a more powerful movement than pronation and screws and screwing instruments are made accordingly. (See also p. 367.)

Carpus

The skeleton of the **carpus** or **wrist** consists of *eight* small bones closely held together by ligaments, and arranged in two rows—a proximal and a distal. From lateral to medial side, the names of those in the **proximal row** are: scaphoid,

lunate, triquetrum, pisiform; and in the **distal row**: trapezium, trapezoid, capitate, hamate.

The **pisiform bone** is the hard knob at the medial border of the front of the wrist. It is rather loosely attached and can be moved slightly from side to side if the hand is held slack; the sinew seen and felt descending to it, along the medial border of the forearm, is the tendon of the flexor carpi ulnaris muscle.

The **other bones** of the wrist are so tightly bound together that, until the ligaments are cut, they form **one compact mass** with *six* surfaces—palmar, dorsal, medial, lateral, proximal, and distal. (See Fig. 332, p. 369.)

The *proximal surface* is smooth and convex, and measures much more from side to side than from before backwards; it articulates with the radius and the articular disc to form the radio-carpal joint or wrist joint. The *distal surface* is uneven, and its transverse measurement also is much greater than the antero-posterior; it articulates with the bases of the five metacarpal bones to form the carpo-metacarpal joints. The *medial surface* is small, and can be felt on the medial side of the wrist. The *lateral surface* also is small; it is partly palpable in the "anatomical snuff-box", and is partly hidden by the tendons in the anterior boundary of that hollow; the radial artery crosses it obliquely, under cover of those tendons.

The *dorsal surface* is large, rough and convex from side to side, and is to a large extent concealed by tendons. The *palmar surface* is concave from side to side, the concavity being deepened and, indeed, largely caused by the shape and position of the bones at the sides. The concavity is the **carpal groove** which is converted into a **carpal canal** or tunnel by the *flexor retinaculum*. The retinaculum is a strong flattened band which bridges the groove and holds the flexor tendons in place in the groove. It is attached to projections which can be felt in the living hand. The pisiform bone has been referred to above. Distal to it, the **hook of the hamate bone** (hamatus = hooked) can be felt if deep pressure is made by the thumb of the other hand on the ball of the little finger—*i.e.*, the fleshy eminence on the medial side of the palm. The pressure should be made 15-25 mm. from the pisiform bone on a line drawn from the pisiform towards the centre of the palm. A nerve can often be felt slipping from side to side on the hook; that is the superficial branch of the ulnar nerve.

The **tubercle of the scaphoid bone** can always be felt and is often a visible projection. The guide to its position is the tendon of flexor carpi radialis. This is the most lateral of the group of tendons which run down the middle of the front of the forearm to the wrist. Where it passes out of sight at the wrist the tubercle of the scaphoid bone can be felt—partly under cover of the tendon and partly lateral to it—immediately above the ball of the thumb.

The **crest on the trapezium** is less easily felt. It is immediately distal to the tubercle of the scaphoid in the medial edge of the ball of the thumb, and pressure should be made there with the hand bent backwards; the bony resistance encountered is the crest. It may be felt as a prominence separate from the tubercle of the scaphoid, but the two often are felt as one continuous bony resistance.

If the student has a skeleton of the hand in which the carpal bones are strung or wired together he will be able to identify them from their position. If they are separate he may require the aid of a demonstrator, but should try to identify them himself by means of their chief characters—beginning with those that are more easily recognized.

The **pisiform bone** is the smallest of all. It resembles a large pea with a slice cut off [*pisum* = a pea].

The **hamate bone** has a compressed, curved process that projects from its palmar surface.

The **capitate bone** is usually the largest. Its proximal surface or end is smooth and rounded—resembling a head.

The **scaphoid bone** is one of the larger bones. It bears a slight resemblance to a comma—the tubercle being the bent, narrower end of the comma. Of its *articular* surfaces two are convex and one is concave, fitting the tip of a finger. The bone is called the "scaphoid" from a far-fetched resemblance to a boat given to it by that concave surface [σκάφη (scaphē) = anything dug out—a boat].

The **lunate bone** is one of the smaller bones. Its distal surface is markedly concave in one direction and fits the tip of a finger. On another surface (the lateral) it has an articular facet shaped like a crescent moon, which gives the bone its name.

The **trapezium** is medium in size. One of its articular surfaces is saddle-shaped; one of its non-articular surfaces has the thick crest—mentioned before—with a groove alongside the crest.

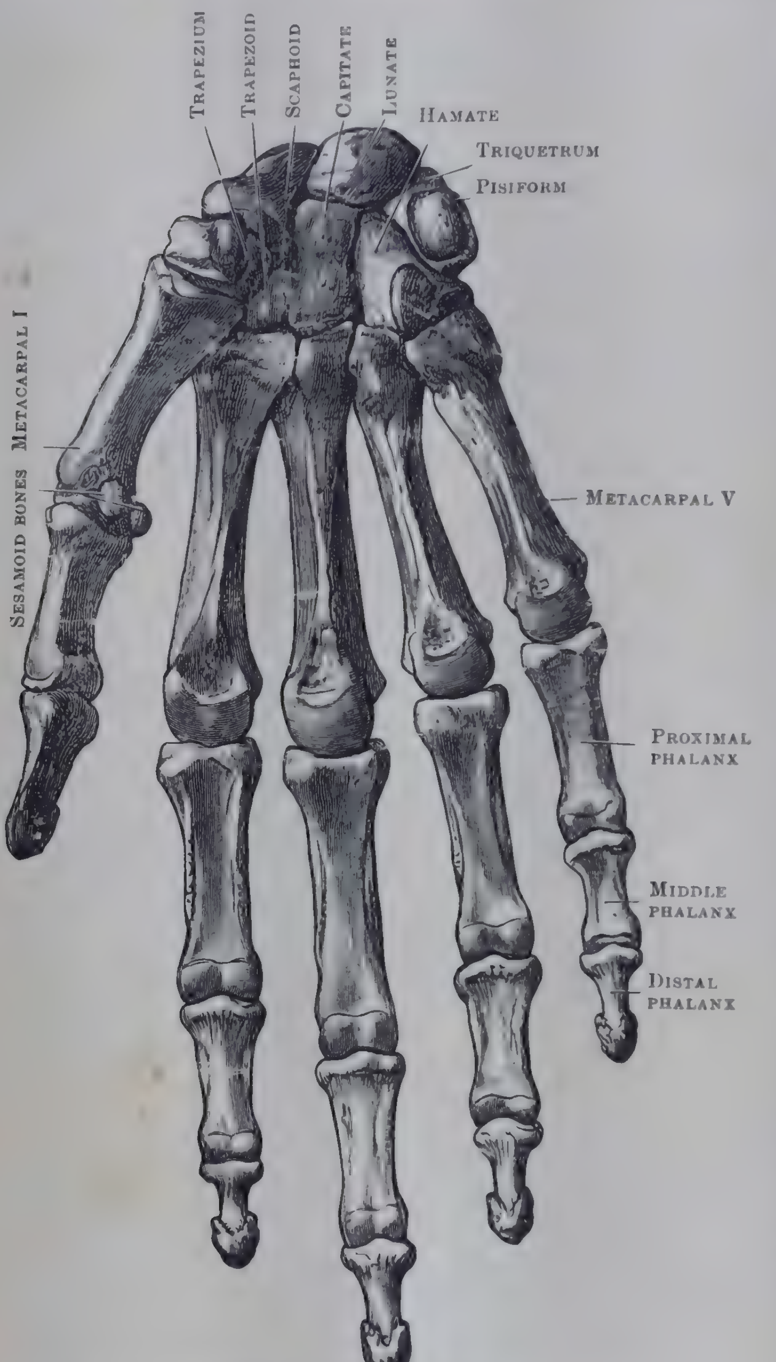

FIG. 237.—PALMAR ASPECT OF BONES OF RIGHT HAND.

The triquetrum and the trapezoid are the only two left. The **triquetrum** is more or less pyramidal in shape [*triquetrus*=three-cornered] and on one of its surfaces it has a circular, flat facet which occupies a great part of that surface. The **trapezoid** though very unlike the others, has no outstanding characters. It has four definite articular surfaces set almost at right angles to one another, and two non-articular surfaces, one of which is considerably larger than the other; when it is placed on that larger surface it has a fanciful resemblance to a Chinese boot.

Each of the carpal bones is conveniently described as having six surfaces—proximal, distal, palmar, dorsal, lateral, and medial.

Scaphoid Bone.—The *proximal surface* is the larger of the two convex articular surfaces; it articulates with the lower end of the radius. The *distal surface* is the smaller of the two convex surfaces, and it articulates with the proximal surfaces of the trapezium and trapezoid. The *dorsal surface* is the narrow strip between the proximal and the distal surface, and it is rough for the attachment of ligaments. The *medial surface* has a smooth area—concave in each direction—for articulation with the lateral surface of the head of the capitate bone, and above that there is a semilunar strip that articulates with the lateral surface of the lunate bone. The *lateral surface* is greatly reduced and is represented by the **tubercle**. The *palmar surface* is concave in one direction and is the concave side of the comma, which forms part of the lateral wall of the carpal tunnel.

Lunate Bone.—The *distal surface* is the concave surface and articulates with the top of the head of the capitate. The *proximal surface*, directly opposite, is convex; it articulates with the lower end of the radius and with the articular disc. The *lateral surface* is the one shaped like a crescent moon, and it articulates with the scaphoid bone. The *medial surface*, directly opposite, is flat and nearly quadrilateral and articulates with the base or lateral surface of the os triquetrum. Between the medial and the distal surfaces there is usually a narrow strip that articulates with the upper edge of the hamate. The *palmar* and *dorsal surfaces* give attachment to ligaments; the palmar surface is convex and is larger and smoother than the dorsal surface.

Triquetrum.—The *palmar surface* is nearly flat; its medial two-thirds is covered with a flat, circular facet that articulates with the pisiform bone. The *distal surface* is concavo-convex

or undulating, and articulates with the medial surface of the hamate bone. The *lateral surface* is the base of the pyramid and articulates with the lunate bone. The *medial surface* is greatly reduced—being only the apex of the pyramid—and can be felt on the side of the wrist distal to the styloid process of the ulna and behind the pisiform bone. The *proximal* and *dorsal surfaces* are confluent, making one uneven convex surface; its lateral part has a poorly marked facet that articulates with the medial ligament of the wrist joint, and, during adduction of the wrist, with the articular disc.

Pisiform Bone.—The *dorsal surface* is oval or circular and is covered with a flat or slightly concave facet for articulation with the triquetrum. It is marked off by a very narrow, circular groove that gives attachment to the capsular ligament of the joint. The remainder is non-articular and rounded. It is shaped as though it had been pulled distally and laterally when soft so that the *distal surface* bulges beyond the articular facet and the *lateral surface* is slightly concave. The concavity of the lateral surface forms part of the medial wall of the carpal tunnel and is related to the flexor synovial sheath. Its anterior edge forms a low overhanging ridge for attachment of the flexor retinaculum, and the adjacent lateral slope of the *palmar surface* is related to the ulnar nerve.

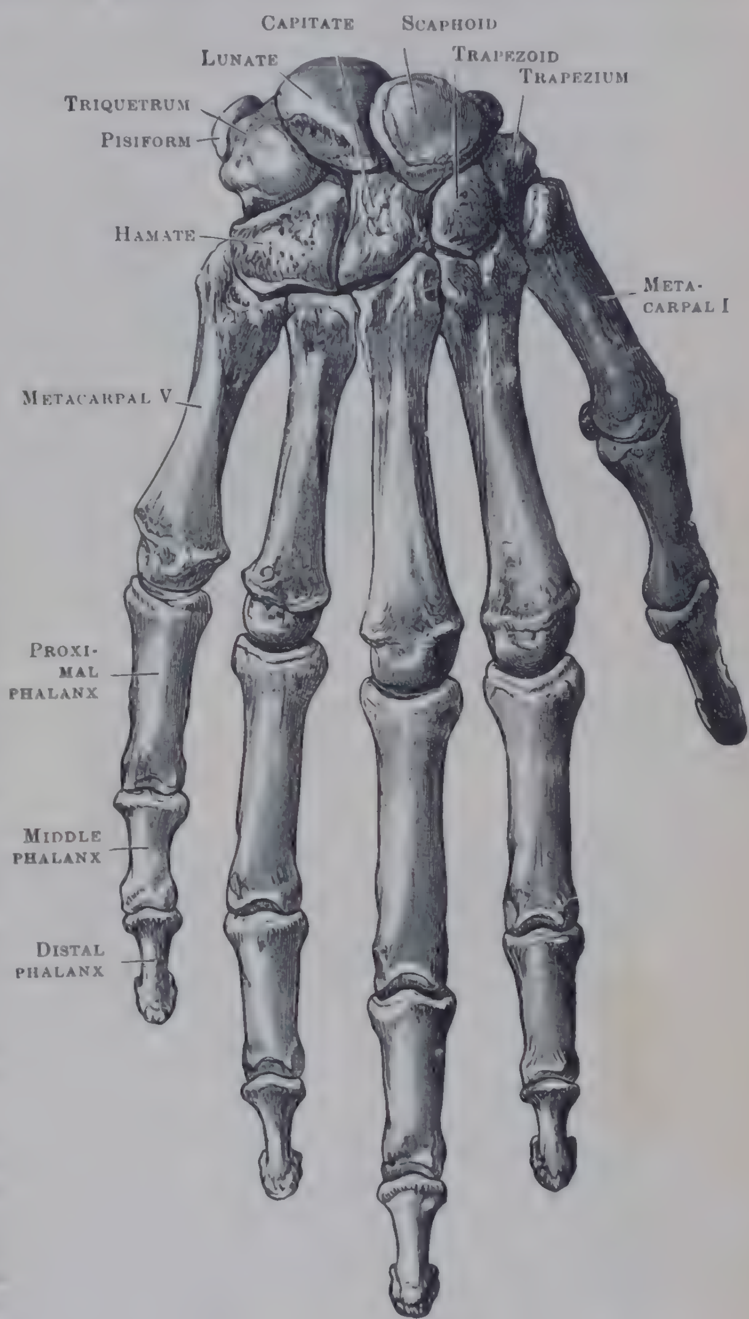

Fig. 238.—Dorsal Aspect of Bones of Right Hand.

Trapezium.—The *distal surface* is saddle-shaped and articulates with the base of the first metacarpal bone. The *proximal surface* is the small, smooth, concave surface opposite; it articulates with the scaphoid bone. The *medial surface* has a large facet which is separated by a smooth ridge from the proximal surface, and it articulates with the lateral surface of the trapezoid; lower down there is a small facet for articulation with the base of the second metacarpal bone. The *palmar*, *dorsal*, and *lateral surfaces* are non-articular. The palmar surface is distinguished from the other two by having the thick *crest* along its lateral margin and a well-defined, narrow groove along the lodges the tendon of the flexor carpi medial side of the crest; the groove radialis. The lateral surface is continuous with the lateral side of the crest, and the dorsal surface is directly opposite the palmar.

Trapezoid.—Beginners find difficulty in identifying its surfaces. The *dorsal* and *palmar surfaces* are both non-articular; the palmar surface is much the smaller. The other four surfaces are articular. The *distal surface* is the largest of these four; it is concave from before backwards and convex from side to side; it articulates with the base of the second metacarpal bone. From the palmar surface a rough strip, which may be V-shaped, passes backwards between the distal and lateral surfaces, and so the *lateral surface* can be identified; it articulates with the trapezium. The *proximal surface*, opposite the distal, articulates with the scaphoid bone. The *medial surface* articulates with the lateral surface of the capitate.

Capitate Bone.—The *proximal surface* is the rounded top of the head and articulates with the concave surface of the lunate bone. The *distal surface* is the base; its greater part articulates with the base of the third metacarpal bone, but at the edges it articulates also with the second and the fourth. The *palmar surface* is rough and protuberant. The *dorsal surface* also is non-articular, but is nearly flat. The *lateral surface* of the head is convex and articulates with the concave facet of the scaphoid bone; lower down, on the lateral surface of the body, there is a facet for articulation with the medial surface of the trapezoid. The *medial surface* has a large, nearly flat facet, which includes the medial side of the head, for articulation with the lateral surface of the hamate bone.

Hamate Bone.—The *hook* juts forwards from the distal and medial part of the palmar surface. The concave side of the hook looks in a lateral direction; it forms the lower part of the medial wall of the carpal tunnel and is lined with the flexor synovial sheath. The medial surface and the tip of the hook are covered with muscles and ligaments; the superficial branches of the ulnar vessels and nerve cross the tip; the deep branches cross the medial surface, and the nerve may groove it. The body of the bone is shaped like a wedge. The base of the wedge is the *distal surface*; it is concave from before backwards and convex from side to side; it articulates with the bases of the fourth and fifth metacarpal bones, and usually an indication of the division into two corresponding parts can be made out. The *proximal surface* is reduced to a blunt border between the medial and lateral surfaces and is the edge of the wedge; it articulates with the lunate bone. The distal and anterior part of the *lateral surface* is rough; the remainder is covered with a large facet for articulation with the capitate bone. The *medial surface* is wholly articular except at its distal margin, and it is undulating; it articulates with the distal surface of the tri-

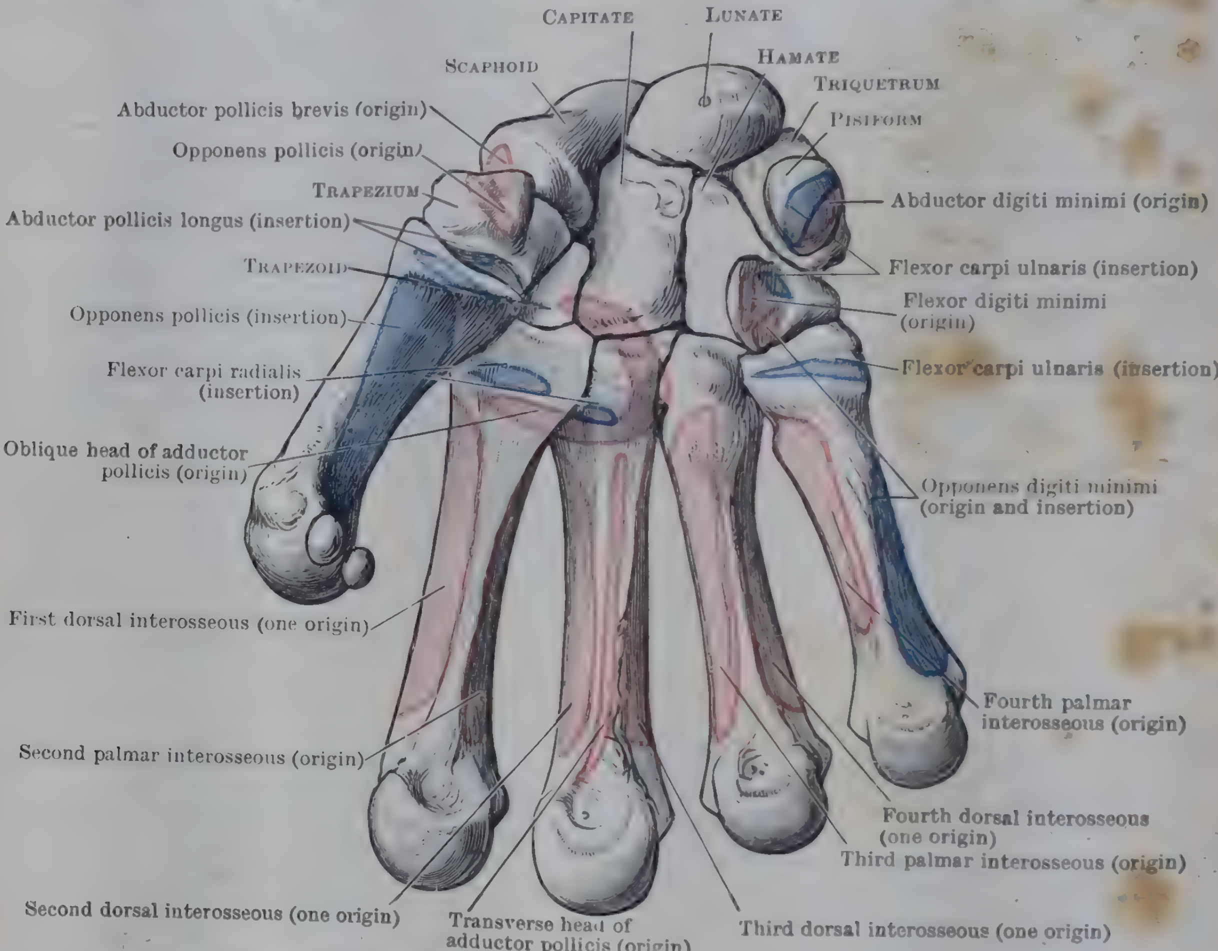

FIG. 239.—FRONT OF RIGHT CARPUS AND METACARPUS WITH ATTACHMENTS MARKED.

quetrum, which is correspondingly concavo-convex. The *dorsal surface* is non-articular and fairly flat. The *palmar surface*, also non-articular, bears the hook.

Attachments.—The pisiform is attached to the front of the triquetrum by a capsular ligament. The other seven bones are closely bound together by ligaments attached (1) to their *palmar* and *dorsal* surfaces, (2) to the rough areas and edges of *contiguous surfaces*, and (3) to the surfaces on the *ulnar and radial borders of the wrist*. The medial and lateral ligaments of the wrist joint also are attached to these surfaces, while the anterior radio-carpal ligament is attached to the palmar surfaces of the *scaphoid* and *lunate bones*, and the posterior ligament to the dorsal surfaces of the *scaphoid, lunate*, and *triquetrum*. The *distal row* of bones is closely bound to the bases of the medial four metacarpal bones by dorsal and palmar carpo-metacarpal ligaments, but the *trapezium* is more loosely attached to the base of the first metacarpal bone by a separate capsular ligament.

One end of the flexor retinaculum is attached to the *pisiform* bone and the *hook* of the hamate, and the other end to the *tubercle of the scaphoid* bone and the palmar surface of the *trapezium*. The extensor retinaculum stretches obliquely from the lower end of the radius to the *triquetrum* and the *pisiform*.

The tendon of the flexor carpi ulnaris is inserted into the front of the *pisiform bone*, leaving the proximal surface of the bone in relation to the fatty, fibrous tissue behind the tendon; but many of the tendinous fibres are continued onwards to the *hook* of the hamate and the base of the *fifth metacarpal* in two distinct strong bands called the piso-hamate and piso-metacarpal ligaments. The abductor digiti minimi arises partly from the *pisiform bone*. The flexor and opponens digiti minimi arise partly from the *hook* of the hamate. The abductor pollicis brevis arises in great part from the *tubercle of the scaphoid* and the *crest* on the *trapezium*; portions of the flexor

PLATE XV

FIG. 1.—RADIOGRAPH OF SHOULDER REGION OF BOY AGED 7. (Dr. J. Duncan White.)

Note that the proximal epiphysis of the Humerus (formed by union of centres for head, greater (and sometimes lesser) tuberosity) fits like a cap on the end of the shaft.

FIG. 2.—RADIOGRAPH OF WRIST OF GIRL AGED 14, TO SHOW THE DISTAL EPIPHYSES OF RADIUS AND ULNA.

PLATE XVI

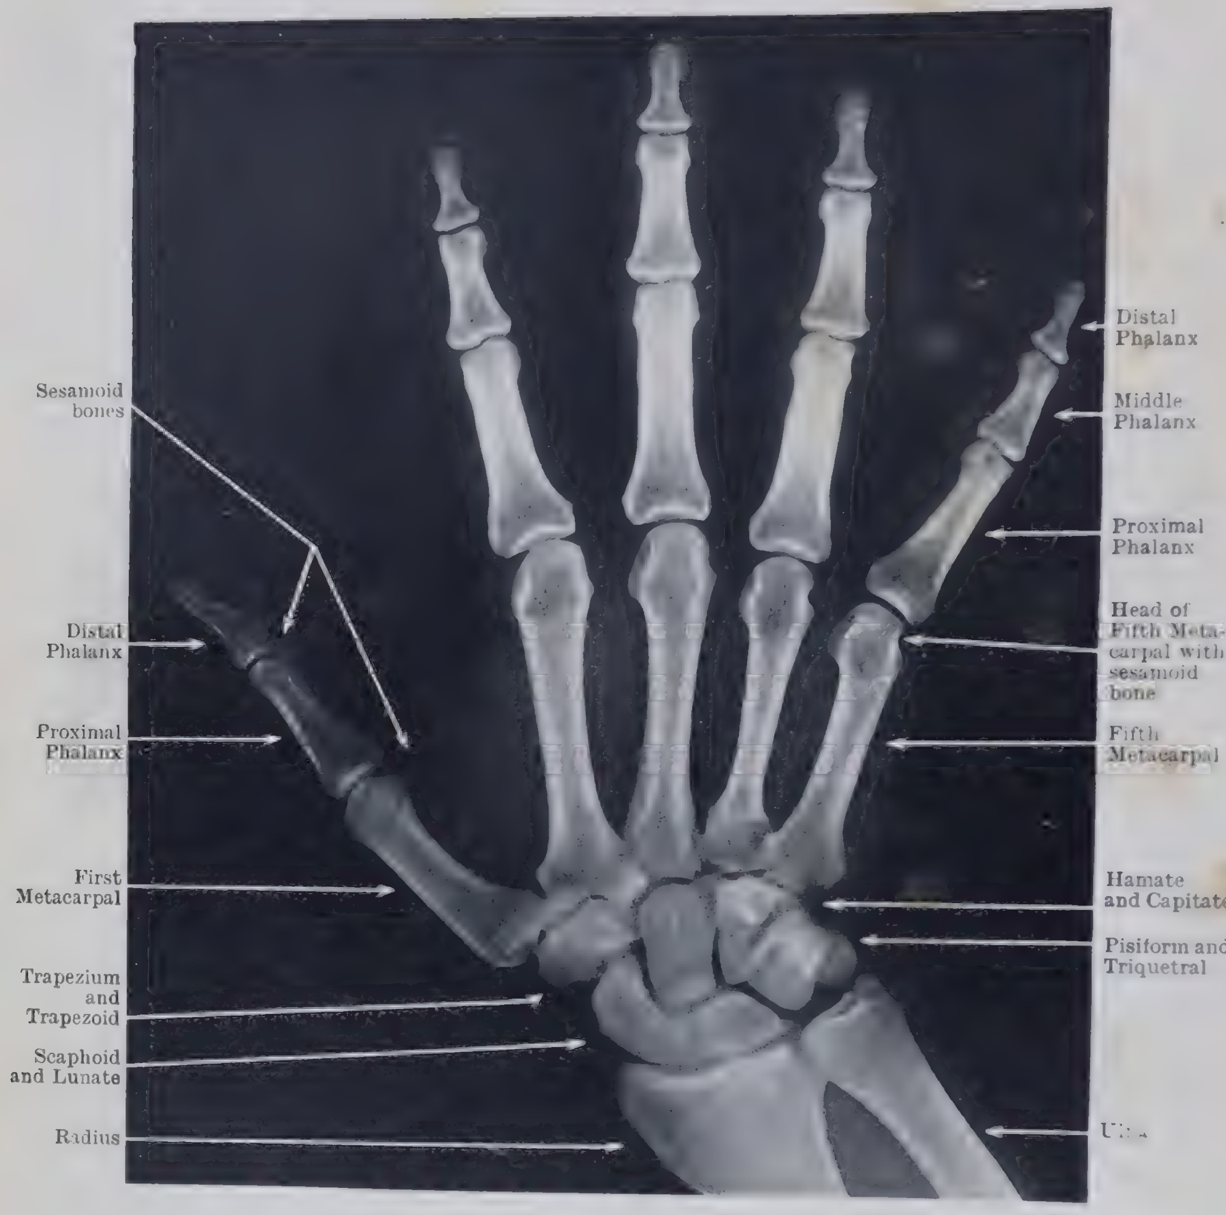

Plate XVI.—Radiograph of Wrist and Hand of Man aged 25.
(Dr. J. Duncan White.)

Compare with Plate XVIII, Fig. 2, p. 273, for the identification and relative position of the carpal bones.

pollicis brevis and opponens pollicis also arise from that crest; and, distal to the crest, the trapezium often receives a slip from the abductor pollicis longus. A portion of the oblique head of the adductor pollicis arises from the palmar surfaces of the *trapezium*, *trapezoid*, and *capitate*.

Metacarpus

The **metacarpus** is the skeleton of the hand proper [μετά (meta) = next after; καρπός (carpos) = wrist]. It consists of five separate bones, called **metacarpal bones**, one corresponding to each digit. They are named by number, *first*, *second*, etc., beginning with the one that corresponds to the thumb. Each of them is a miniature long bone and has a **shaft** and **two ends**. Each is slightly concave lengthwise on the **palmar** surface; the **distal end** is the rounded end and is called the *head*; the **proximal end** is called the *base*. The lateral surface can be distinguished from the medial after the base is examined.

Fig. 240.—First Right Metacarpal Bone.

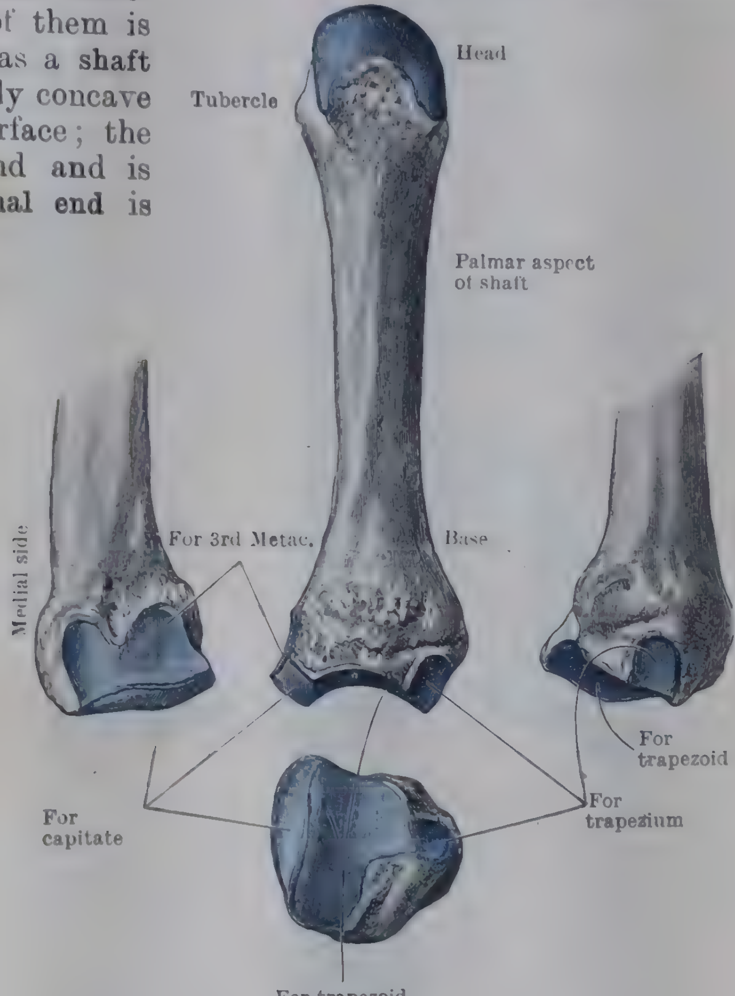

Fig. 241.—Second Right Metacarpal Bone.

The corresponding bones of the **foot** are called *metatarsal bones* and a beginner may mistake the one for the other if they are loose and mixed. Typical metatarsals, however, have tapering shafts terminating in narrow heads, compressed from side to side. The massive first metatarsal has its own special characters (see p. 320). The second to fifth **metacarpals** are between two and three inches long. Each has a rounded head, a more or less cubical base and a shaft which is slightly curved with the concavity on its palmar surface. The *heads* articulate with phalanges of the fingers, but during full flexion they are uncovered distally (except for a thin layer of the soft parts) to form the upper row of knuckles. The *shafts* are largely concealed by the soft parts of the hand but the dorsal surface can be felt in its whole length on the back of the hand. The *dorsal surface* is an elongated nearly flat *triangular area* with its base close to the head of the bone; it is covered to a large extent by an extensor tendon. The *bases* articulate with the carpal bones and with each other, and they also are palpable though covered by tendons. The *styloid process* which can be felt projecting from the lateral side of the base of the third metacarpal should be noted as it may be a separate bone or may be fused with the adjacent capitate

bone or may be broken off. The *first metacarpal* is not unlike a large proximal or middle phalanx (p. 272), its dorsal surface being rounded from side to side, but its base is saddle-shaped and its distal end is large and lacks the groove that gives the head of a phalanx its pulley-shape. In addition, the palmar surface is divided into two areas by a longitudinal ridge never seen on a phalanx.

The **distal ends** or **heads** are familiar as the upper row of knuckles. Each head has pits and tubercles at the *sides* for the attachment of ligaments; the *distal surface* is convex and smooth for articulation with the base of the proximal phalanx when the digit is straightened; the articular surface extends much farther on to the palmar surface than on to the dorsal, for when a digit is *flexed*, as when the hand is closed, the phalanx articulates with the palmar surface of the head. When a finger is *extended* it is in straight line with the hand, and the phalanx articulates with the distal surface of the head. The degree to which the finger can be *dorsiflexed, i.e.*, bent backwards beyond the straight line, varies considerably in different people, and the greater the degree of dorsiflexion possible the more does the articular surface extend on to the back of the head. The edge of the palmar articular surface is notched in the middle, especially in the first and second; the margins of the notch end proximally in prominent tubercles, which may be grooved if sesamoid bones have been present.

The **shaft** is thinnest in the middle. It is slightly curved—being concave forwards to provide room for the structures in the palm. It has a *dorsal surface* which can be felt on the back of the hand, and a *medial* and a *lateral surface*. The *palmar border*, which separates the lateral and medial surfaces, is blunt and broadens out into a surface near each end.

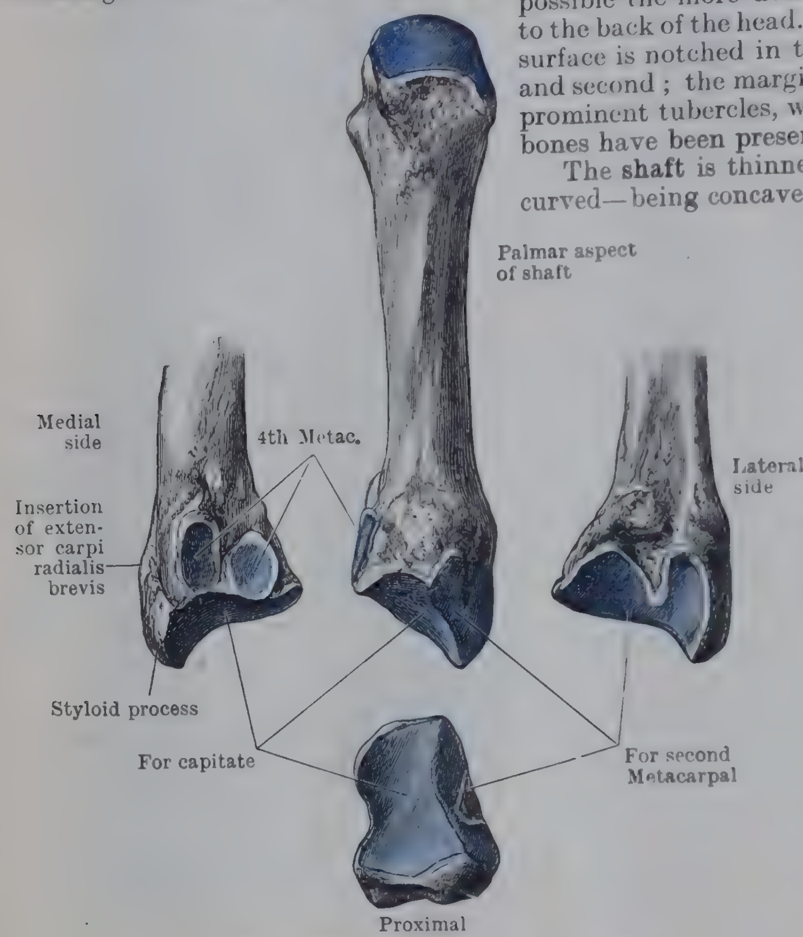

FIG. 242.—THIRD RIGHT METACARPAL BONE.

The **proximal end** or **base** of a metacarpal bone articulates with the carpus by its *proximal surface*, which is therefore smooth; the bases of the medial four articulate with each other by their *sides*, which therefore have articular facets. The readiest means of identifying the individual metacarpal bones is found in the base, and in the medial four the base provides the means of distinguishing the lateral surface from the medial surface.

The **first** metacarpal bone is shorter than the others and is placed farthest forwards; it is set obliquely—diverging from the others, and with its dorsal surface looking laterally rather than backwards. This position and obliquity make it possible to oppose the thumb to the other digits. The bone is slightly compressed from before backwards, and the surfaces of the **shaft** are therefore usually regarded as two—a *dorsal* and a *palmar*; but the palmar surface is divided by a blunt ridge into a radial and an ulnar half, of which the radial or *lateral* half is slightly the larger; the dorsal surface is of equal width from end to end. The **base** has no facets on its *sides*; its *proximal surface* is saddle-shaped and articulates with the distal surface of the trapezium—that surface also being saddle-shaped. The *palmar surface* of the **head** articulates with two sesamoid bones and is grooved for them (p. 274).

The **second** is the longest of the metacarpal bones and its base is the largest. It has a wide groove or *notch* on the *proximal surface* of its **base**, where it articulates with the trapezoid. The edge of the ridge that bounds the notch medially articulates with the capitate bone; the *lateral side* is a pointed tubercle which articulates with the trapezium. The *medial side* of the base bears a facet for articulation with the lateral surface of the base of the third metacarpal.

The **third** metacarpal has a thick, pointed projection, called its **styloid process**, projecting from the junction of the *dorsal* and *lateral* surfaces of the **base**, and by that the **lateral** side can be recognized. The *proximal surface* of the base articulates with the capitate bone; and on the sides there are facets for articulation with the second and fourth metacarpals.

The **fourth** is usually the most slender of the metacarpal bones. It has a cubical **base**. Its *proximal surface* is nearly flat and articulates chiefly with the hamate bone and slightly with the capitate. There are two nearly circular facets on the *lateral surface* of the base for articulation with the third metacarpal, and a single facet on the *medial surface* for articulation with the fifth.

The **fifth** is the shortest metacarpal bone, except the first; the dorsal surface reaches the base, and is wide enough there to exclude the medial surface from the dorsum. Being on the side of the hand, it has a facet on only one side of the **base**, on the *lateral surface*, for articulation with the fourth. There is a tubercle on the *medial surface*. The *proximal surface* is convex from before backwards, slightly concave from side to side, and articulates with the hamate bone.

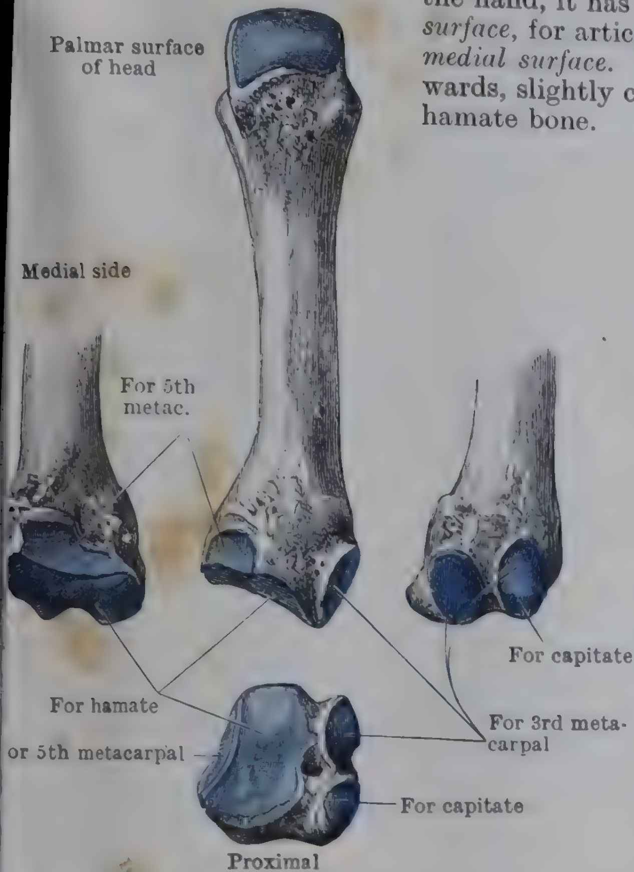

FIG. 243.—FOURTH RIGHT METACARPAL BONE.

FIG. 244.—FIFTH RIGHT METACARPAL BONE.

Attachments.—The **base** of the *first metacarpal* is attached to the trapezium by a capsular ligament. The *other four* are bound to the carpus by carpo-metacarpal ligaments attached to their palmar and dorsal surfaces; they are bound to each other by palmar and dorsal intermetacarpal

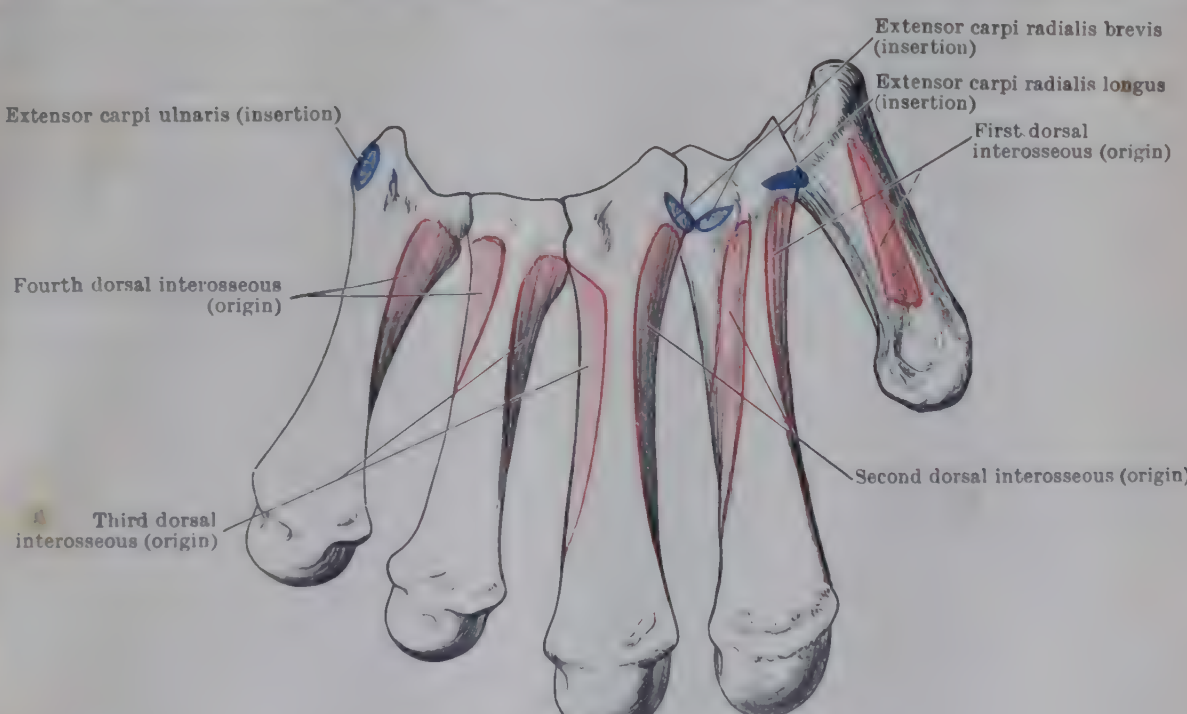

FIG. 245.—BACK OF RIGHT METACARPUS WITH ATTACHMENTS MARKED.

ligaments and by interosseous ligaments attached to the rough parts of their sides; the base of the *fifth* has two additional ligaments—the piso-metacarpal attached to the palmar surface, and the medial ligament of the carpus, which stretches to the tubercle on its medial side. The **head** of each metacarpal is attached to the proximal phalanx by a capsular ligament; this ligament is thickened at the sides to form radial and ulnar collateral ligaments, which are attached to the

sides of the head. It is greatly thickened in front to form the palmar ligament, which is attached loosely to the *palmar surface* immediately above the smooth articular part. On the back, the capsular ligament is fused with the extensor tendon that overlies the joint.

The abductor pollicis longus is inserted into the radial and palmar surfaces of the **base** of the *first*; the flexor carpi radialis into the palmar surface of the base of the *second* and slightly into the base of the *third* also; the extensor carpi radialis longus into the radial part of the back of the base of the *second*; the extensor carpi radialis brevis into the radial part of the base of the *third* at the root of the *styloid process*, and slightly also into the base of the *second*; the extensor carpi ulnaris into the back and ulnar side of the *fifth*. The first palmar interosseous arises from the ulnar side of the base of the *first*; part of the oblique head of the adductor pollicis from the palmar surfaces of the *second*, *third*, and *fourth*.

The opponens pollicis is inserted into the radial half of the palmar surface of the **shaft** of the *first*; the opponens digiti minimi into the ulnar surface of the *fifth*. The four dorsal interosseous muscles lie between the metacarpal bones and are attached to *all* of them; each arises by two heads which spring from the adjacent sides of the two metacarpal bones between which the muscle lies. The medial three palmar interosseous muscles lie in front of the dorsal interosseous; they arise by single heads from the *second*, *fourth*, and *fifth*. The transverse head of the adductor pollicis arises from the palmar border of the *third*.

Phalanges of Fingers

Each **phalanx** is a miniature long bone having a **shaft** and **two ends** [φάλαγξ (phalanx) = a round log or roller]. The **proximal** end is the larger and is called the *base*; the **distal** end is the *head*. The **shaft** is markedly *convex* from side to side on its *dorsal* surface and nearly flat on the *palmar* surface. There is little distinction between the lateral and medial margins of a phalanx.

Fig. 246.—Phalanges of a Finger (Palmar View).

The **proximal** phalanx of a digit is the largest; the proximal surface of its **base** is hollowed out as a single concavity, and its **head** is pulley-shaped. The **head** of the **middle** phalanx also is pulley-shaped, but its **base**, since it articulates with the head of the proximal phalanx, is the reverse of a pulley, having two shallow concavities with a low intervening ridge; that distinguishes the middle phalanx of a large hand from the proximal phalanx of a small hand. The **base** of the **distal** phalanx also is the reverse of a pulley, but it is the smallest phalanx and its **head** is non-articular.

The **thumb** has only *two* phalanges. They are shorter and broader than those of the fingers; the **proximal** phalanx resembles the proximal phalanx of a finger, and the **distal** resembles the distal phalanx of a finger.

The middle finger is the longest; the little finger is the shortest; the other two fingers are nearly equal in length, the ring finger being usually slightly longer than the index. But the relative lengths of the phalanges are such that the finger-tips come into line when the interphalangeal joints are bent.

The phalanges of the toes should not be mistaken for those of the fingers. The proximal phalanx of a toe is about the same length as the middle phalanx of a finger, but its body is much thinner and its base is relatively large. Both of the phalanges of the big toe are so thick, and the middle and distal phalanges of the other toes are so short, that they cannot be mistaken.

The **proximal phalanx** of a finger measures 35-45 mm. in length, and it is slightly curved lengthwise, with the concavity on the palmar surface. The *proximal surface* of its **base** is concave and articulates with the head of the metacarpal; the *sides* of the base are slightly enlarged and give attachment to ligaments. The *dorsal surface* of the **shaft** is markedly convex sideways. The *palmar surface* is nearly flat from side to side and is separated from the dorsum by sharp margins. The **head** articulates with the base of the middle phalanx; the articular surface extends much farther on to the front than on to the back, just as on the head of a metacarpal bone and for the same reason. The *sides* of the head show shallow pits for the attachment of ligaments.

[Facing p. 272

PLATE XVIII

Fig. 1.—Radiograph of Wrist and Hand of Full-Time Fœtus.

Note the absence of centres of ossification for the carpal bones. (Cf. Plate XXVIII, Fig. 1, p. 321). In contrast to Fig. 2, the soft tissues are clearly seen owing to differences in the radiographic technique (see p. 1554).

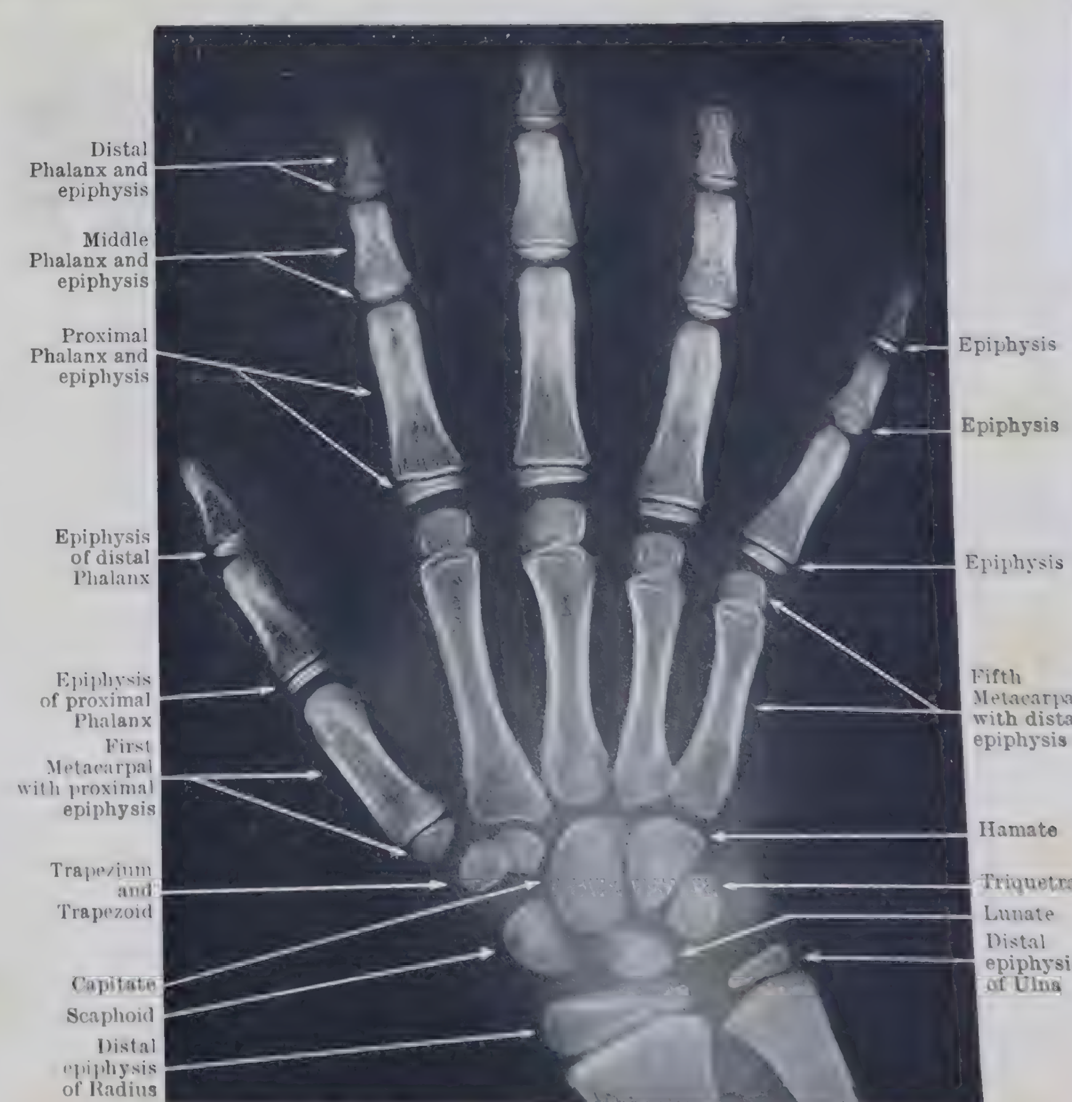

Fig. 2.—Radiograph of Wrist and Hand of Girl aged 7. (Dr. J. Duncan White.)

Note the relative position of the ossifying carpal bones—the pisiform centre has not yet appeared—and compare with Plate XVI, p. 269. Cf. also Plate XXVIII, Fig. 2, p. 321.

The **middle phalanx** is 25-30 mm. Its **shaft** and **head** resemble those of a proximal phalanx, but the **base** differs in the way already mentioned. The **distal phalanx** is very small and is not curved. Its **base** is relatively large and resembles that of a middle phalanx. The **shaft** is short. The **head** is expanded sideways, is non-articular, and is very rough on its palmar surface.

Attachments.—The **base** of the *proximal* phalanx is attached to the metacarpal bone by a capsular ligament, the characters of which are briefly indicated in the account of the metacarpals; the palmar ligament is attached firmly to the palmar surface of the base, and the collateral ligaments to its sides. The *middle* phalanx is attached to the first and the third by similar capsules. Each of the four tendons of the extensor digitorum spreads out on the back of a proximal phalanx to form an *extensor expansion* which is inserted into the back of the base of the middle and distal phalanges of a finger; the tendon of the extensor indicis joins the tendon of the digitorum for the forefinger, and the tendon of the extensor digiti minimi joins that for the little finger; the tendons of the interossei and of the lumbricals are inserted into the extensor tendon of a finger; therefore each *extensor expansion* is made up of several tendons. Each of the four tendons of the flexor digitorum sublimis is inserted into the margins of the **shaft** of a *middle* phalanx. Each of the four tendons of the flexor digitorum profundus is inserted into the palmar surface of the **base** of a *distal* phalanx. The abductor and flexor digiti minimi are inserted into the ulnar side of the **base** of the proximal phalanx of the *little finger*.

The tendons of the long flexors of a digit are held in place along its palmar surface by a fibrous strap, called the fibrous flexor sheath, the edges of which are attached to the margins of the **shaft** of the *proximal* phalanx of the *thumb* and of the *proximal* and *middle* phalanges of the *fingers*, and its distal extremity is attached to the palmar surface of the *distal* phalanx immediately beyond the insertion of the flexor tendon.

Thumb.—The extensor pollicis brevis is inserted into the *dorsal* surface of the **base** of the **proximal phalanx**; the flexor brevis and abductor brevis together into the *radial* side of the base; the first palmar interosseous and transverse head of adductor into the *ulnar* side; oblique head of adductor into both sides. The extensor longus into the *dorsum* of the **base** of the **distal phalanx**; and the flexor longus into the *palmar* surface. The fibrous flexor sheath is attached to the *margins* of the **shaft** of the **proximal phalanx** and the *palmar surface* of the **distal**. Capsular ligaments, like those of the fingers, connect the proximal phalanx with the metacarpal bone and the distal phalanx.

FIG. 247.—RADIOGRAPH OF THE HAND AT BIRTH.

Metacarpus and phalanges well ossified; carpus still cartilaginous. Compare with tarsus at birth, p. 324 and Pl. XXVIII, p. 321.

Ossification of Bones of Hand (Pl. XVIII).—The **carpus** is cartilaginous at birth. Each carpal bone has **one** centre; ossification is completed between 20 and 25.

	Capitate.	Hamate.	Triquetrum.	Lunate.	Scaphoid.	Trapezium.	Trapezoid.	Pisiform.
Centre appears	6 months	6 months	M. 3-4 yr. F. 2-3 yr.	M. 4-5 yr. F. 3-4 yr.	M. 6 yr. F. 4 yr.	M. 6 yr. F. 4-5 yr.	M. 6 yr. F. 4-5 yr.	M. 13-14 yr. F. 9-10 yr.

Metacarpus.—The *primary* centre, one for each metacarpal bone, appears in the ninth week of intra-uterine life. The metacarpal bones are well ossified at birth.

The **first** differs from the other in having the epiphysis at the base instead of at the head, possibly because movement is more free at the carpo-metacarpal joint of the thumb than at the metacarpo-phalangeal joint, while the reverse is the case at the joints of the other metacarpal bones. In rare cases the first has an epiphysis at its head also; and, still more rarely, the second or one of the others has an epiphysis at its base.

Secondary Centre.	Appears at	Epiphysis joins at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For base of first	M. $3\frac{1}{2}$ yr. F. $2\frac{1}{2}$	M. 19 yr. F. 17 yr.	Outside.
For head of others	M. 3 yr. F. 2		Outside.

Phalanges.—The *primary* centre for each appears between the eighth and the twelfth week of intra-uterine life. At birth the phalanges are well formed.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For base	M. 3rd yr. F. 2nd yr.	M. 19 F. 17	Outside.

The **distal phalanges** are the first bones of the hand to ossify, and their primary centres appear near their distal ends instead of in the middle.

In rare cases the proximal phalanx has an epiphysis at its head as well as at its base.

It is possible that "double epiphysis" in metacarpals and phalanges is hereditary.

Structure and Variations of Bones of Hand.—**Carpal bones** have the typical structure of short bones. **Metacarpal bones** and **phalanges** have the structure of long bones. The walls of the medullary cavity are thick compared with the size of the bone; that is especially the case in the dorsal wall in a phalanx. The *nutrient foramen* of a metacarpal is near the palmar margin; it is directed towards the head in the first, and towards the base in the others. There are usually two on each phalanx. They are on the palmar surface and are directed towards the head.

Variation in the number of carpal bones may arise from the fusion of two carpal bones or the division of one; but fusion is caused usually by disease. The hook of the hamate bone may be separate; the **os centrale**, though normally a separate bone in the carpus of most mammals, and represented by a separate cartilage in the earlier months of intra-uterine life, is almost always fused with the scaphoid bone, but sometimes it is a separate ossicle on the back of the carpus between the scaphoid, capitate, and trapezoid. Radiographs sometimes reveal what appear to be small additional nodules in the carpus. The *styloid process* of the third metacarpal bone may have an epiphysial centre and may be a separate bone, or it may be fused with the capitate bone or the trapezium instead of with the metacarpal.

Sometimes a *distal phalanx* is bifurcated. The thumb may have three phalanges. Occasionally a phalanx is very short or is absent or has been absorbed by another phalanx.

Sesamoid Bones

The **sesamoid bones** of the hand are two very small nodules that lie in the tendons of insertion of the flexor pollicis brevis and the adductor pollicis. They are blended with the palmar ligament of the metacarpo-phalangeal joint and play against the palmar surface of the head of the metacarpal bone. Occasionally little nodules are found also in the palmar ligament of the other metacarpo-phalangeal joints and in the interphalangeal joint of the thumb (Pl. XVI, p. 269).

The sesamoid bones of the hand are cartilaginous in childhood; they begin to ossify after 13, and they may have more than one centre for each.

BONES OF THE LOWER LIMB

The parts of the **lower limb** are the hip and buttock, the thigh, the leg, and the foot (Figs. 129, 130, pp. 119 and 120).

The **hip** (*coxa*), above and at the side, and the **buttock** (*natis*), below and behind, make up the **gluteal region**, which extends from the waist and the small of the back down to the level of the horizontal crease that limits the buttock below; the crease is called the *fold of the buttock*; the interval between the buttocks is the *natal cleft* [γλουτός (glutos) = *natis* = buttock]. The lower end of the trunk, between the thighs and between the buttocks, is called the *perineum* [περίνεος (perineos) = the perineum: derivation uncertain].

The skeleton of the hip and buttock of each side is a single bone called the **hip-bone** (os coxæ). It is part of the framework of the trunk also, for the right and left hip-bones, together with the sacrum and the coccyx, form the bony walls of the pelvis; and the hip-bone is sometimes referred to as the *pelvic girdle*. (The sacrum and coccyx are the lowest divisions of the backbone; the pelvis is the lower part of the abdomen or belly, and the perineum is included in the pelvis.)

The **thigh** (*femur*) extends from the gluteal region to the knee. On the lateral side it is continuous with the hip; posteriorly it joins the buttock at the fold of the buttock; on the medial side it joins the perineum, which separates it from the other thigh; anteriorly it joins the anterior wall of the abdomen and reaches a higher level than it does behind; the depression between the front of the thigh and the front of the abdomen is the *groin* or *inguinal region* [*inguen* = groin, from *inquinare* = to stain].

The bone of the thigh is the **femur**. At its upper end the femur articulates with the hip-bone to form the *hip joint*. At the *knee joint* the distal end of the femur

articulates (1) with the tibia or shin-bone, which is the larger of the two bones of the leg, and (2) with the patella or knee-cap—the small bone that lies in the front of the knee joint. The ham is the back of the knee and the lower part of the back of the thigh; and the hollow of the ham is called the *popliteal fossa* [*poples* = the hough; the ham of the knee].

The term **leg** (*crus*) is often applied to the whole free part of the lower limb, but anatomically it is limited to the segment between the knee joint and the ankle joint. The two bones of the leg are called the **tibia** and the **fibula**. They articulate with each other at their upper and lower ends, and the joints so formed are the *tibio-fibular joints*. The tibia articulates with the femur at the *knee joint*, but the fibula does not do so; the tibia and fibula both articulate with one of the bones of the foot, the talus, to form the *ankle joint*.

The **foot** (*pes*) is joined to the leg at the ankle joint, and it is divided into the foot proper and the toes. The **foot proper** is all the region from the point of the heel to the roots of the toes. Its upper surface is called the *dorsal surface* or *dorsum* of the foot; the *sole* is often called the *plantar surface* [*planta* = the sole]. The foot proper is divided into—(1) the *tarsus*, which is the hinder half of the foot proper and corresponds to the carpus or wrist, and (2) the *metatarsus*, which is the half next the toes and corresponds to the metacarpus or hand proper.

The bones of the **tarsus** are seven in number, named collectively the **tarsal bones**, and they articulate with one another, forming *intertarsal joints*.

The bones of the **metatarsus** are called **metatarsal bones**. There are five of them, placed side by side, one corresponding to each toe. They are named by number: **first** metatarsal, **second**, etc., beginning with the one that corresponds to the big toe. The posterior ends of the metatarsal bones articulate (1) with the second row of tarsal bones, forming *tarso-metatarsal joints*, and (2) with one another, side by side, forming *intermetatarsal joints*.

Toes or **Digits**.—The big toe is called the **hallux** [probably from *allex* = thumb or big toe]. The other toes are usually designated by number—**second**, **third**, etc.

The bones of the toes are called **phalanges**. The big toe has two phalanges, named the **proximal** phalanx and the **distal** phalanx. Each of the other toes has three phalanges—**proximal**, **middle**, and **distal**. The distal phalanx is sometimes called the *ungual phalanx*, because the nail (*unguis*) is associated with it. The proximal phalanx of a digit articulates with the distal end of the corresponding metatarsal bone to form a *metatarso-phalangeal joint*; and the middle phalanx articulates with the other two, forming *interphalangeal joints*.

Hip-Bone

The **hip-bone** is large, expanded, and unevenly compressed. On one side of it there is a deep cup or cavity with a broken rim; the cavity is the **acetabulum**, and near it there is a large aperture called the **obturator foramen**.

The hip-bone lies in the side-wall and the anterior wall of the pelvis. In the anterior wall it articulates with its fellow of the opposite side to form the *pubic symphysis*. Posteriorly the hip-bone articulates with the side of the sacrum, which lies in the back-wall of the pelvis between the two hip-bones; and the joint is called the *sacro-iliac joint*.

The hip-bone is made up of three originally distinct bones which in the adult are fused together at the acetabulum. The three bones or parts are named the *ilium*, *ischium*, and *pubis*.

The **ilium** is the largest and broadest of the three parts. It is the uppermost part of the hip-bone; and the bone should be held in the hand so that this broad part is uppermost and the deficient side of the acetabulum looks directly downwards. The **ischium** is the thick, three-sided part below and behind the acetabulum and behind the obturator foramen; from the lower end of the ischium a broad, fairly flat bar of bone, the *ramus of the ischium*, projects forwards; it is the lower boundary of the obturator foramen, and it joins the pubis. The **pubis** is the remaining part of the hip-bone, and completes the boundaries of the obturator

foramen. The pubis has three main parts: (1) an expanded part in front, called the *body* of the pubis; (2) a compressed bar of bone, the *inferior ramus* of the pubis, which extends backwards from the body and fuses with the ramus of the ischium; (3) a thicker bar, the *superior ramus*, which extends from the body to the acetabulum.

The position of parts is roughly as follows: the ilium is the upper part; the ischium is the lower and posterior part; the pubis is the lower, anterior, and

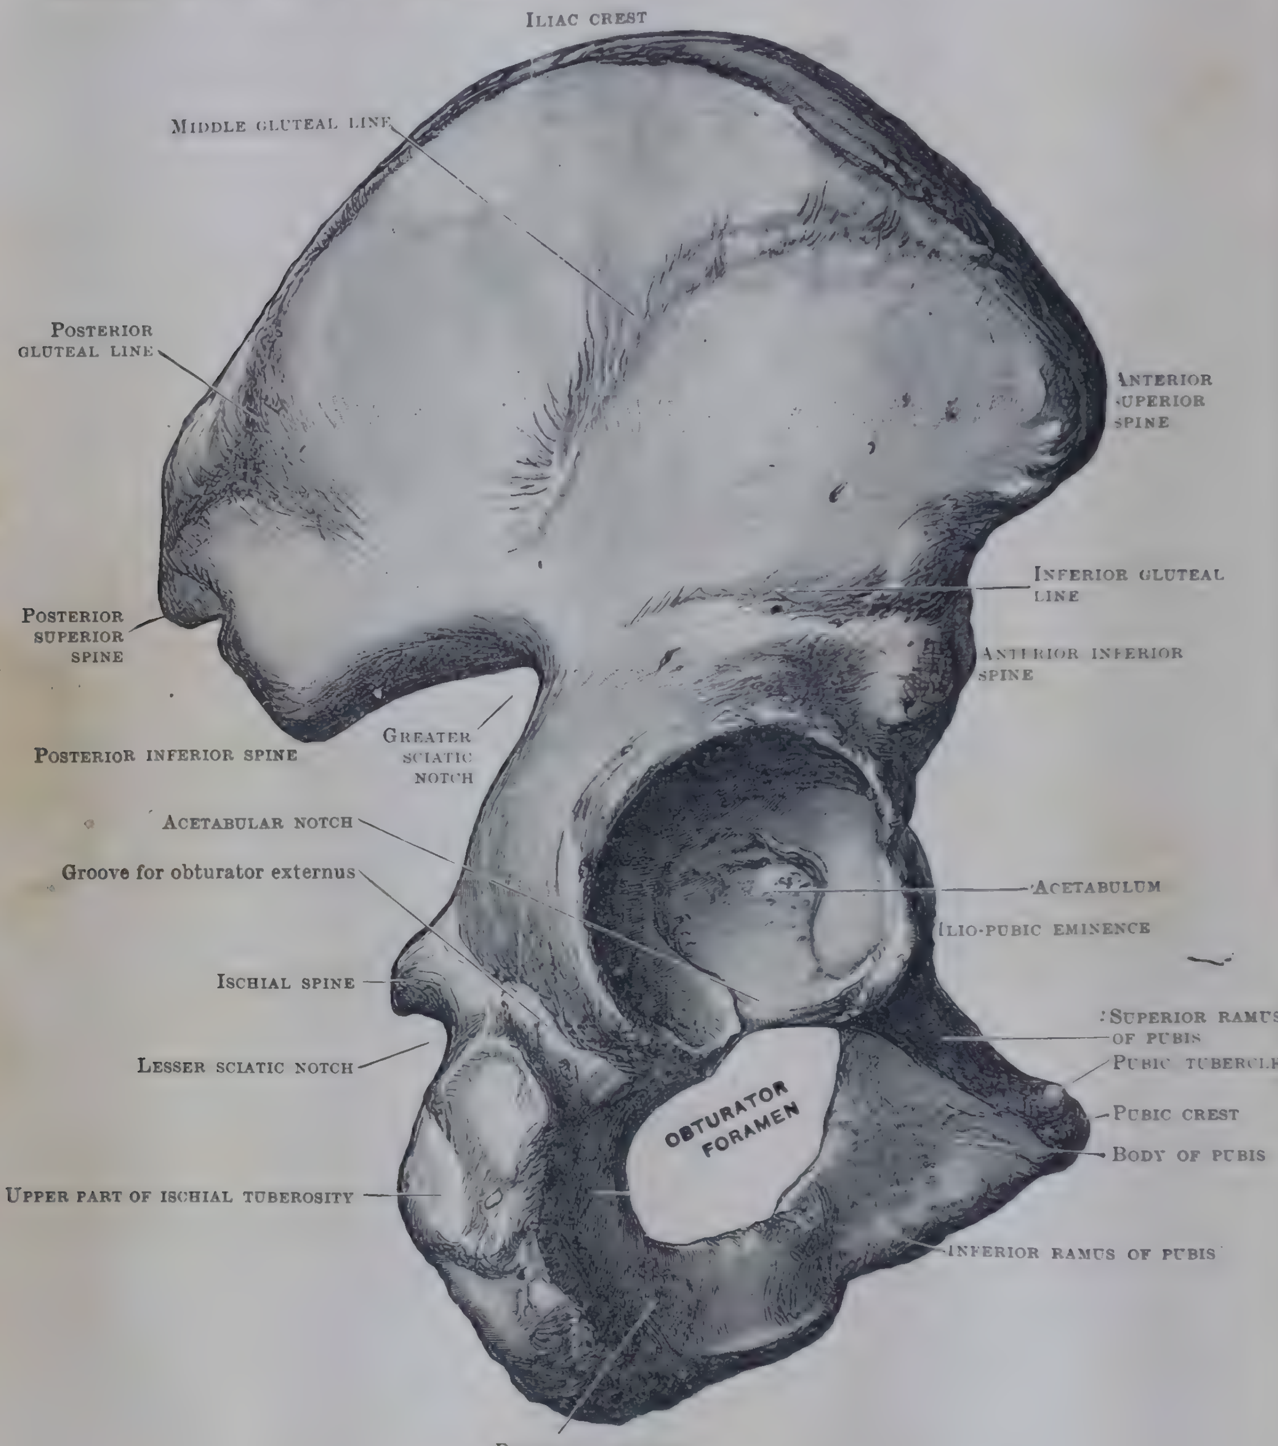

FIG. 248.—RIGHT HIP-BONE SEEN FROM THE LATERAL SIDE.

medial part; the acetabulum is on the lateral surface; the obturator foramen is below and medial to the acetabulum.

The **ilium** (os ilium) is the bone of the flank [*ilia* (plural) = the flank]. It lies below the waist in the uppermost part of the hip. It is large, compressed, and fluted; and it has two ends, three borders, and three surfaces.

The two **ends** are upper and lower. The **lower end** forms the upper part of the acetabulum and is fused there with the ischium and the pubis. The **upper end** is scarcely recognizable as an end, for the ilium in Man is so expanded that the upper end is drawn out like the wide end of an open fan and resembles a border; it is

called the **iliac crest.** The crest is curved like the *italic* letter *f*; the curve of the anterior half is convex in the lateral direction, and the curve of the posterior half is convex in the medial direction. The anterior and posterior ends of the crest are named the **anterior superior iliac spine** and the **posterior superior iliac spine.** The margins of the crest are its *outer* and *inner lips*; the interval between the lips is the *intermediate area.* Two or three inches above and behind the anterior superior spine the crest is thicker than it is elsewhere; the thickening produces a low prominence on the outer lip called the **tubercle of the crest.**

The iliac crest can be felt from end to end in the living body along the lower boundary of the waist. By tracing the crest forwards one can find the anterior superior spine and can almost grip it between finger and thumb when the muscles attached to it are relaxed—as they are when one is sitting. The tubercle of the crest is easily felt, two or three inches behind and above the anterior spine. The posterior superior spine is not distinctly palpable in the living body like the anterior spine; but it can be felt in the floor of a dimple in the skin which can be seen above the buttock about two finger-breadths from the median plane. The spine is at the level of the second spine of the sacrum and the middle of the sacro-iliac joint. The highest point of the crest is about its middle point, one or two inches behind the tubercle of the crest, and it is at the level of the fourth lumbar vertebra. The tubercle of the crest is the highest point that can be seen when the body is examined from the front, and is at the level of the fifth lumbar vertebra.

The **borders** of the ilium are anterior, posterior, and medial.

The **anterior border** begins at the anterior superior spine and extends downwards and backwards to end at the anterior margin of the acetabulum. On the anterior border, a little above the acetabulum, there is a considerable prominence called the **anterior inferior iliac spine.** About an inch medial to the lower end of the anterior border, in front of the acetabulum, the ilio-pubic eminence, a low, diffuse swelling, marks the region where ilium and pubis fuse.

The **posterior border** begins at the posterior superior spine and runs in an undulating manner downwards and forwards to end immediately above the level of the middle of the acetabulum, where it becomes continuous with the posterior border of the ischium. At a point about an inch below the posterior superior spine, the posterior border makes an abrupt bend forwards at the **posterior inferior iliac spine.** The wide notch which is bounded by the part of the posterior border below the inferior spine and by the adjoining part of the posterior border of the ischium is called the **greater sciatic notch.**

The **medial border** is a ridge on the medial aspect of the ilium. It begins at the crest at the point where the posterior half of the crest is most convex, and it ends at the ilio-pubic eminence. Its *lower half* is smooth and blunt; its *upper half* separates a rough region behind from a smooth, concave region in front.

The three **surfaces** of the ilium are the gluteal, the sacro-pelvic, and a third surface moulded into the large concavity of the iliac fossa.

The **iliac fossa** is situated between the anterior and medial borders. Its floor is smooth, and it lodges the iliacus muscle.

The **sacro-pelvic surface** is the region between the posterior and medial borders. Its uppermost and largest part is the iliac tuberosity and is rough for the attachment of muscles and ligaments. The middle part is the **auricular surface**, usually sharply defined and so named because it resembles an ear in shape. It articulates with a corresponding "auricular" surface on the sacrum to form the *sacro-iliac joint*, but though it is an articular surface it is uneven and rather rough. The lobe of the "ear" is the posterior inferior iliac spine. The lowest part of the sacro-pelvic surface is smooth; it is the area between the lower, smooth part of the medial border and the bottom of the greater sciatic notch; it forms part of the side-wall of the true pelvis, which is the basin-like, lower part of the pelvis. By far the thickest, strongest, and oldest part of the ilium is the part in the neighbourhood of the auricular surface; for it is the part that transmits the weight of the trunk to the acetabulum or the ischial tuberosity.

The **gluteal surface** of the ilium is the wide, concavo-convex or undulating surface above the acetabulum, between the anterior and posterior borders; it looks

laterally and backwards, and it is sometimes called the **dorsum ilii**. It is divided into areas by three curved gluteal lines which vary in distinctness with the muscularity of the subject. The *inferior gluteal line* is the least distinct; it begins at the anterior border above the anterior inferior spine and curves backwards, about

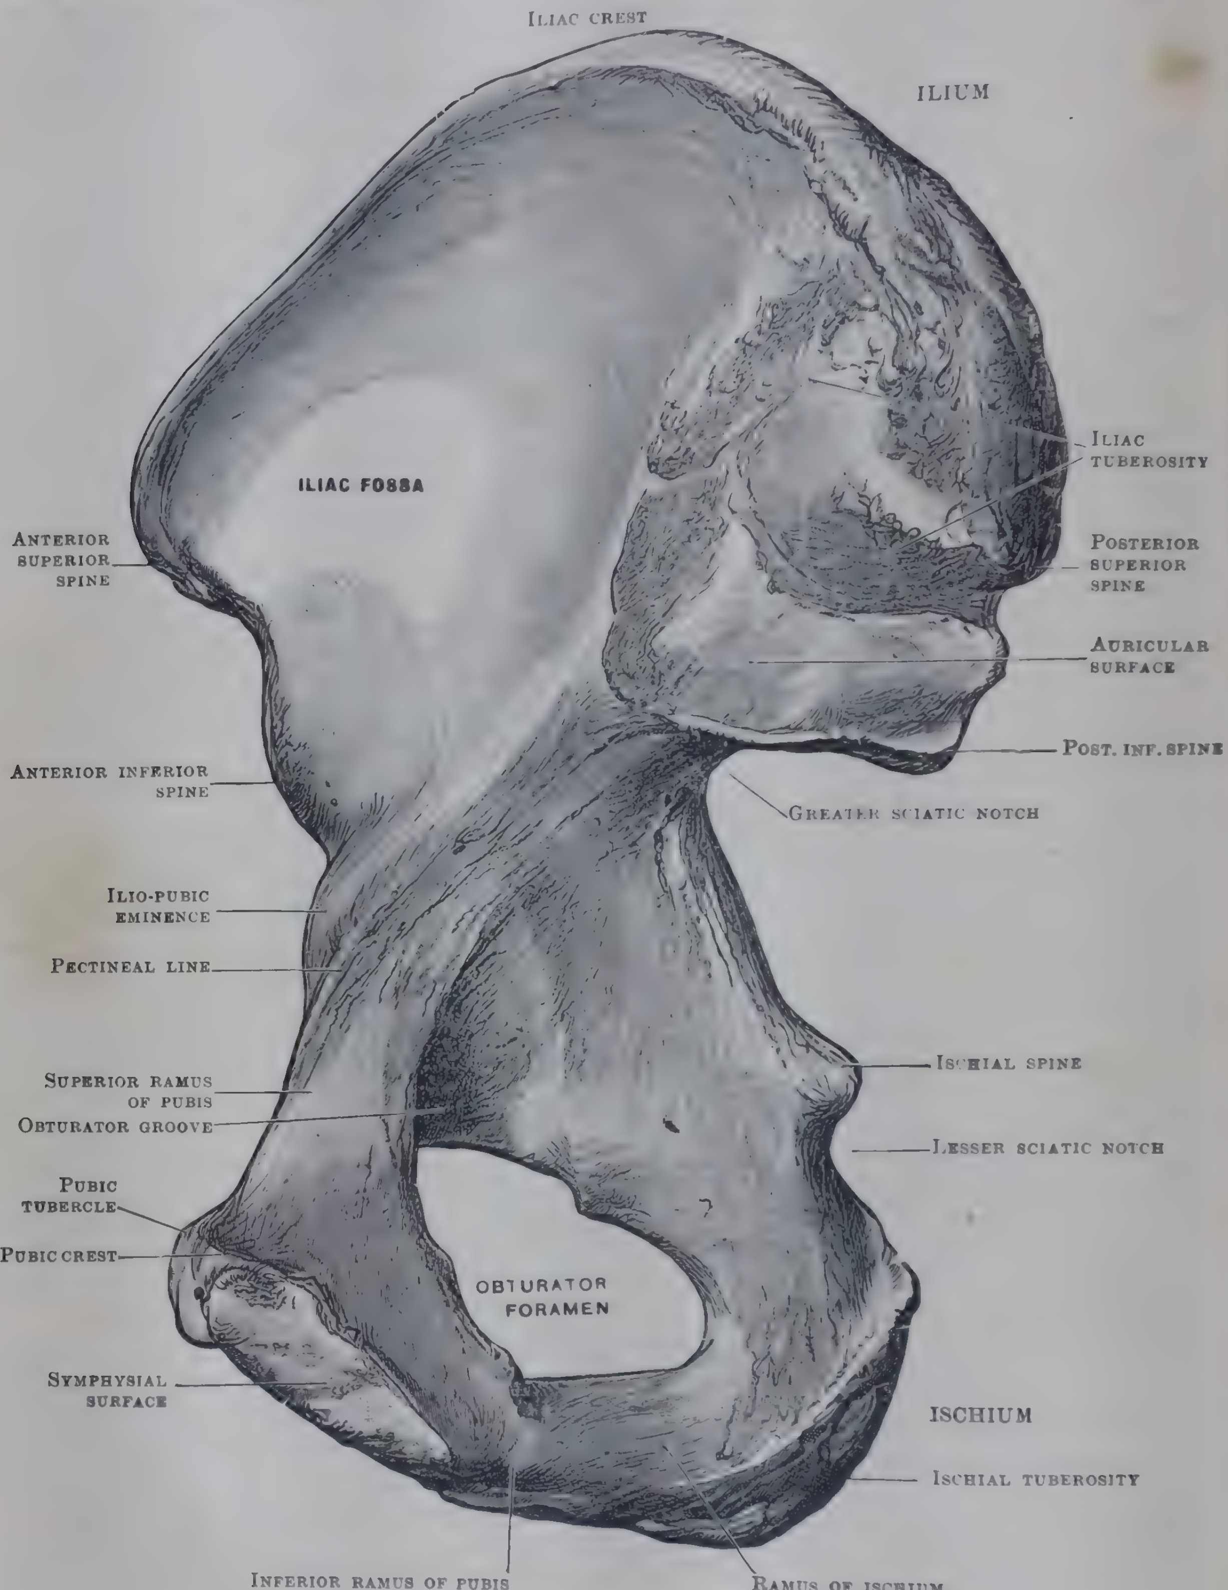

Fig. 249.—Right Hip-Bone seen from the Medial Side.

an inch above the acetabulum, towards the greater sciatic notch. The *middle gluteal* line begins at the crest an inch or more behind the anterior superior spine and arches across the middle of the surface towards the greater sciatic notch. The *posterior gluteal line* begins at the crest two or three inches in front of the posterior superior spine and curves downwards to the greater sciatic notch.

The **ischium** is the thick, prismatic part of the hip-bone below and behind

the acetabulum. In the upright sitting posture the body rests on the two ischia [ἰσχίον (ischion) = buttock. The adjective *ischiadic* has been reduced by time to *sciatic*].

The ischium has two ends, three borders, three surfaces, and a ramus.

The two **ends** are upper and lower. The **upper end** forms part of the acetabulum and is fused with the ilium and the pubis. The **lower end** is free and rough; the rough, lower extremity of the ischium, together with the rough, lower part of its dorsal surface, is the **ischial tuberosity**. The **ramus** of the ischium is the compressed bar of bone that projects from the lower end of the ischium and fuses with the inferior ramus of the pubis below the obturator foramen.

The **borders** of the ischium are anterior, posterior, and lateral. The **anterior border** is one of the boundaries of the obturator foramen. The **posterior border** is continuous with the posterior border of the ilium at the lower part of the greater sciatic notch and extends to the lower end of the ischium; near its upper end a sharp, triangular **ischial spine** juts backwards and medially from it. The spine forms the lowest part of the boundary of the greater sciatic notch and the upper boundary of the **lesser sciatic notch**, which is the smooth, shallow concavity between the ischial spine and tuberosity. The **lateral border** extends from the posterior margin of the acetabulum to the lower end of the ischium; its lower part is the lateral margin of the tuberosity; between the tuberosity and the acetabulum it is almost obliterated by a short, wide, horizontal groove.

The **surfaces** of the ischium are dorsal, pelvic, and femoral. The **dorsal surface** is continuous with the gluteal surface of the ilium across the back of the acetabulum, and its lower part is occupied by the tuberosity. The **pelvic surface** is the large, smooth area between the anterior and posterior borders; it forms part of the side-wall of the cavity of the true pelvis and is continuous superiorly with the sacro-pelvic surface of the ilium. The **femoral surface** is the flat area below the acetabulum; it looks towards the thigh.

The **pubis** lies in the anterior or lower wall of the pelvis; and it can be felt at the lowest part of the front of the abdomen and at the upper end of the thigh where the medial side and the front of the thigh merge into each other. It is named from the region in which it lies. [The *pubis* is the region covered with hair at the lowest part of the front of the abdomen: from *pubes* = the hair that appears at puberty.]

The pubis is divisible into an expanded, compressed *body*, and two bars of bone, the superior and inferior *rami*.

The **body** lies alongside the median plane, articulating with the body of the other pubis. The two are joined by a plate of fibro-cartilage to form the pubic symphysis and the articulating surface is called the *symphysial surface*. It is a narrow oval in outline and is rough and ridged. The other surfaces of the body are named pelvic and femoral. The *pelvic surface* is smooth, and is gently convex antero-posteriorly; it looks *upwards* into the cavity of the pelvis and is closely related to the urinary bladder. The *femoral surface* looks downwards into the thigh and is nearly flat. It is roughened for the attachment of muscles. The anterior border of the body is thick, rough, and bent downwards, and is called the **pubic crest**. The lower, lateral part of the crest swells out into a small prominent **pubic tubercle**. The pubic symphysis, crest, and tubercle can all be felt at the lower part of the abdomen; the tubercle is about an inch from the median plane, and it is often referred to as a landmark. When the hip-bone is held in the position it occupies in the erect body, the pubic tubercle and the anterior superior iliac spine lie in one vertical plane; the hip-bone is therefore in its proper position when it is placed against a wall with only those two points touching, and the defective side of the acetabulum looking straight downwards. The *inguinal ligament* stretches between the pubic tubercle and the anterior superior iliac spine. It can be felt in the living groin as a tense, resisting cord along the floor of the curved groove between those two bony points. Though called a 'ligament' it is the lower edge of the aponeurosis of the external oblique muscle of the abdomen. [An *aponeurosis* is a tendon or sinew in the form of a wide sheet: ἀπό (apo) = from; νεῦρον (neuron) = *nervus* = a sinew (though now both *neuron* and *nervus* always signify *nerve*).]

The **inferior ramus** is the short, compressed bar which begins at the posterior part of the body of the pubis and passes backwards, downwards, and in a lateral direction to meet and fuse with the ramus of the ischium; the position of their junction may be marked by a thickening or a ridge, but it is often difficult to make it out in an adult bone. The two fused rami form the **conjoined rami** of ischium and pubis. This bar of bone has two surfaces and two borders. The *inner surface* is divided lengthwise by a ridge into an upper and a lower part; the upper part looks into the pelvis; the lower part looks into the perineum and gives attachment to the crus of the penis or of the clitoris. The *outer surface* is directed towards the thigh and gives attachment to muscles of the thigh. The *upper border* is the lower boundary of the obturator foramen. The *lower border* can be felt in the boundary between the medial side of the thigh and the anterior part of the perineum. The conjoined rami of the right and left hip-bones constitute the sides of the **pubic arch** which lies below and behind the pubic symphysis.

The **superior ramus**, though named 'ramus', is the true pubic bone. It has two ends, three borders, and three surfaces.

The **ends** are medial and lateral. The **medial end** is wide and compressed, and is described above as the 'body' of the pubis. The **lateral end** is expanded to form part of the acetabulum, and it fuses there with the ilium and the ischium. The *ilio-pubic eminence*, in front of the acetabulum, marks the position of its union with the ilium.

The **borders** are anterior, posterior, and inferior. The *anterior border* is the **pectineal line** [*pecten* = a crest or comb], a sharp edge which begins at or near the pubic tubercle and extends to the upper part of the ilio-pubic eminence. There it is continuous with the lower, smooth part of the medial border of the ilium. The *inferior border* is the **obturator crest**. It is a strong ridge which begins near the pubic tubercle and runs to the acetabulum to end at the anterior part of the gap in its rim. The **posterior border** is seen best from the pelvic side. It is the anterior boundary of the obturator foramen as seen from that aspect.

The **surfaces** of the superior ramus are named pectineal, pelvic, and obturator. The **pectineal surface** is the triangular area between the pectineal line and the obturator crest; the pectineus muscle arises from it. The femoral artery crosses its lateral end, but is separated from the bone by the psoas major muscle. The **pelvic surface** is continuous with the pelvic surface of the body. The **obturator surface** forms the floor of a broad, oblique groove in the anterior boundary of the obturator foramen; through that groove the obturator vessels and nerve pass out of the pelvis into the thigh.

The **acetabulum** is the large, cup-shaped cavity on the lateral side of the hip-bone [*acetabulum* = a vinegar-cup]. It looks not only in a lateral direction, but also forwards and downwards and articulates with the head of the femur to form the *hip joint*. The lower part of its wall is deficient, and the gap is called the **acetabular notch**. The notch is bridged by the *transverse ligament*, a fibrous band which completes the rim. The floor of the acetabulum above the notch shows a large, rough depression called the **acetabular fossa**. The rest of the inside of the cup is smooth and articular. The pubis forms about one-fifth of the acetabulum, the ischium rather more than two-fifths, and the ilium rather less than two-fifths.

The **obturator foramen** is bounded by the ischium and pubis and their rami. It is almost completely closed by the *obturator membrane*, a thin strong membrane from which the foramen gets its name [*obturare* = to close up]. The outer and inner surfaces of the membrane are directed, respectively, towards the thigh and towards the cavity of the pelvis.

Ossification.—From *three* **primary** centres and several secondary centres (Pls. XX, p. 289; XXII, p. 296).

Primary Centre appears for	**Ilium**, above greater sciatic notch, early in 3rd month.	**Ischium**, below acetabulum, in 4th month.	**Pubis**, in superior ramus, in 5th month.

At birth the larger part of each bone is ossified, including a portion of its acetabular end, but a great deal is still cartilage, viz.: upper part of ilium, greater part of acetabulum, lower end of

ischium, medial part of body of pubis, and the conjoined rami. By the tenth year most of the cartilage is ossified, that between the three bones at the *acetabulum* being reduced to a triradiate strip; and the *conjoined rami* are completely ossified and fused together. Secondary centres appear in the acetabulum at twelve and in the other parts at puberty.

Secondary Centre.	Appears at	Epiphysis unites at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
Two or three for triradiate strip	12th year	17	Inside laterally, outside medially.
One or two for iliac crest including superior spines	Puberty	20-25	None.
For anterior inferior spine	Puberty	20-25	Outside.
For ischial tuberosity	Puberty	20-25	None.
For symphysial part of pubis	Puberty	20-25	No joint cavity.

Occasionally small epiphyses, which appear and fuse at the same times as those in the list above, are present for the ends of the pubic crest and for the ischial spine. The portions ossified from the centres in the acetabulum fuse with the nearest bone; *os acetabuli* is the name given to the part that joins the pubic bone.

Structure and Variations.—The hip-bone is composed of spongy bone enclosed in compact bone. In the centre of the iliac fossa and the floor of the acetabulum the bone is so thin that the spongy substance is absent and the bone is translucent or even, on occasion, defective. The compact bone is thick on the gluteal side of the ilium, and more so at and near the medial border. The whole bone is thickest and strongest above the acetabulum, between it and the auricular surface, for through that part the weight of the trunk is transmitted from the sacrum to the femur. The ischium is wider at its upper end than at its lower end and is widest at the ischial spine. The *nutrient foramina* are scattered.

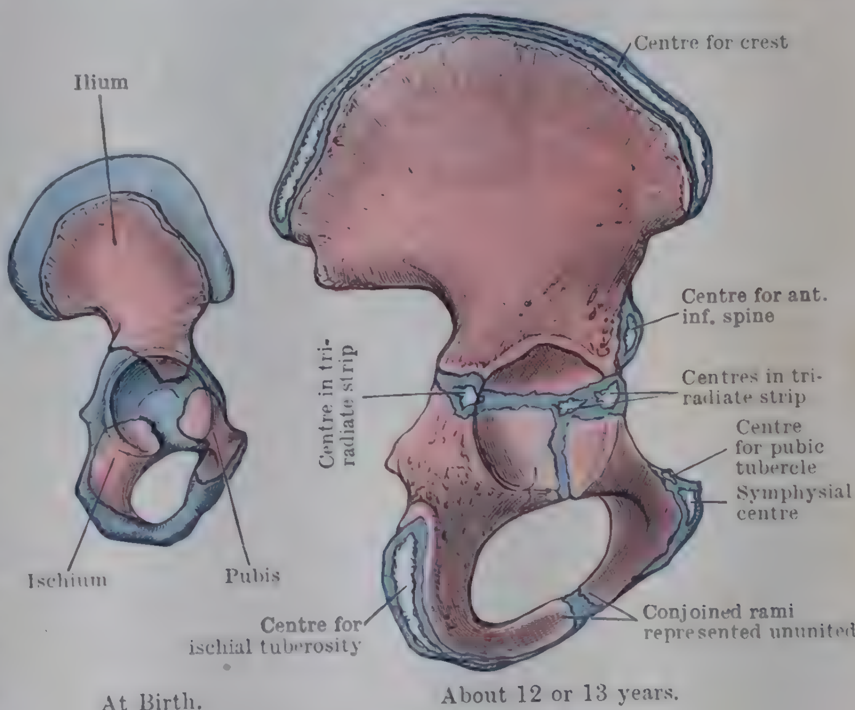

FIG. 250.—OSSIFICATION OF HIP-BONE.

The obturator foramen varies in outline from oval to triangular; and it is relatively wider in women than in men. The **anterior obturator tubercle** is a small spur occasionally present on the posterior border of the superior ramus of the pubis. The **posterior obturator tubercle**, more often present, is a little, rough protuberance on the free edge of the acetabular fossa at or near the junction of the pubis and the ischium. The thickened upper part of the obturator membrane stretches across between the tubercles and converts the groove for the obturator nerve and vessels into the *obturator canal*; in rare cases it is ossified. The *os acetabuli* may remain a separate bone; the acetabular notch may be absent. A separate articular facet may be present above the auricular surface for articulation with a small facet on the back of the sacrum lateral to the first sacral foramen (Derry, 1911*a*). The ischial and pubic rami sometimes fail to unite.

Attachments.—See p. 286.

Pelvis

The **pelvis** is the lower division of the abdomen [*pelvis* = a basin], and its bony framework is also called the pelvis. The bony pelvis is made up of the two hip-bones and the portions of the backbone or vertebral column which are called the

sacrum and the coccyx. The two hip-bones form the sides of the pelvis and its ventral wall, the right and left pubic bones being joined together by the symphysis at the median plane in front; the sacrum and coccyx form its dorsal wall, the sacrum being wedged in between the hip-bones and held in place by strong ligaments, while the coccyx lies below the sacrum between the hip-bones and also is attached to them by ligaments.

The pelvis provides a large surface for the attachment of muscles, especially those which move the lower limb; it contains and protects the urinary bladder, some of the organs of reproduction, and part of the alimentary canal; but the chief use of the bony pelvis is to serve as a firm base for the trunk resting on the thighs. The curved or ring-like construction of the pelvic framework prevents

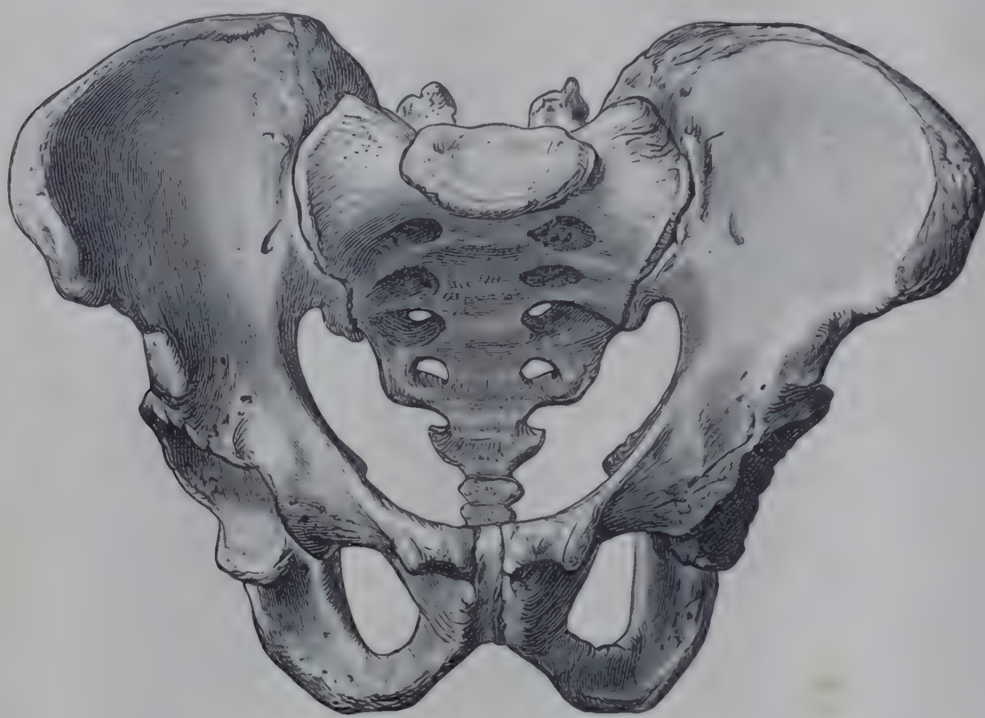

FIG. 251.—MALE PELVIS SEEN FROM IN FRONT.

its collapse under the weight of the body, which is borne at only two points on the framework—where the thigh-bones articulate with the pelvis.

The pelvis does not occupy the position in the body which is suggested by its stance when it is set on a table. Its upper part is tilted forwards, so that when the body is in the erect posture the pubic tubercles and the anterior superior iliac spines are all in one vertical plane, and the tip of the coccyx is on a level with the upper margin of the pubic symphysis. The ventral wall is therefore largely *inferior*, and the dorsal wall is largely *superior*.

A wide interval separates the lower part of the hip-bone from the coccyx and the lower part of the sacrum. The interval is crossed by two fibrous bands, named the *sacro-tuberous* and *sacro-spinous ligaments*, which are preserved in many prepared skeletons. The **sacro-tuberous ligament** is a long, strong band which stretches from the sacrum and coccyx to the ischial tuberosity. The **sacro-spinous ligament** is a shorter, flatter band that stretches across the pelvic surface of the sacro-tuberous ligament from the sacrum and coccyx to the ischial spine. Those two ligaments convert the sciatic notches of the hip-bone into the **greater** and **lesser sciatic foramina**, through which muscles, nerves, and vessels pass between the pelvis and the gluteal region. The dissector of the lower limb encounters both the ligaments and the foramina during the dissection of the gluteal region. (See Figs. 334, 335, pp. 374, 376, in the Section on Joints.)

The **pubic arch** is the arch formed by the conjoined rami of ischium and pubis of the two sides. The apex of the arch is the posterior end of the pubic symphysis. The archway is to a large extent filled in by the *perineal membrane*, a fibrous sheet which is comparable to the obturator membrane.

The bony pelvis as a whole is divisible into two parts—false and true. The **false pelvis** is the upper part; it is the skeleton of the lower part of the abdomen proper, and it bounds the iliac fossæ.

The **true pelvis** is more important. When reference is made to "the pelvis" in the description of muscles, viscera, etc., it is usually the true pelvis only that is meant. The bones that enclose it are the sacrum and coccyx and the lower half of the hip-bone—the pubis, the ischium, and the lower part of the sacro-pelvic surface of the ilium.

The **cavity** of the true pelvis is a short, wide canal or tunnel which is curved in general conformity with the curve of the sacrum and coccyx; in length it measures five or six inches along the sacrum and coccyx, but only one and a half or two inches along the pubic symphysis. The cavity is continuous with that of the abdomen proper at the **inlet** of the pelvis. The inlet looks forwards and slightly upwards, and its boundary is the **brim** of the pelvis. The brim is formed by the

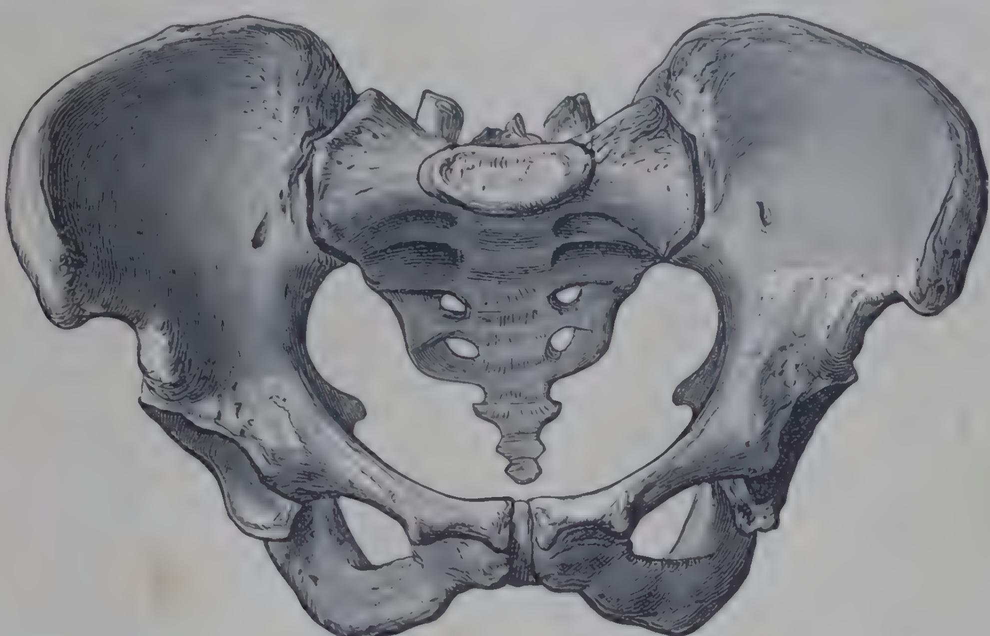

FIG. 252.—FEMALE PELVIS SEEN FROM IN FRONT.

arcuate lines, a pair of curved bony edges divided into sacral, iliac, and pubic parts. The *sacral part* of the arcuate line is the sacral promontory and the lower margin of the ala; the *iliac part* is the lower half of the medial border of the ilium; the *pubic part* is the pectineal line and the pubic crest and symphysis. The **outlet** is *bounded* by: (1) the coccyx in the median plane *behind*; (2) the pubic symphysis in the median plane *in front*; and, *on each side* from behind forwards, (3) the sacro-tuberous ligament, (4) the lower end of the ischium, and (5) the side of the pubic arch. These are also the boundaries of the *perineum*, which is shut off from the cavity of the pelvis by (1) a sheet of muscle, called the sphincter urethræ, that lies in the pubic archway on the upper surface of the perineal membrane; and (2) a pair of thin, curved sheets of muscle, the levatores ani, which are placed farther back—between the ischia.

Planes and Axes of the Pelvis.—The **plane of the inlet** forms an angle of about 60° with the horizontal. The **plane of the outlet** forms an angle of only 10° to 15° with the horizontal, because the symphysis is much shorter than the sacrum and coccyx. The **planes of the cavity** are a plane that passes through the middle of the third sacral vertebra and the middle of the pubic symphysis, and any number of planes set between that plane and those of the inlet and outlet. The **axis of the inlet** is a line drawn at right angles to the centre of its plane; the line, if continued, would pass through the umbilicus and through the tip of the coccyx. The **axis of the outlet** is a line drawn at right angles to the centre of its plane; if continued upwards the line would strike the sacral promontory. The **axis of the pelvis** is a line drawn through the centres of all the planes; it is therefore nearly parallel to the curve of the sacrum and coccyx.

Diameters of the Pelvis.—The **intercristal diameter** is the distance between the outer lips of the two iliac crests where they are farthest apart. The **interspinous diameter** is the distance between the two anterior superior iliac spines. The **external antero-posterior diameter**

is the distance between the first sacral spine and the anterior (upper) margin of the pubic symphysis. Those three diameters are usually slightly greater in a man than in a woman.

The **diameters of the true pelvis** are of more importance.

Diameters of Inlet.—*Antero-posterior* or conjugate: from the middle of the sacral promontory to the anterior (upper) margin of the symphysis. *Transverse*: across the inlet where it is widest. *Oblique*: from one sacro-iliac joint to the ilio-pubic eminence of the other side.

Diameters of Cavity.—*Antero-posterior*: from the centre of the pelvic surface of the middle piece of the sacrum to the middle of the pelvic surface of the pubic symphysis. *Transverse*: across the cavity where it is widest. *Oblique*: from the posterior end of one sacro-iliac joint to the centre of the obturator membrane of the other side.

Diameters of Outlet.—*Antero-posterior*: from the tip of the coccyx to the posterior (lower) margin of the pubic symphysis; it varies in the same pelvis, especially in the female, owing to the mobility of the coccyx. *Transverse*: between the ischial tuberosities. *Oblique*: from the point where the sacro-tuberous and sacro-spinous ligaments cross each other to the junction of the pubic and ischial rami of the other side.

All the diameters of the true pelvis are longer in a woman than in a man. Measurements vary in individuals of the same sex. In the following table the figures are average measurements in millimetres as given by Bryce (1915). The source of his material is not mentioned; and the figures for the female pelvis differ slightly from those given in standard obstetrical text-books.

	Female.			Male.		
Intercristal . . .	279			286		
Interspinous . . .	250			241		
External antero-posterior	180			184		
True Pelvis.	Inlet.	Cavity.	Outlet.	Inlet.	Cavity.	Outlet.
Antero-posterior . .	114	127	108	102	108	85
Transverse . . .	133	127	121	127	121	88
Oblique	127	140	114	121	114	102

More recent measurements have been made by Nicholson (1943, 1945) by stereometric radiography of 640 living subjects. They also are open to the same criticism, but in the opposite sense, in that the patients measured were a selected group, all being primigravidae. The results, however, indicate the pelvic capacity in living subjects at a time when such measurements are important.

Nicholson measured the obstetrical conjugate, which is about 5 mm. less than the anatomical, or true, conjugate, and the transverse diameter of the inlet of the pelvis. Yearly averages over seven years ranged from 118·1 mm. to 121·6 mm. for the *antero-posterior* (conjugate) measurement; but the yearly averages for the previous three years were significantly lower, 114·2 mm. to 115·4 mm., leading to the suggestion that malnutrition (during the 1914–1918 war) might have affected growth and the length of the conjugate. Yearly averages for the *transverse diameter* did not appear to be affected in this way, the figures ranging from 130·2 mm. to 133·3 mm. for the 7-year period and from 130·5 mm. to 133·3 mm. for the preceding years.

The above figures indicate that pelvic measurements not only vary between selected groups but may vary within a more or less homogeneous group as a result of external conditions. Shrinkage of macerated specimens also has to be taken into account when making comparisons.

Sexual Differences.—The pelvis of a woman differs from that of a man in many particulars, because the female pelvis is modified for the function of child-bearing. Distinctive sex-characters are present in the fœtal pelvis—appearing as early as the third or the fourth month of intra-uterine life (Fehling, 1876, quoted by Thompson, 1899). They are less marked in childhood; they become fully developed after puberty. The essential differences between male and female pelves are in the true pelvis. In the female it is absolutely wider in all the diameters; this is especially marked in those of the outlet, and the cavity is therefore less funnel-shaped. But the cavity is shorter. Nearly all the differences in detail are due to the fact that the cavity of the **true pelvis** in the **female** is *roomier*, *less funnel-shaped*, and *shorter*.

When a series of pelves is examined it may be surprisingly difficult to find samples which are female in all respects and pelves are often found which are intermediate in most characters or which are, for example, female in type anteriorly but show male characters posteriorly. It is

advisable to know what types of pelvis to expect and the significance of the features found, especially those which can be detected in the living subject.

In the normal female pelvis the subpubic arch is wide (about 90°) with a rounded apex and can be represented fairly well by the angle between outstretched thumb and forefinger; the depth from the pectineal line to ischial tuberosity averages 90 mm., or $3\frac{1}{2}$ inches. In the male the angle is narrow and pointed and can be represented by the angle between outstretched index and middle finger. (Cf. pls. XIX and XX, p. 288.) The depth is greater, averaging 101 mm., or 4 inches. A wide intertubercular measurement or a shallow pelvis will automatically increase the slope of the ramus and produce a wide subpubic angle. A slender ramus set at the lateral side of a pubic body which has been widened by growth at the pubic symphysis will cause a wide rounded apex to the subpubic angle. The subpubic angle, then, indicates the form of the ischio-pubic part of the pelvis and, in particular, a narrow angle means side-walls converging towards the outlet. A wide angle indicates a female type of fore-pelvis but in practice it is not a reliable indication of the size of the pelvic cavity.

In the female the great sciatic notch is wide (about 90°); in a heavy male pelvis its outline resembles a hairpin bend. Heavy bone and an extensive sacro-iliac articulation tend to depress the posterior part of the upper margin of the notch and the posterior inferior iliac spine, and a sacrum with its lower end tilted in has a similar effect on the margin of the notch. A wide angle then indicates a roomy posterior part of the pelvis, a narrow angle indicates a long narrow pelvis.

In the female the space between the spine of the ischium and the sacrum should accommodate three fingers with ease; in the male the distance is about two finger-breadths indicating a short sacro-spinous ligament and a spine which projects into the cavity. For further information on this subject and its clinical applications see Caldwell & Moloy (1933) and Caldwell, Moloy & D'Esopo (1934; 1935).

Apart from severe pathological conditions, the normal mechanics of the pelvis may produce a further variant if there has been slight abnormal softening of the bone. Since the body-weight tends to thrust the sacrum down into the pelvis, it produces a pull on the posterior sacro-iliac ligament. This in turn pulls the posterior part of the iliac crest medially and, using the ala of the sacrum as a fulcrum, levers out the side wall of the pelvis to put the fore-part of the pelvic wall under tension. If this yields, its curve will straighten out to produce a flat pelvis with a reduced antero-posterior diameter while, at the same time, widening the measurement between the anterior superior spines of the iliac crest and reducing the difference between it and the intertubercular measurement of the crest.

The differences in detail are very numerous. The chief of them are that **in the female**:—The bones are lighter and thinner, and muscular markings are less evident. The *ilium* is less everted and the *iliac fossa* is shallower. The **inlet** is larger and is kidney-shaped rather than heart-shaped; its *plane* forms a wider angle with the horizontal, for the tilt of the pelvis is greater (the anterior superior iliac spines being even farther forward than the pubic tubercles); the *sacral promontory* projects less, and the *pubic tubercles* are wider apart. The **cavity** is less funnel-shaped, is shorter, but is much roomier. The *sacrum* is shorter and wider, and its curve is less uniform—being flatter above and more sharply turned forwards below—and each ala nearly equals the first sacral body in width. The **outlet** is much larger. The *coccyx* is more movable. The *ischial spine* is less inturned. The *obturator foramen* is smaller and may be triangular in outline rather than oval. The *acetabula* are farther apart and are smaller, especially relatively, for the head of the femur is smaller in a woman while the hip-bone is larger, so that the width of the acetabulum is about an inch less than the distance of its anterior border from the symphysis. A pre-auricular sulcus is present immediately in front of the convex margin of the auricular surface of the ilium (Derry, 1911*b*).

Growth of the Pelvis.—At birth, in both sexes, the pelvis is relatively small; the ilium is relatively narrow and is more upright than in the adult; the iliac fossa is shallower and looks more forwards. The pubic arch is more acute, the ischia are closer together, and the cavity is consequently more funnel-shaped. The sacrum is narrow, more upright and less curved, and its promontory projects less. The lower limbs also are relatively small—being only about a quarter of the length of the body. After birth the lower limbs grow much more rapidly than the rest of the body, especially after the first year when the child begins to learn to walk. The whole pelvis keeps pace with the lower limbs; it gives origin to a great number of the muscles that move the limbs, and grows concurrently with them to provide them with adequate attachments. At birth the true pelvis is not big enough to hold the pelvic organs; the greater part of the urinary bladder and, in the female, the uterus and ovaries are in the abdomen proper. By the sixth year the pelvis has grown large enough to contain the greater part of them, but the pelvic organs are not wholly pelvic in position till puberty. The rate and manner of growth are similar in boys and girls till puberty, when the growth is modified to produce the distinctive sex-characters of the adult pelvis. Such growth will take place at the cartilaginous surfaces of the bones where they join in the acetabulum, at the sacro-iliac joint and symphysis pubis and between the pubic and ischial rami. In addition, absorption and accretion on the surfaces will produce modelling of the bone such as is required to maintain its proper strength and shape (Payton, 1935).

Besides mere relative increase of size, there are other changes in the pelvis when the child, learning to walk, straightens out the lower limbs and adopts the erect attitude. The principal changes are: (1) The upper part of the pelvis is tilted forwards so that the sacro-vertebral angle becomes less obtuse. (2) The basal part of the sacrum, now bearing the weight of the trunk

obliquely, sinks more deeply between the two hip-bones, and that further accentuates the sacro-vertebral angle. (3) The sacrum becomes more curved also, for, while the weight of the trunk bends the basal part downwards, the apical part is held down and prevented from tilting up by the sacro-tuberous and sacro-spinous ligaments. (4) At the same time the hip-bone, where it bounds the true pelvis, becomes curved outwards, and thus the true pelvis is widened; for those parts of the two hip-bones, at that time, resemble the limbs of the letter V, the apex being at the symphysis; the sacrum lies between the upper ends of the limbs of the V, and the weight of the trunk is transmitted to them through the sacrum; they are fastened to the sacrum at their upper ends and to each other at the apex, *i.e.*, at the symphysis, and therefore, under the weight of the trunk, have to bend outwards in the middle. (5) The acetabulum (which is relatively shallower at birth than it is at the sixth month of intra-uterine life) becomes deeper to make the hip joint more stable, especially after the third year, when the child begins to run about more actively and to jump. (6) The part of the ilium between the acetabulum and the auricular surface, which transmits the weight of the trunk from sacrum to femur, grows stronger, and in consequence of its growth the iliac part of the arcuate line becomes better defined.

Attachments.—(A) **Of Structures encountered in the Dissection of Lower Limb.**—The lateral end of the inguinal ligament is attached to the **anterior superior iliac spine**. The sartorius arises from that spine and from part of the notch below; the tensor fasciæ latæ from the spine and the adjoining two inches of the outer lip of the **iliac crest**. The lateral part of the fascia lata is attached to the whole length of the outer lip of the crest, its ilio-tibial tract being attached to the **tubercle of the crest**; the ilio-femoral ligament to the lower part of the **anterior inferior spine**; the straight head of the rectus femoris from its upper part; the reflected head from the rough depression on the **gluteal surface** immediately above the acetabulum; the gluteus minimus from the area between the *inferior* and *middle gluteal lines*; the gluteus medius from the area between the *middle* and *posterior gluteal lines*; the gluteus maximus from the upper, rough part of the area behind the *posterior line* and from the *back* of the **sacrum** and *sacro-tuberous ligament*; the iliacus from the floor of the **iliac fossa**; the piriformis from the *pelvic surface* of the middle three pieces of the **sacrum**, and from the upper margin of the **greater sciatic notch** and the sacro-tuberous ligament as the muscle emerges from the pelvis through the *greater sciatic foramen*; the obturator internus from the side-wall of the cavity of the pelvis, viz., the inner surface of the **obturator membrane**, the bone around the obturator foramen, especially the wide, flat area between the foramen and the greater sciatic notch, and the fibres converge on the tendon, which leaves the pelvis through the *lesser sciatic foramen*; the superior gemellus from the **ischial spine** where it forms the upper boundary of the lesser sciatic foramen; the inferior gemellus from the **ischial tuberosity** where it forms the lower boundary. The sacro-spinous ligament stretches from the tip of the *ischial spine* to the side of the last piece of the *sacrum* and first piece of the *coccyx*. The sacro-tuberous ligament covers the dorsal surface of the medial and larger part of the sacro-spinous ligament; its upper end widens out to be attached to the side of the *coccyx* and *sacrum* and to the **posterior superior** and **posterior inferior iliac spine**; its lower end widens out to be attached to the medial margin and lower medial area of the **ischial tuberosity**, and it sends a prolongation, called its *falciform process*, forwards along the inner surface of the *ischial ramus*. The quadratus femoris arises from the *lateral margin* of the **ischial tuberosity**. The surface of the tuberosity is divided by a transverse line into an upper and a lower part, and each of those is divided into a lateral and a medial part. The tendon of the semimembranosus arises from the *upper lateral* area; the tendons of the semitendinosus and the long head of the biceps conjointly from the *upper medial* area; the adductor magnus muscle from the *lower lateral* area and from the lower part of the outer surface of the *conjoined rami*, the sacro-tuberous ligament being attached to the *lower medial* area.

The medial end of the inguinal ligament is attached to the **pubic tubercle**, and its pectineal part to the medial inch of the **pectineal line**. The pectineus muscle arises from the *pectineal line* and *pectineal surface* of the **pubis**; the tendon of the adductor longus from the *femoral surface* of the body of the pubis in the angle between the crest and the symphysis; the gracilis muscle from the margin of the *symphysis* and of the **inferior ramus**; the adductor brevis muscle from a broad strip lateral to the gracilis and below the adductor longus; the obturator externus muscle from the area below and in front of the obturator foramen and from the adjoining half of the **obturator membrane**, and as it winds backwards below the neck of the femur the deeper part of it lies in the wide groove below the acetabulum.

The fascia lata has a continuous attachment to the inguinal ligament, the lower lip of the pubic crest, the margin of the pubic symphysis, the lower margin of the conjoined rami, the medial margin of the ischial tuberosity, the medial margin of the sacro-tuberous ligament, the back of the sacrum and coccyx, and the whole length of the outer lip of the iliac crest.

The transverse ligament bridges across the *acetabular notch* and completes the rim of the acetabulum. The ligament of the head of the femur spreads out to be attached to the transverse ligament and the margins of the **acetabular notch** and **fossa**. A fibro-cartilaginous ring, called the labrum acetabulare, is attached to the *rim* and serves to deepen the cavity of the acetabulum and narrow its mouth. The capsular ligament of the hip joint is attached to the labrum below and in front, to the bony rim above and behind, and to the rough strip above the acetabulum. The thickened parts of the capsule are attached as follows: the ilio-femoral ligament to the lower part of the *anterior inferior iliac spine*; the pubo-femoral ligament to the lateral end of the *obturator crest*; the ischio-femoral ligament to the *ischium* below the acetabulum.

(B) **Of Structures encountered in the Dissection of other Parts.**—The iliacus arises

from the upper and larger part of the floor of the **iliac fossa**. The fascia iliaca and part of the transversalis fascia are continuous with each other at the *inner lip* of the **iliac crest** above the iliac fossa and are loosely attached to that part of the lip. Part of the transversus abdominis arises from the anterior half of the inner lip; part of the quadratus lumborum from the inner lip immediately behind the transversus, above the posterior part of the iliac fossa; a slip of the latissimus

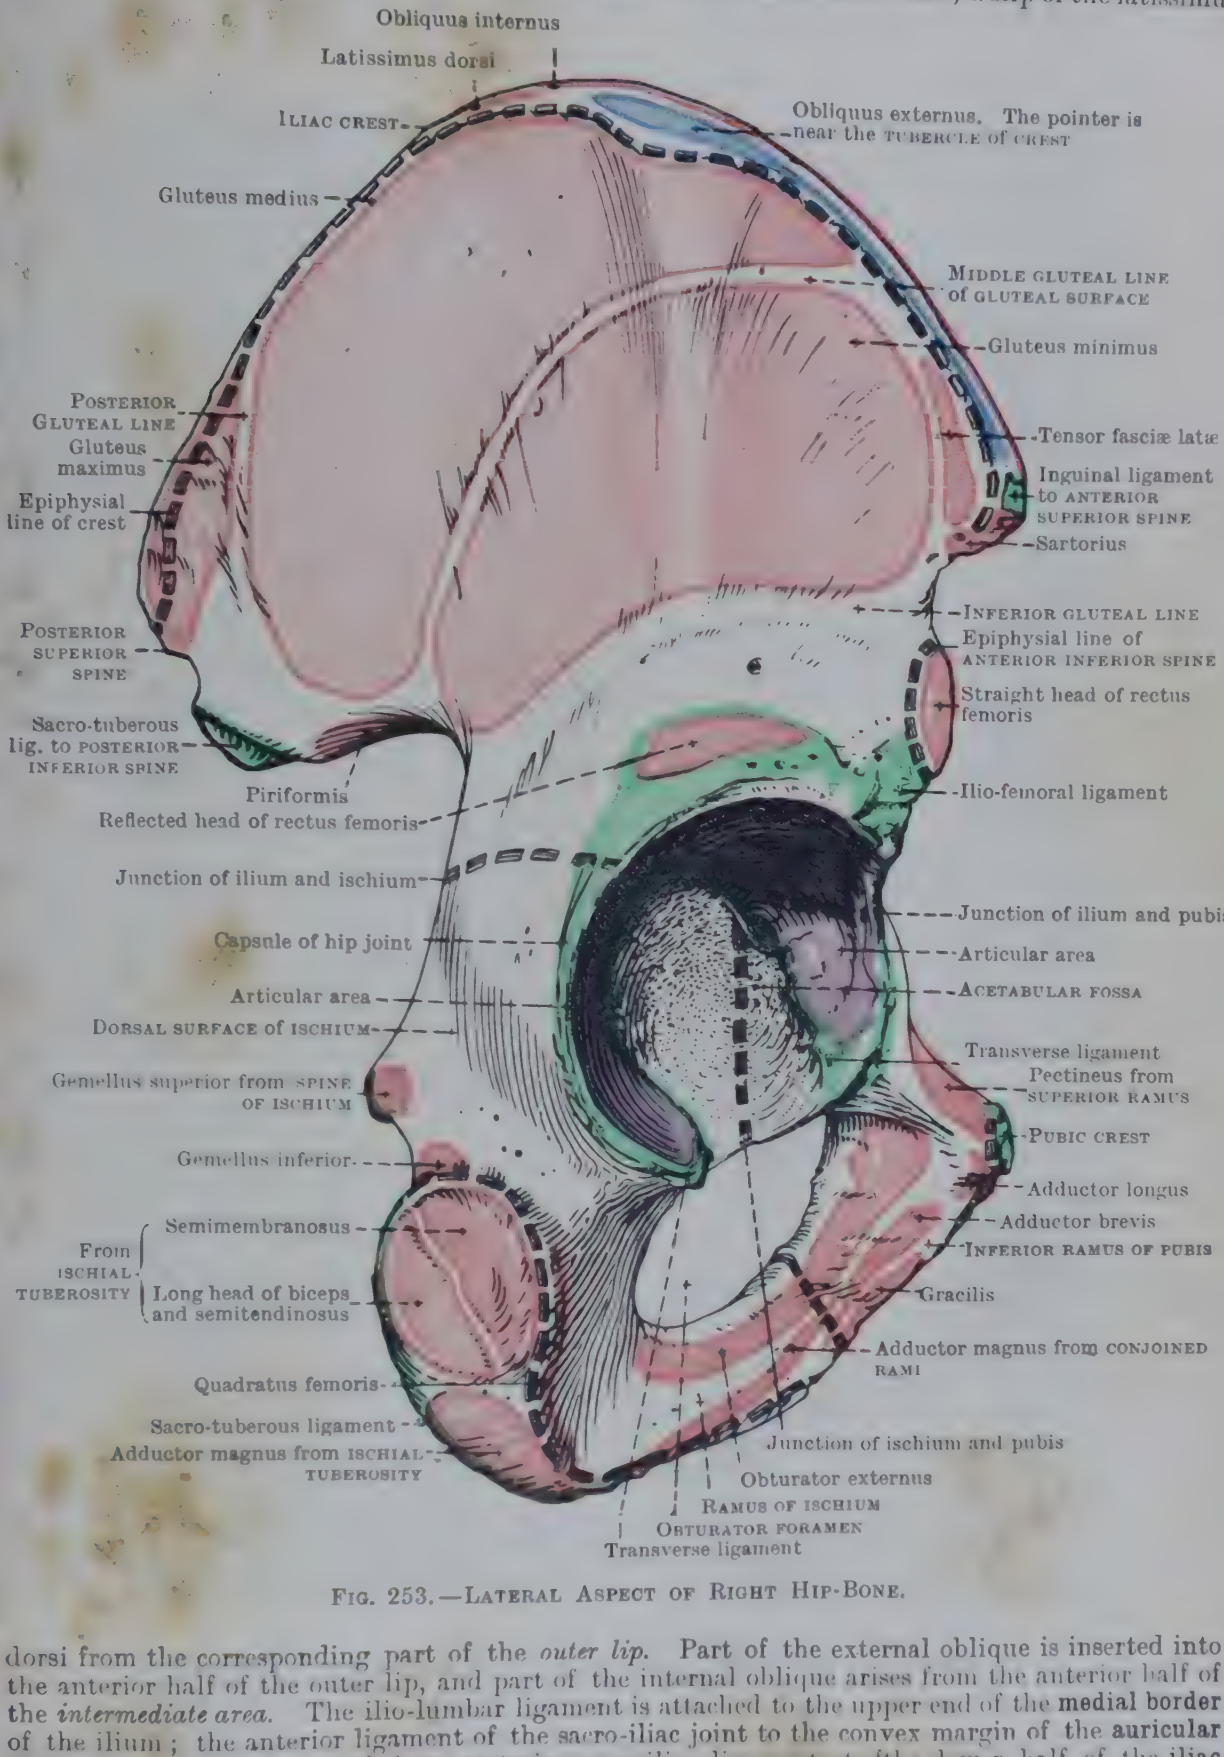

FIG. 253.—LATERAL ASPECT OF RIGHT HIP-BONE.

dorsi from the corresponding part of the *outer lip*. Part of the external oblique is inserted into the anterior half of the outer lip, and part of the internal oblique arises from the anterior half of the *intermediate area*. The ilio-lumbar ligament is attached to the upper end of the **medial border** of the ilium; the anterior ligament of the sacro-iliac joint to the convex margin of the **auricular surface**; the interosseous and short posterior sacro-iliac ligaments to the lower half of the **iliac tuberosity**; the lower part of the sacro-spinalis arises from the upper half, and from the back of the *sacrum*. The long posterior **sacro-iliac ligament** stretches from the **posterior superior iliac spine** to the side of the back of the sacrum half-way down; the sacro-tuberous ligament stretches from both *posterior spines* and from the side of the sacrum and coccyx to the lower part of the **ischial tuberosity** and the *ischial ramus*. The **sacro-spinous ligament** stretches from the tip of the ischial

spine, across the pelvic surface of the sacro-tuberous ligament, to the side of the last piece of the sacrum and the first piece of the coccyx ; the coccygeus muscle lies on the front of the sacro-spinous ligament and has the same attachments—the ligament being merely the degenerated dorsal fibres of the muscle. The piriformis muscle arises from the *pelvic surface* of the second, third, and fourth pieces of the **sacrum**, from the upper margin of the *greater sciatic notch*, and from the sacro-tuberous ligament ; the obturator internus from the side-wall of the pelvic cavity ; the

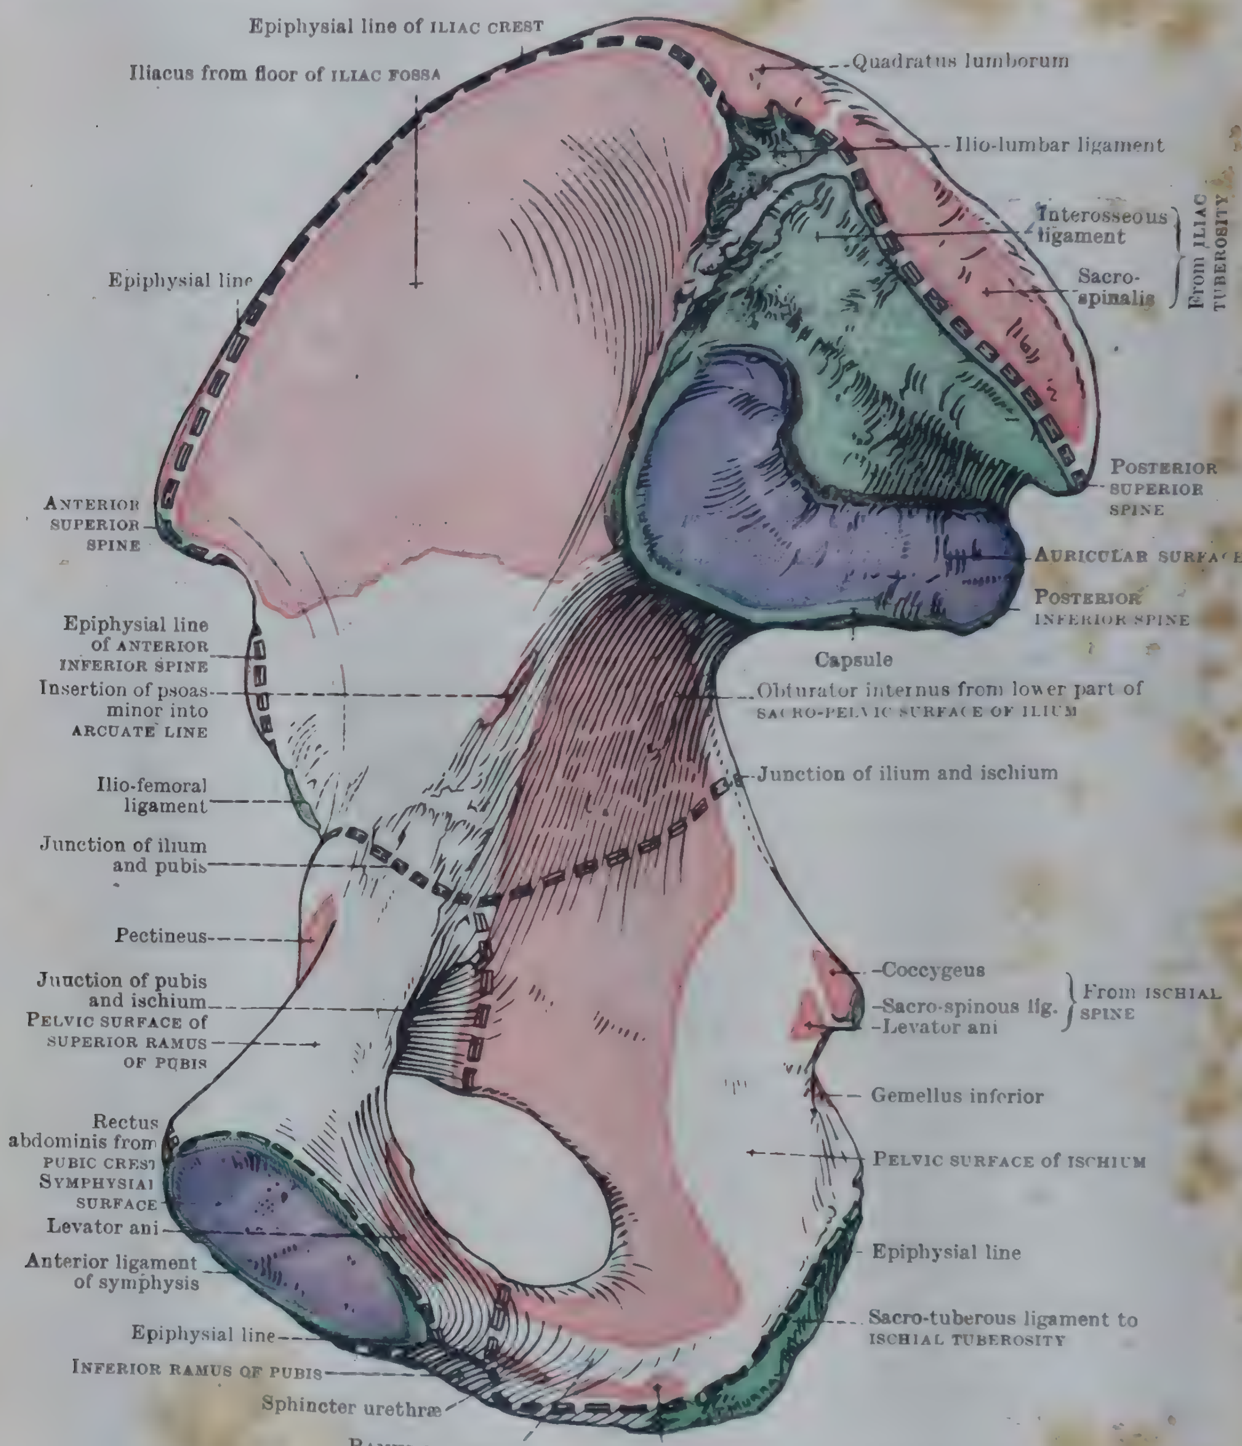

FIG. 254.—MEDIAL ASPECT OF RIGHT HIP-BONE.

posterior fibres of the levator ani from the *ischial spine*, its anterior fibres from the *pelvic surface* of the **body of the pubis** below its middle, and the rest of the muscle from the fascia that covers the obturator internus. The pubo-prostatic ligaments are attached to the pubis above the levator ani.

The cartilage of the pubic symphysis is attached to the **symphysial surface** ; the superior, anterior, posterior, and inferior pubic ligaments to the *margins* of that surface, and the inferior ligament curves backwards on to the inferior pubic ramus.

Part of the fascia transversalis is attached to the upper lip of the **pubic crest** and to the medial half of the **pectineal line**. The rectus abdominis arises from the crest below the fascia and from the anterior pubic ligament ; the pyramidalis from the crest below the rectus. The conjoint tendon is attached to the anterior ligament of the *symphysis* below the rectus, to the

PLATE XIX.—RADIOGRAPH OF DRIED MALE PELVIS (MAN AGED 22).

Compare with Fig. 251, p. 282, and with radiograph of Female Pelvis, Plate XX, noting the differences in proportion of the Pelvis as **a whole and in the form of the Pubic Arch and the Inlet of the True Pelvis.**

PLATE XX

PLATE XX.—RADIOGRAPH OF LIVING FEMALE PELVIS (GIRL AGED 17).
(Dr. J. Duncan White.)

[Facin

crest below the pyramidalis, and to the *pectineal line* below the fascia transversalis; the lower medial part of the external oblique aponeurosis to the lower lip of the pubic crest and to the anterior ligament of the pubis below the conjoint tendon (Fig. 391, p. 460).

The inguinal ligament stretches from the anterior superior iliac spine to the pubic tubercle and, by means of its pectineal part, to the medial inch of the *pectineal line* below the conjoint tendon. One end of the loops of the cremaster muscle is attached to the pubic tubercle behind the inguinal ligament. The tendon of the psoas minor is inserted partly into the arcuate line and iliopubic eminence.

The membranous layer of the superficial fascia of the perineum is attached to the lower margin of the **ischial ramus**. The crus penis or crus clitoridis is attached to the lower half of the *inner surface* of the **conjoined rami**, the lower half usually being grooved lengthwise for the lodgment of the crus. The ischio-cavernosus and superficial transversus perinei arise from the posterior end of the groove. The deep transversus and sphincter urethrae are attached to the ridge between the upper and lower halves of the surface. The same ridge gives attachment to fibrous structures:—(1) the perineal membrane immediately below these muscles; (2) the falciform process of the sacro-tuberous ligament and the prolongation of the inferior pubic ligament immediately above the muscles. Fibres of the obturator internus arise from the upper half of the surface, *i.e.*, the strip between the ridge and the obturator foramen, and the fascia that covers that muscle blends with the falciform process.

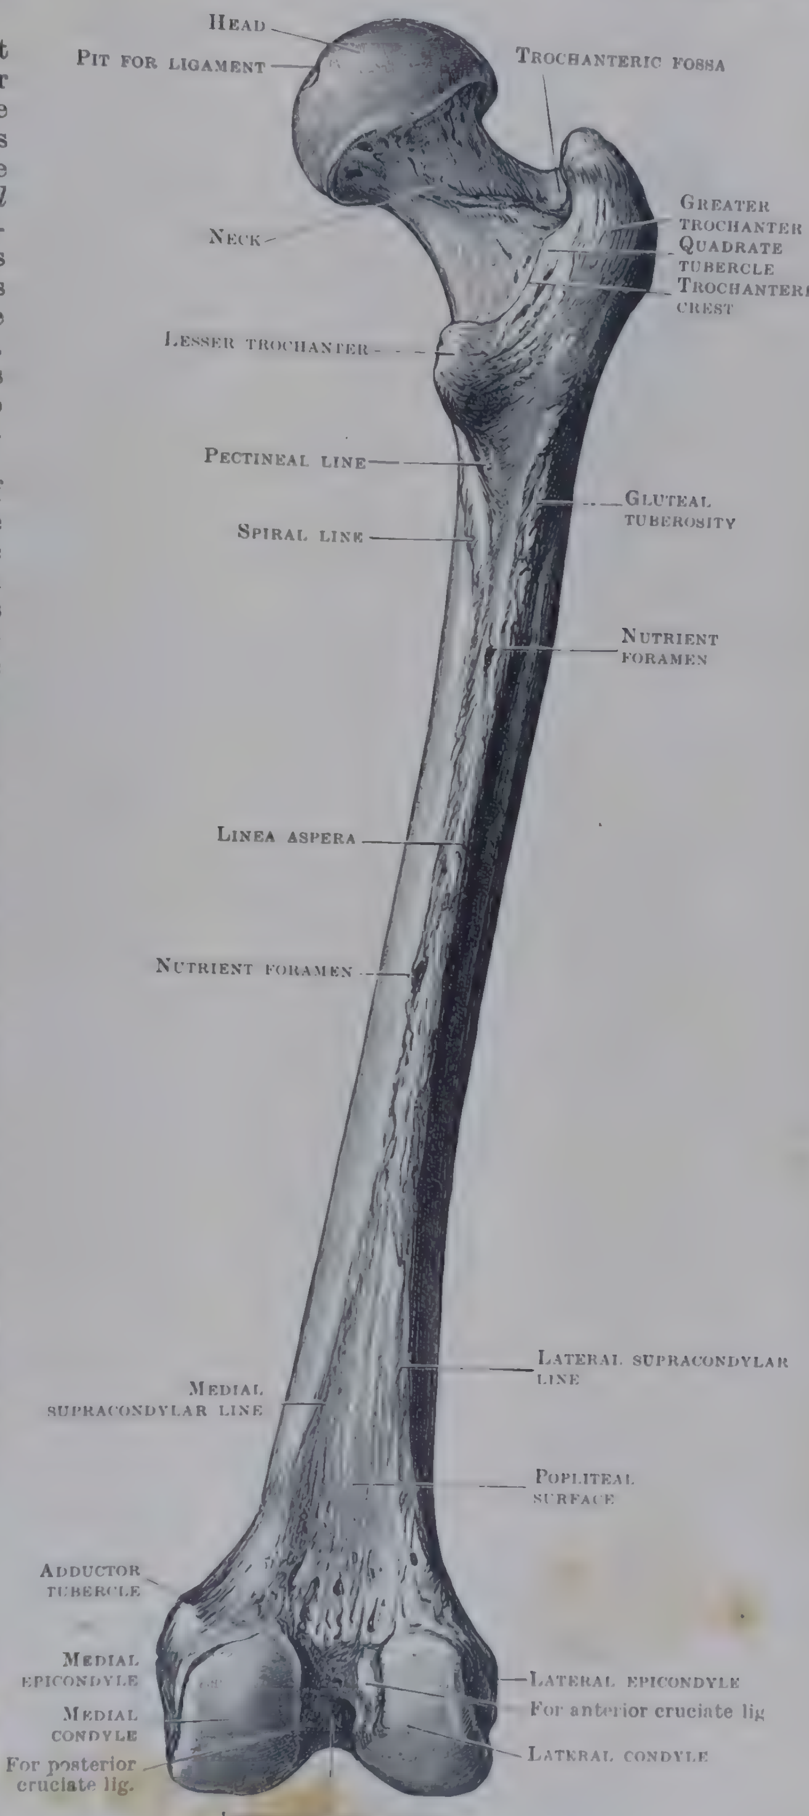

Fig. 255.—Right Femur seen from Behind.

Femur

The **femur** or thigh-bone is the longest and strongest and heaviest bone in the skeleton, and is between a third and a fourth of the length of the body. It has a **shaft** and **two ends**. It is so thickly covered with muscles that, in the living body, it can be palpated only at and near the ends. The beginner should at once proceed to distinguish the upper

end from the lower end, the front of the bone from the back, and the medial side from the lateral side. The larger end of the bone is the **lower end,** and it is partially divided into two, the wide notch between the two parts being on the **posterior** aspect; the globular head at the upper end is on the **medial** side.

Fig. 256.—Right Femur seen from in Front.

The **upper end** includes the head, the neck, the greater trochanter and the lesser trochanter.

The **head** is smooth and is about two-thirds of a sphere. It fits into the acetabulum to form the *hip joint.* On its medial aspect there is a rough, shallow pit for the apex of a triangular fibrous band.

The **neck** is the thick bar that connects the head with the shaft in the region of the trochanters. It is nearly two inches long, is narrowest in the middle and widens towards each end, especially the end which joins the shaft, and the lower border is therefore more oblique than the upper. The neck joins the shaft at an angle and is therefore liable to be broken; but a long neck joined to the shaft at an angle enables the femur to be moved freely and extensively, even though the head is deeply and stably socketed in the side of the pelvis.

The **greater trochanter** is the large, square prominence on the lateral side where the neck joins the shaft; its upper part stands up above the level of the adjacent part of the neck; its root is marked off from the shaft by a more or less horizontal ridge. It is the bone felt in front of

the hollow on the side of the hip, and the body falls on it in a fall sideways; its upper border is at the level of the upper border of the pubic symphysis and the centre of the hip joint. Many of the muscles of the gluteal region are inserted into the greater trochanter [τροχαντήρ (trochantēr) = a runner]. The rough pit on the medial side of the trochanter, where it joins the back of the neck, is the **trochanteric fossa.**

The **lesser trochanter** is the rounded, conical projection on the postero-medial aspect of the bone where the lower part of the neck joins the shaft.

The ridge that connects the lesser trochanter with the back of the greater trochanter is the **trochanteric crest.** The low, rounded swelling on or alongside the crest, on the back of the trochanter major, is called the **quadrate tubercle** because part of the quadratus femoris muscle is inserted into it. The **trochanteric line** is the rough, broad line which extends from the upper part of the front of the greater trochanter towards the lesser trochanter and marks the union of the front of the neck with the front of the shaft; it does not reach the lesser trochanter but becomes continuous with a faint *spiral line*, which winds to the back of the bone below the lesser trochanter.

The **lower end** of the femur is made up of two large masses called *condyles*, separated posteriorly by a wide, deep interval called the *intercondylar notch.*

Anteriorly the **condyles** are nearly in line with the front of the shaft, but they bulge backwards considerably beyond the shaft. The anterior, lower, and posterior surfaces of each condyle are confluent, smooth, and articular. The *anterior parts* of the two are joined together, forming a wide surface for articulation with the patella. This **patellar surface** is deeply concave from side to side and slightly convex from above downwards; its lateral part is more prominent than the medial and extends farther up, and the upper margin of the surface is therefore sloping. The tibia articulates with the *lower surfaces* when the knee is extended, and with the

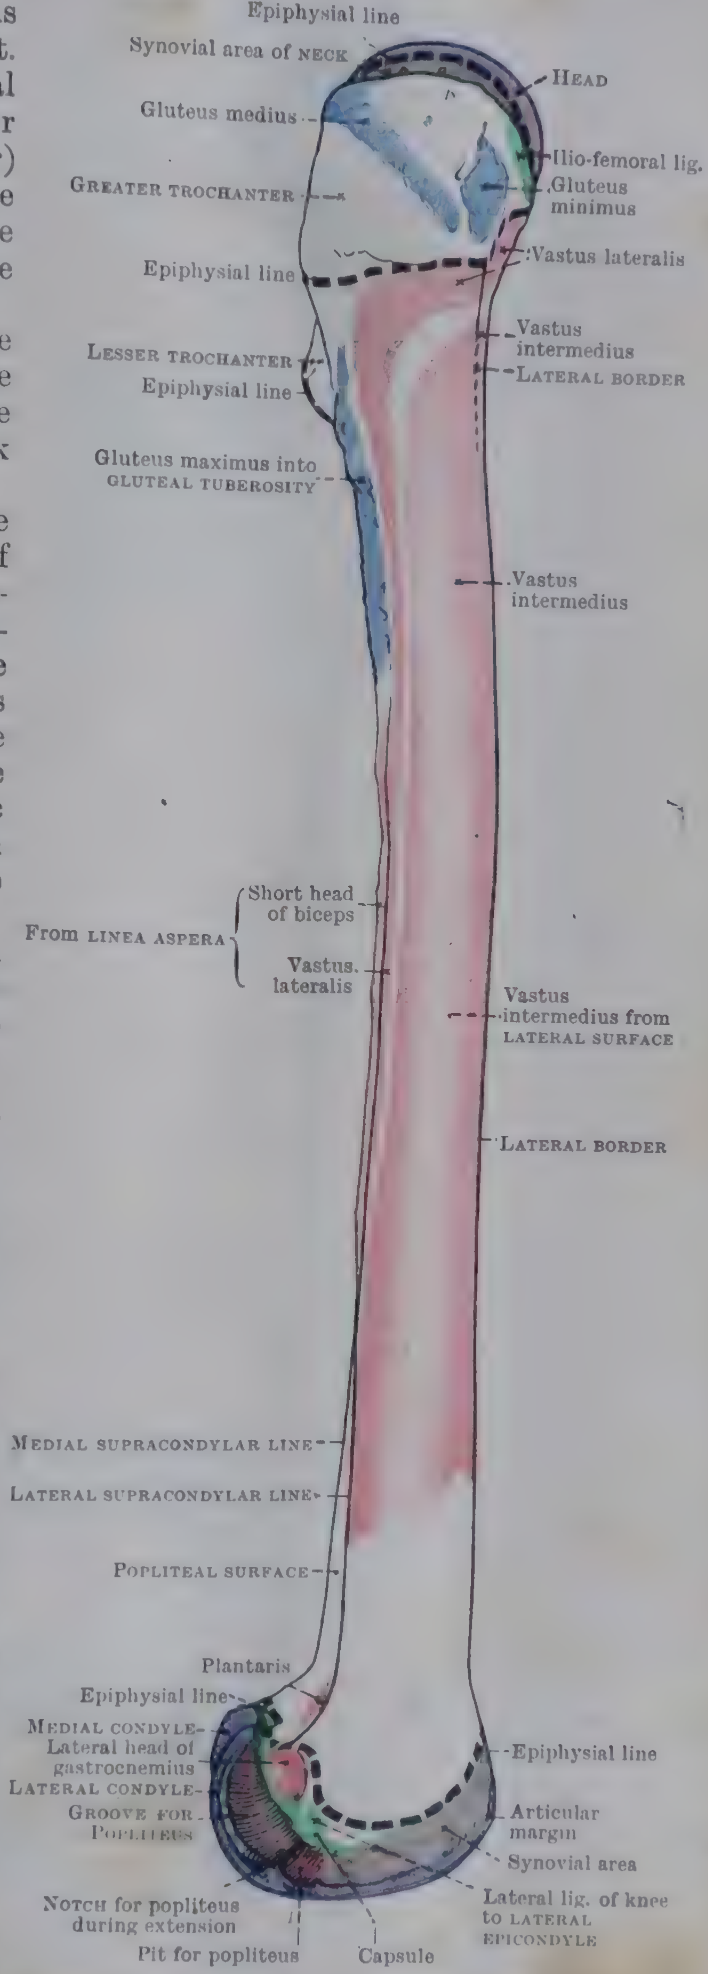

FIG. 257.—LATERAL ASPECT OF RIGHT FEMUR.

posterior surfaces when the knee is flexed. The surfaces that form the sides of the intercondylar notch are rough for the attachment of the cruciate ligaments, which lie between the condyles and hold the femur and tibia together.

On the *lateral surface* of the **lateral condyle** there is a prominence, called the *lateral epicondyle* —much nearer the back of the bone than the front. Above the epicondyle there is a pit or impression for the origin of the lateral head of the gastrocnemius muscle which forms the superficial part of the fleshy mass of the calf. Below the epicondyle there is a pit for the origin of the tendon of the popliteus muscle; a groove, in which the tendon lies when the knee is acutely flexed, runs upwards and backwards from the pit close alongside the articular margin.

The **medial condyle** stands farther away from the shaft than the lateral condyle does. Its medial surface is rough and convex and its most prominent part is the *medial epicondyle*. On the uppermost part of the condyle there is a small, sharp prominence, called the **adductor tubercle** because the tendon of the adductor magnus is inserted into it.

The condyles can be felt as large prominences at the sides of the knee; the adductor tubercle can be felt at the uppermost part of the medial condyle, and is often used as a landmark; if the knee is bent to a right angle, the tendon of the adductor magnus can usually be felt as it descends to the tubercle (but it is not the only tendon that can be felt at the medial side of the knee). When the knee is flexed, the patellar surface of the femur can be felt (or, at any rate, its lateral and medial margins), for the patella is drawn off it when the knee is bent; and a portion of the distal surface of each condyle can be felt at the side of the *ligamentum patellæ*—which is the thick, broad band felt between the patella and the tibia.

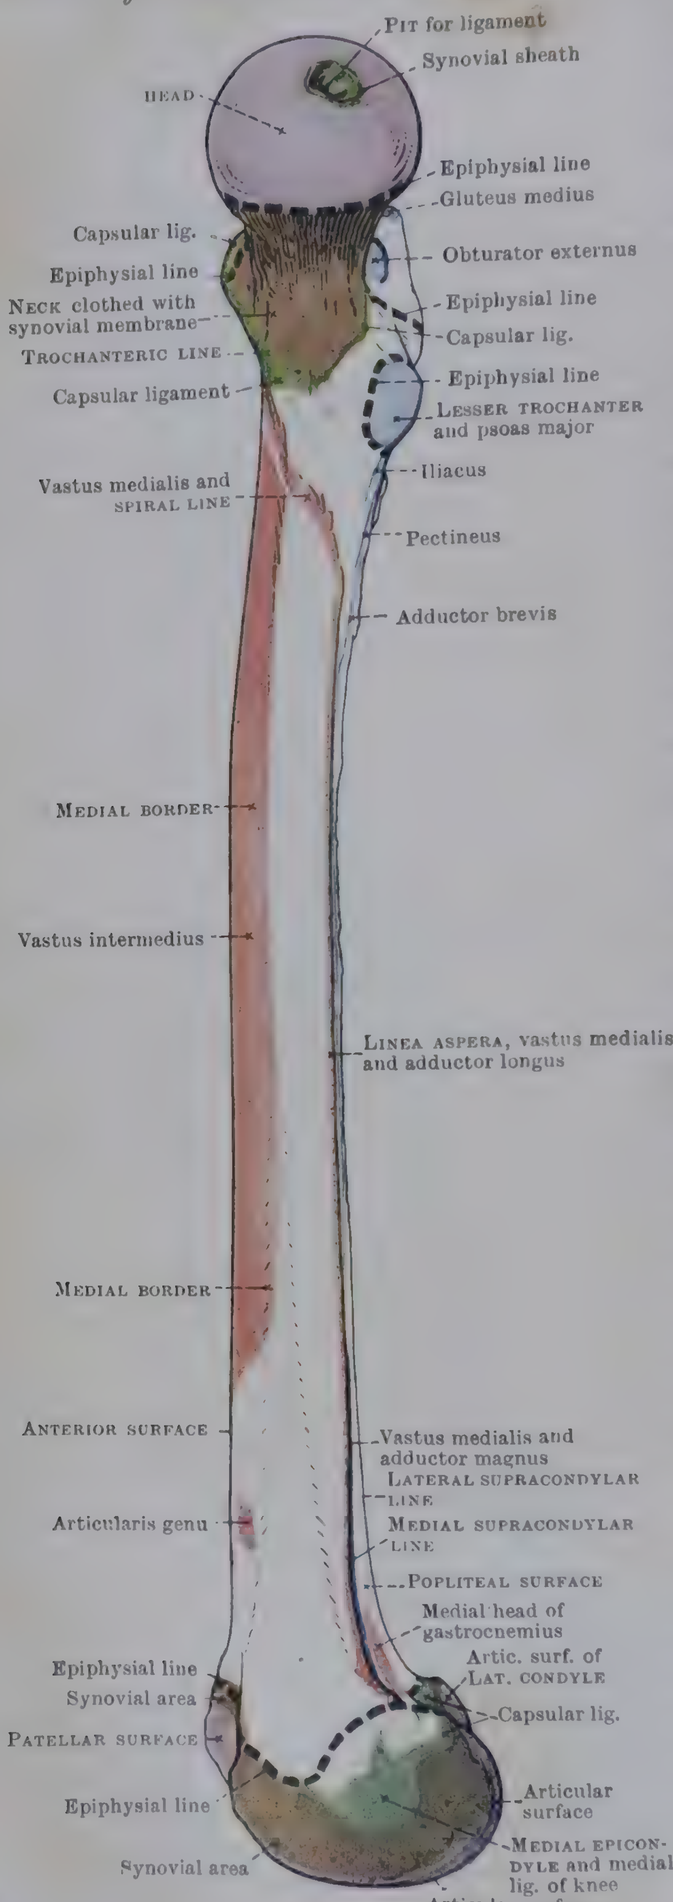

Fig. 258.—Medial Aspect of Right Femur.

The **shaft** is thinnest in its middle third and widens sideways towards each end, especially the lower end.

The **middle third** has three surfaces and three borders. The *surfaces* are anterior, medial, and lateral; the *borders* are posterior, lateral, and medial.

The *lateral* and *medial borders* are blunt and ill-defined, so that the *anterior surface* is not sharply marked off from the *lateral* and *medial surfaces*; but the *posterior border*, or linea aspera, which separates the medial surface from the lateral surface, is well-defined.

The **linea aspera** is the rough ridge on the back of the femur, limited to the middle

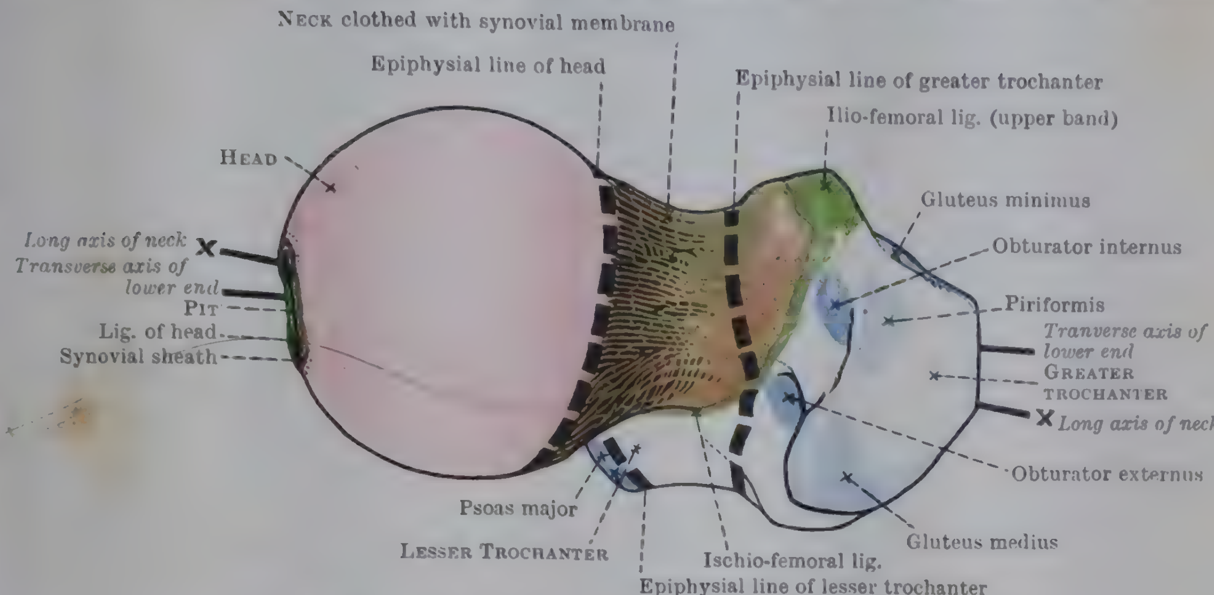

FIG. 259.—UPPER ASPECT OF UPPER END OF RIGHT FEMUR.

third of the bone. Its margins are called its *lips—lateral* and *medial*; the lateral lip is the sharper and better defined of the two. At the upper and lower ends of the linea aspera the lips diverge from each other and become continuous with ridges, bearing different names, on the upper and lower thirds of the femur.

At the **upper third** the *medial* lip becomes continuous with the **spiral line**, which winds obliquely round the medial side of the femur on to the front of the bone and becomes continuous with the trochanteric line. The *lateral* lip becomes continuous with a long, broad, rough mark, the **gluteal tuberosity**, which is situated on the back

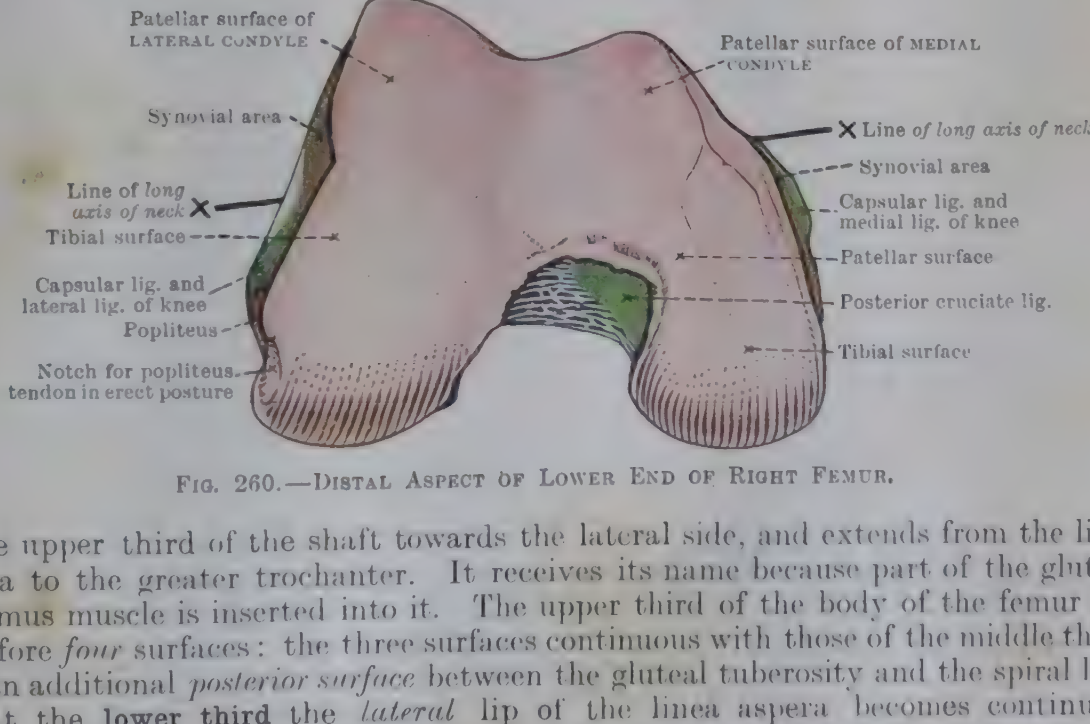

FIG. 260.—DISTAL ASPECT OF LOWER END OF RIGHT FEMUR.

of the upper third of the shaft towards the lateral side, and extends from the linea aspera to the greater trochanter. It receives its name because part of the gluteus maximus muscle is inserted into it. The upper third of the body of the femur has therefore *four* surfaces: the three surfaces continuous with those of the middle third, and an additional *posterior surface* between the gluteal tuberosity and the spiral line.

At the **lower third** the *lateral* lip of the linea aspera becomes continuous with the **lateral supracondylar line**, which extends as a well-defined line to the lateral condyle. The *medial* lip becomes continuous with the **medial supracondylar line**, which extends to the adductor tubercle and serves as a guide to it.

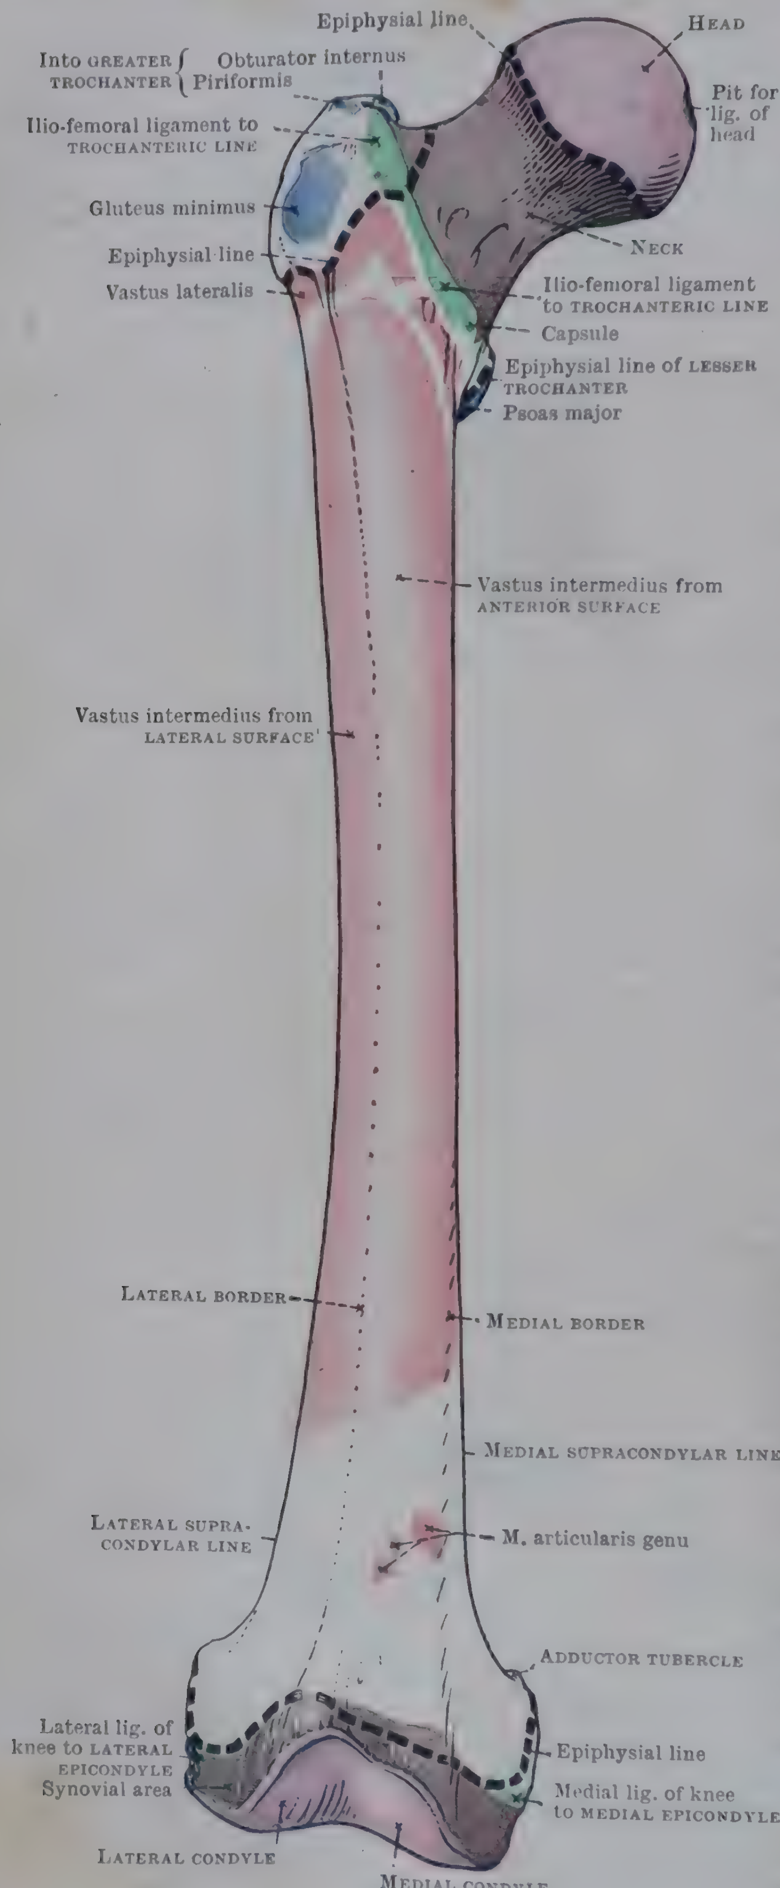

FIG. 261.—FRONT OF RIGHT FEMUR.

The medial supracondylar line is never so well defined as the lateral, largely because it is smoothed by the femoral vessels as they pass from the medial side of the thigh into the popliteal fossa and change their name to popliteal vessels. The lower third of the shaft also has *four* surfaces: anterior, medial, and lateral, continuous with those of the middle third, and a *posterior surface* between the supracondylar lines. The posterior surface is usually called the **popliteal surface**, because it forms a great part of the floor of the popliteal fossa; on its lower part, above the medial condyle, there is a rough, raised mark, about half an inch wide each way, from which the medial head of the gastrocnemius muscle arises.

The **nutrient foramen** of the femur is situated on or near the linea aspera and is directed towards the upper end. There may be two nutrient foramina.

The **head** usually looks upwards and slightly forwards as well as medially. It is relatively smaller in women than in men. The pit for the ligament of the head of the femur is situated below and behind the centre of the head; blood-vessels from the ligament enter through it, and the head thus obtains a double blood-supply; sometimes the pit is absent, as in the orang. The articular margin is undulating and is sharper behind than in front.

The **neck** extends laterally, downwards and slightly backwards from the head. Its antero-posterior diameter is less than the vertical. Its posterior surface is concave lengthwise and convex from above downwards; usually a shallow, horizontal groove can be seen on it, leading into the trochanteric fossa; the tendon of the obturator externus lies in the groove. Its anterior surface is nearly flat and nearly in the same plane as the head and shaft. Near the head it often presents a smooth patch, produced by pressure against the ilio-femoral ligament.

The neck is joined to the shaft at an angle which varies but averages 125°. The angle is less in the adult than in the child, and less in short-limbed people, especially in women; the upper ends of the shafts are separated by the width of the pelvis and by the length of the two necks, but the knees are in contact or almost so; the shaft is therefore oblique; the obliquity is more marked in short-limbed men, and still more so in women, for the pelvis is wider; and the greater the obliquity, the less is the angle. At the upper end of the **trochanteric line** there is often a little tubercle for the attachment of the stronger part of the ilio-femoral ligament.

The **greater trochanter** is under cover of the aponeurotic insertion of the gluteus maximus into the ilio-tibial tract during extension, but it slips under the fleshy part of the muscle during flexion. The highest point or tip of the trochanter is the angle between its upper and posterior borders, and it overhangs the trochanteric fossa.

Sometimes part of the **gluteal tuberosity** is so raised that it makes a prominent excrescence, easily felt in the living person, comparable to the **third trochanter** which is always present on the thigh-bones of some animals. Sometimes the tuberosity is represented by a depression.

The **shaft** of the femur is slightly twisted, making the transverse diameter of the condyles and the long axis of the neck lie in two vertical planes that intersect each other—the neck plane being a little in front of the condylar plane medially. The acute angle between the planes is the **angle of torsion** of the femur. The shaft is also curved, with the convexity forwards, and that partly accounts for the fullness of the front of the thigh; the degree of curvature varies considerably, and is usually most pronounced at the upper part. The **linea aspera** may be a prominent keel; or it may be absent, as it is in apes. Sometimes a small tubercle on the lateral supracondylar line, about two inches above the condyle, marks the lower limit of the lateral intermuscular septum; and above that there is a shallow groove for a muscular artery. The upper and lower parts of the shaft are rather compressed from before backwards; a femur showing an exaggerated degree of compression is called **platymeric**; this condition is more common in the femora of prehistoric races.

The articular surfaces of the **condyles** are spirally curved. Their tibial parts articulate partly with the upper end of the tibia and partly with the semilunar cartilages that lie within the knee joint between the femur and tibia; faint grooves,

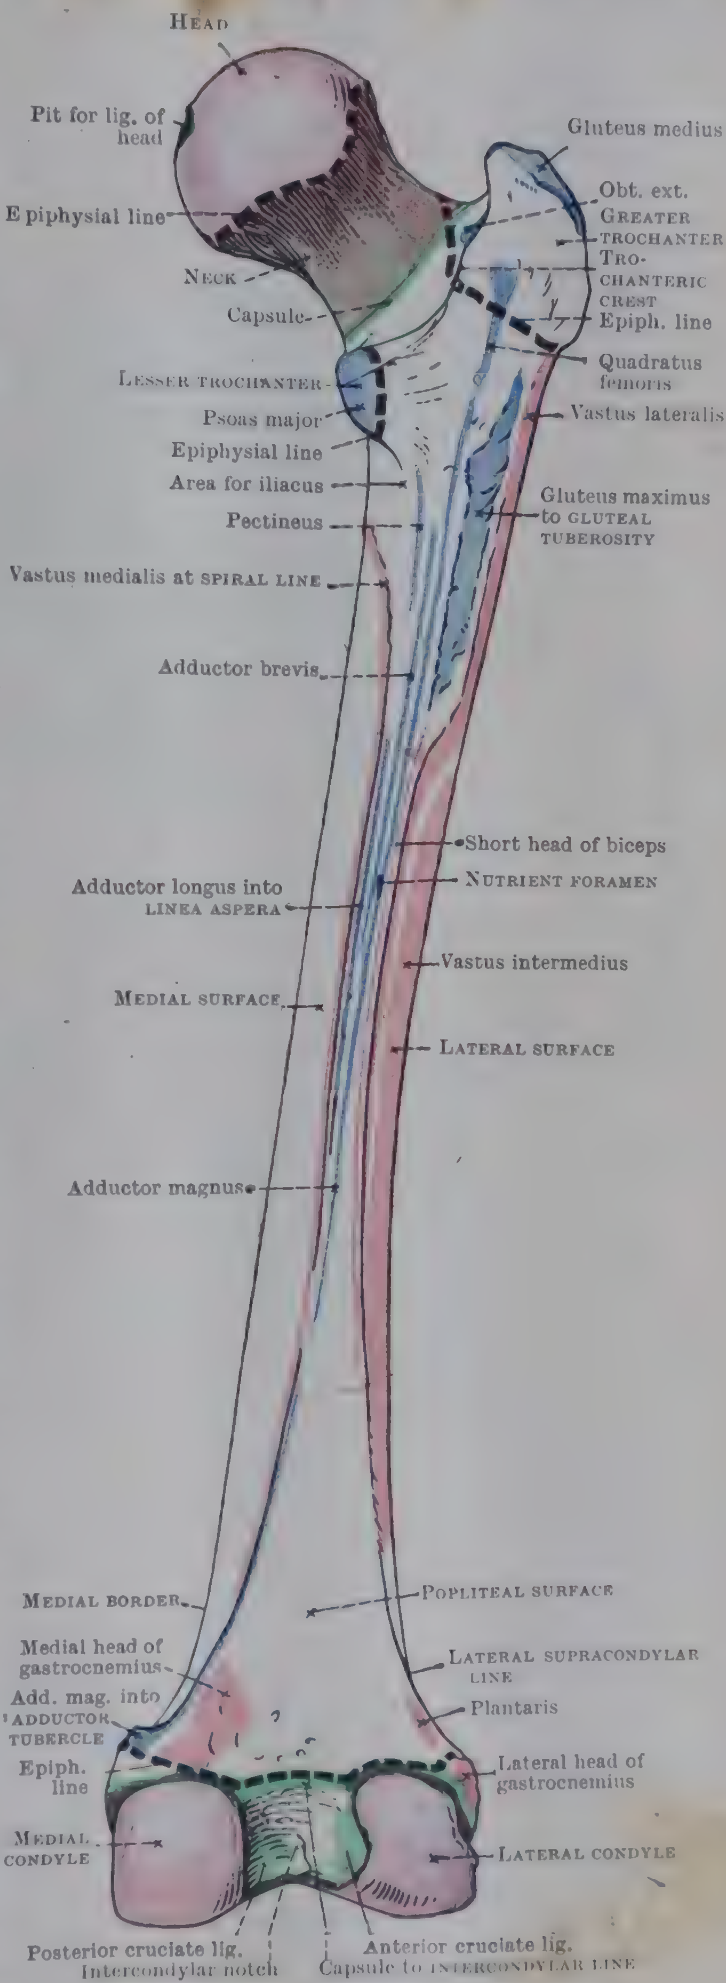

Fig. 262.—Back of Right Femur.

made by the anterior edges of these cartilages, separate the *distal* articular surfaces from the *patellar* surface. The distal surfaces are on the same horizontal plane when the femur is held in its proper oblique position; the lateral condyle is then the one more directly in line with the shaft.

On the distal aspect (Fig. 260) the patellar surface can be seen in front of the intercondylar notch; the two tibial surfaces are separated by the notch. The tibial surface on the *lateral condyle* is relatively broad and is rounded. The same aspect of the *medial condyle* is narrower and curved, with the centre for the curve in the middle of the rounded part of the lateral condyle. Assuming that the tibia is fixed, this indicates a rotation of the femur round a vertical axis passing through the lateral condyle. Actually, medial rotation of the femur on the tibia takes place in the late stages of extension (see p. 387).

The reverse appearance is seen on the posterior aspect of the condyles (Fig. 262). The medial condyle is rounded and the lateral one is narrower and is curved as part of the circumference of a circle, indicating rotation with the medial condyle as centre in the flexed position. The semilunar area for articulation with the patella in extreme flexion of the knee can sometimes be seen on the medial condyle where it bounds the anterior part of the intercondylar notch. The anterior margin of the intercondylar notch is opposite the centre of the lateral condyle; and the floor slopes upwards and backwards to the **intercondylar line**, which separates it from the popliteal surface.

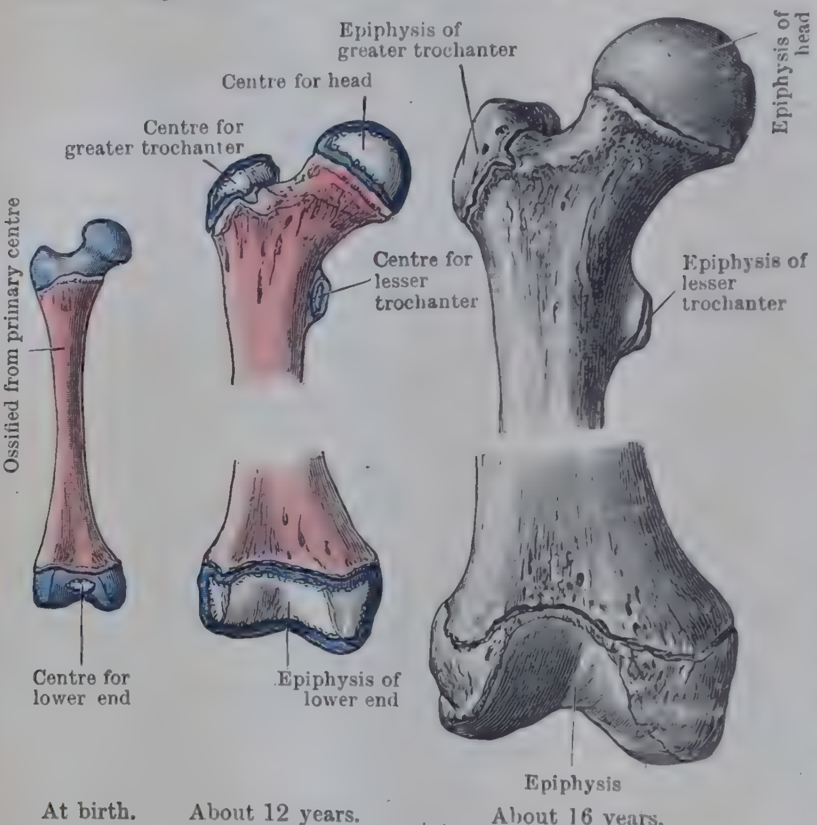

Fig. 263.—Ossification of Femur.

Attachments.—The ligament of the head is attached to the *pit* on the **head**. The capsule of the hip joint is attached to the back of the **neck** a finger's breadth from the trochanter, to the upper and lower borders of the neck near the trochanters, and to the **trochanteric line**; the part of the neck within the capsule is clothed with synovial membrane. The uppermost fibres of the vastus medialis arise from the lower half of the trochanteric line; the uppermost fibres of the vastus lateralis from the upper half of the line and from the front and lateral side of the root of the **greater trochanter**. The gluteus minimus is inserted into the *front* of the greater trochanter and is partly separated from it by a *bursa*; the gluteus medius into its *lateral surface* on a broad, oblique ridge that extends downwards and forwards from the postero-superior angle; the surface in front of the ridge is separated from the gluteus medius by a *bursa*, and another *bursa* intervenes between the gluteus maximus and the surface behind the ridge; the piriformis into the *upper border*; the obturator internus and the gemelli into the *medial surface* above the neck; the obturator externus into the floor of the **trochanteric fossa**; the quadratus femoris into the **trochanteric crest**, into the **quadrate tubercle** and into a strip that runs down from the tubercle for an inch; the psoas major into the **lesser trochanter**; the iliacus into the tendon of the psoas, the lesser trochanter, and the area below and in front of the trochanter.

Part of the gluteus maximus is inserted into the **gluteal tuberosity**, and part of the vastus lateralis arises from its lateral edge; part of the vastus medialis from the **spiral line**. The surface between the spiral line and the gluteal tuberosity gives insertion to four muscles: (1) part of the iliacus (see above); (2) the pectineus into a strip which begins lateral to the back of the root of the lesser trochanter and runs down to the linea aspera; (3) the upper part of the adductor brevis into the same strip, lateral to the pectineus; (4) the uppermost fibres of the adductor magnus between the attachment of the adductor brevis and the gluteal tuberosity.

The **linea aspera** gives attachment to the following structures, named from medial to lateral side: the origin of part of the vastus medialis; the medial intermuscular septum; the insertion of the adductor longus, in the whole length of the line or in the lower two-thirds only; the insertion of the lower part of the adductor brevis, in the upper third of the line; the insertion of a part of the adductor magnus; the posterior intermuscular septum; the origin of the greater part of the short head of the biceps femoris; the lateral intermuscular septum; the origin of part of the vastus lateralis from the upper half of the line, and of part of the vastus intermedius from the lower half.

From medial to lateral side the following structures are attached to the **supracondylar lines**:—Part of the vastus medialis from the upper two-thirds of the **medial** line; the medial septum

PLATE XXI

PLATE XXI.—POSTERIOR RADIOGRAPH OF LEFT KNEE OF YOUNG MAN AGED 22.

The union of the epiphysis of the Femur is not quite complete. Cf. Plate XXIV, Fig. 1, p. 297; and for lateral radiographs of the same knee see Plate XXXIV, p. 371.

PLATE XXII

FIG. 1.—RADIOGRAPH OF PELVIS OF BOY AGED 4.

The pubic and ischial rami are not yet united, and the centre for the epiphysis of the greater trochanter of the femur has not appeared.

FIG. 2.—RADIOGRAPH OF HIP OF BOY AGED 7. (Dr. J. Duncan White.)

The epiphysis of the Lesser Trochanter has not yet appeared.

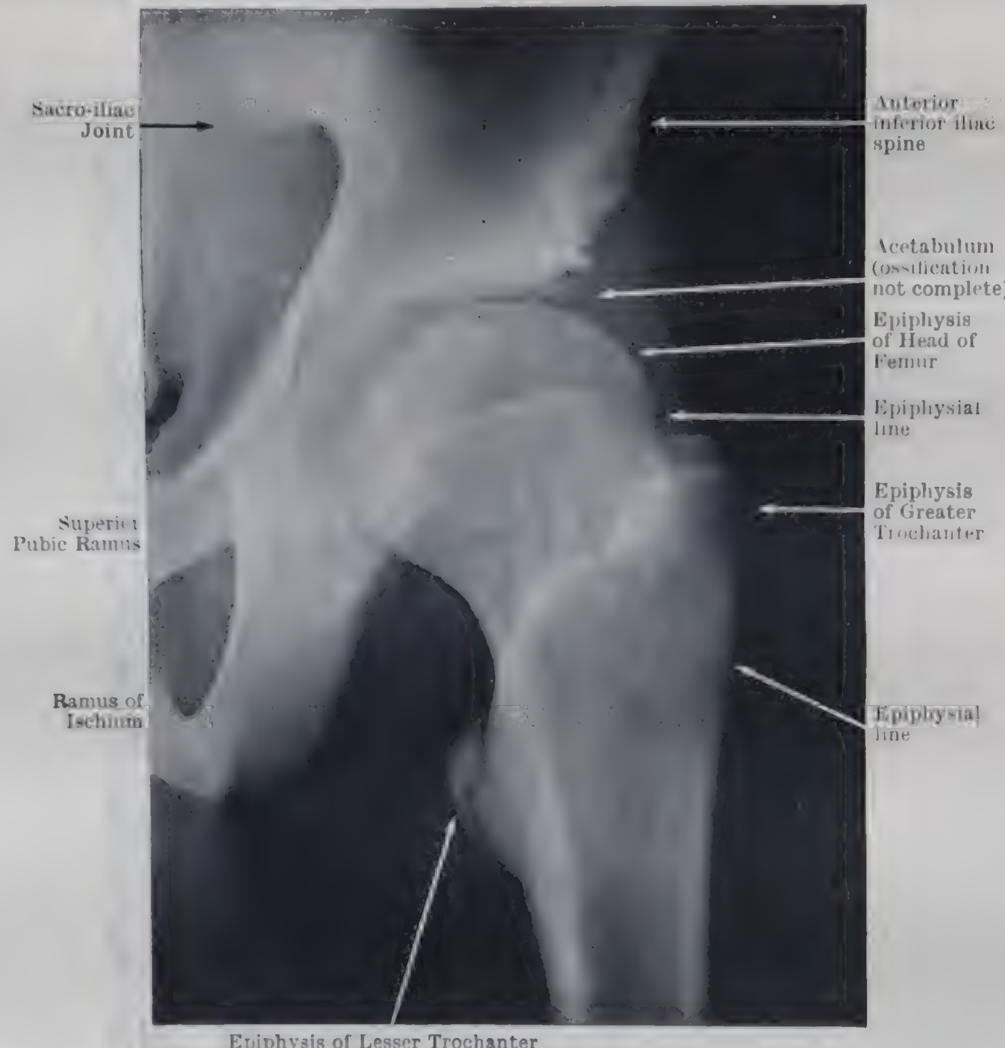

FIG. 1.—RADIOGRAPH OF HIP OF BOY AGED 14.

Note that the edge and floor of the Acetabulum are not yet completely ossified, and that all three epiphyses of the upper end of the Femur are present.

FIG. 2.—RADIOGRAPH OF HIP OF YOUTH AGED 17. (Dr. J. Duncan White.)

All three epiphyses of the Femur are united. Note the continuity of the lines of the lower borders of the Superior Pubic Ramus and the Neck of the Femur (Shenton's line), seen also in Plate XX, p. 289.

PLATE XXIV

Fig. 1.—Posterior Radiograph of Knee of Girl aged 7.
(Dr. J. Duncan White.)

Note the form of the Epiphyses, and compare with Plate XXI, p. 296.

Fig. 2.—Oblique Lateral Radiograph of Slightly Flexed Knee of Girl aged 12. (Dr. J. Duncan White.)

Note the apparent doubling of the femoral epiphysial line, and the extension of the tibial epiphysis to the tubercle—probably ossified in this instance from a separate centre.

[Facing p. 297

and part of the adductor magnus into the whole length, except where interrupted for the passage of the femoral vessels. The lower parts of the short head of the biceps, the lateral septum, and the vastus intermedius from the upper two-thirds of the **lateral** line.

The greater part of the vastus intermedius arises from the upper two-thirds or three-fourths of the **anterior** and **lateral surfaces** of the shaft; the articularis genu muscle (as slender bundles) from the lower part of the anterior surface. The medial surface is covered by vastus medialis, but does not give attachment to any muscle.

The medial head of the gastrocnemius arises from the rough patch on the **popliteal surface** above the medial condyle; the plantaris from a small area above the lateral condyle; the lateral head of the gastrocnemius from an impression on the lateral surface of the **lateral condyle** and the adjoining lower end of the lateral supracondylar line; the tendon of the popliteus from the anterior end of the **popliteal groove**, and when the knee is extended it crosses the lower lip of the groove, which bears therefore a shallow notch near its anterior end. The lateral ligament of the knee is attached to the *lateral epicondyle*; the anterior cruciate ligament to the posterior part of the *lateral wall* of the **intercondylar notch**; the posterior cruciate ligament to the anterior part of the *medial wall*; the medial ligament of the knee to the *medial epicondyle*. The tendon formed by the posterior part of the adductor magnus is inserted into the **adductor tubercle**.

The fascia lata blends with the periosteum of both condyles at the sides of the knee. The posterior ligament of the knee joint is attached to the **intercondylar line**, and the capsular ligament to the bone immediately above the posterior parts of the condyles, to the lateral condyle between the popliteal groove and the epicondyle, and to the medial condyle immediately below the medial epicondyle. There is no definite capsular ligament in front, and the synovial membrane is reflected off the quadriceps on to the femur about a finger's breadth above the patellar surface; but, by means of a wide communication with a large *bursa* that lies under cover of the quadriceps, the cavity of the knee joint extends upwards to a point at least three finger-breadths above the patella. The apex of the infrapatellar synovial fold is attached to the anterior margin of the intercondylar notch.

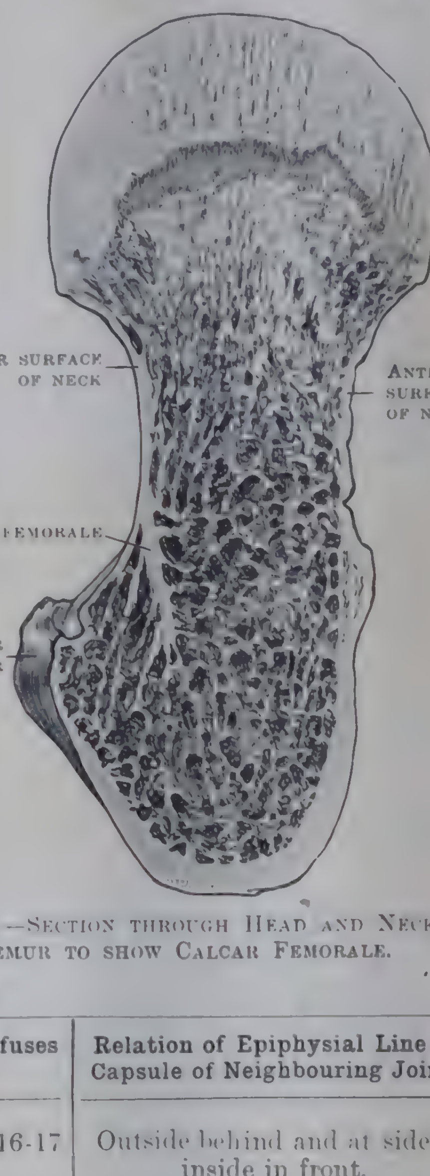

FIG. 264.—SECTION THROUGH HEAD AND NECK OF FEMUR TO SHOW CALCAR FEMORALE.

Ossification (Pls. XXII, XXIII, XXIV).—The **primary** centre for shaft and neck appears at the seventh week of intra-uterine life. At birth the shaft is ossified; ossification extends into the neck after birth.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For lower end	9th month of *intra-uterine* life	**M.** 18; **F.** 16-17	Outside behind and at sides; inside in front.
For head	**M.** ½-1 yr.; **F.** ½ yr.	**M.** 18; **F.** 17	Inside.
For greater trochanter	**M.** 5 yr.; **F.** 4 yr.	**M.** 18; **F.** 16-17	Outside (inside superiorly).
For lesser trochanter	9-11 yr.	**M.** 18; **F.** 16-17	Outside.

The presence of the centre in the cartilage at the lower end in a new-born child found dead is accepted as proof that the child had come to full time. The epiphysial line at the lower end passes through the adductor tubercle, and immediately above the patellar surface, and along the intercondylar line.

Structure.—As in other long bones, the ends are composed of spongy substance enclosed in a shell of compact substance. The shaft is a thick tube of compact bone enclosing a medullary cavity; the cavity begins opposite the lesser trochanter and ends about a handbreadth from the distal articular surface. The walls of the cavity are thickest above the middle of the bone and along the linea aspera. Since the upper end of the femur has become a classical example of bone-architecture (p. 107) its structure is given here in some detail. The following account is based largely on the description given by Dixon (1910) who used stereoscopic radiographs as well as thin sections and dissection of the bone. See also D'Arcy Thompson (1942), Koch (1917) and Murray (1936) for discussion and review of the whole subject, with full historical references.

The compact bone of the shaft gives origin to lamellæ which branch off, diverge and intersect to form the cancellous bone of the neck, the trochanters and the head. Although it is not at first glance obvious, many of these lamellæ are concentrated to form the walls of a curved tube which is an upward continuation of the tubular compact bone of the shaft through the neck to the head of the bone. If the trochanters and intertrochanteric crest are removed carefully it is possible to demonstrate the continuity of this tube from the shaft up into the neck. The part which passes deep to the lesser trochanter to reach the posterior aspect of the neck is termed the **calcar femorale** when seen as a thickened spur in sections through the neck (Fig. 264). Where it lies deep to the greater trochanter it has been referred to as the *lamina femoralis interna*. Lamellæ branch off from the deep and superficial surfaces of the 'tube' as trabeculæ of the adjacent cancellous bone. The arrangement as seen in coronal section is illustrated in Plates II and III (p. 105). The chief systems to be noted are as follows :—

(1) Lamellæ sweep up from the compact bone of the medial and inferior aspects of the shaft and neck and diverge to reach the articular surface of the head—especially the upper weight-bearing part of it. These are obviously subjected to compression from the weight of the body.

(2) Lamellæ spring from the compact bone of the lateral aspect of the shaft, arch across deep to the trochanter and through the upper part of the neck to cross the first series of lamellæ approximately at right angles and so reach the articular surface of the head—mainly the lower part this time. These must be subject to tension when the body weight is applied to the head of the bone.

(3) A series of lamellæ spring from the medial wall of the shaft and arch across to reach the greater trochanter.

(4) Lamellæ also sweep up from the lateral side into the greater trochanter and upper part of the neck of the bone.

The first two of these systems mentioned form the infero-medial and supero-lateral walls of the bent tubular continuation of the shaft. The area enclosed by the first three systems is relatively free of lamellæ and forms a triangle, *trigonum internum femoris*, illustrated by Ward as early as 1838. Many of the lamellæ are arranged spirally as intersecting right and left handed series, an exceedingly efficient arrangement. Dixon found that adult femora could stand compression (applied to the lower end and head of the bone) amounting to between 1800 and 2500 lbs. Weights of this order produced shearing of the neck before fracture from bending stresses took place.

Patella

The **patella** or knee-cap or knee-pan [*patella*, diminutive of *patina* = a pan] lies in the front of the knee and articulates with the femur. It is a small, compressed bone and measures nearly two inches in diameter. The **posterior surface** is largely occupied by an oval *facet* for articulation with the femur; the facet is divided by a blunt ridge into a larger, lateral part, and a smaller, medial part, which correspond to the sloping sides of the patellar surface of the femur. The **anterior surface** is slightly convex and is triangular in outline; the *apex* of the triangle points towards the leg and is on a level immediately above the plane of the knee joint; the base of the triangle is the anterior margin of the *base of the patella*, *i.e.*, its thick, upper border; the *lateral* and *medial borders* are convex.

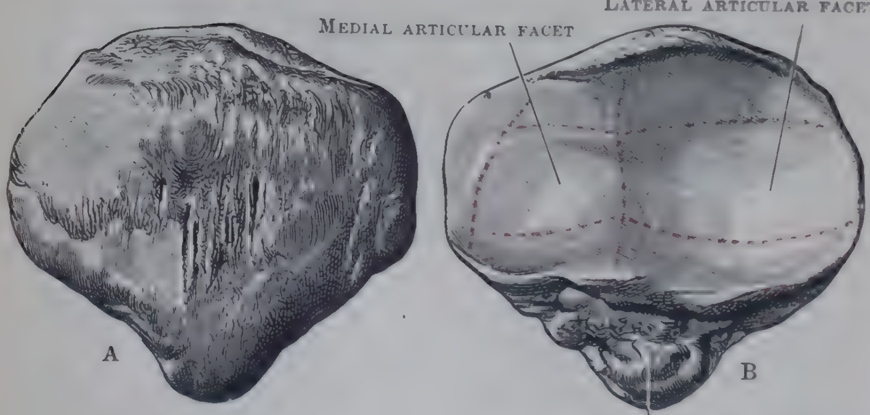

Fig. 265.—Right Patella.
A. Anterior Surface. B. Posterior Surface.

The **patella** is the largest of the *sesamoid* bones; it lies in the tendon of the quadriceps femoris and, playing against the patellar surface of the femur, it increases the leverage of the muscle when it contracts to move the leg. The lower part of the quadriceps tendon is the *ligamentum patellæ*—a strong band that stretches from the patella to the tibia, and on which the body partly rests in the kneeling posture. When the knee is extended and the muscles are relaxed, the patella can be moved from side to side fairly freely, and to some extent also downwards; when the knee

is flexed the quadriceps muscle, including the ligamentum patellæ, is put on the stretch, the patella is jammed hard against the femur and is immovable. The anterior surface has a vertically striated or fibrous appearance. The lateral part of the articular surface is concave in both directions; the medial part is slightly concave from above downwards and is flat or slightly convex from side to side. The vertical ridge lies in the intercondylar notch in extreme flexion. When the cartilage is in place a vertical strip along the medial margin for articulation with the lateral margin of the medial condyle in extreme flexion can be seen; and the rest of the surface is faintly subdivided into six areas (see Fig. 265). The medial, vertical strip can sometimes be seen in the macerated bone.

Attachments.—The three vasti and the rectus femoris are inserted into the upper border; the vastus lateralis and medialis, into the lateral and medial margins also; and these borders give attachment also to the retinacula of the patella. A transverse line or groove divides the upper border into an anterior part for muscular insertion and a posterior part covered with fat and synovial membrane. There is often a well-defined area at the supero-lateral angle for part of the vastus lateralis. Some tendinous fibres of the quadriceps are continued downwards over the front of the patella to the ligamentum patellæ, and, in infancy, they can easily be stripped off the cartilaginous patella. The ligamentum patellæ is attached to the apex and to the adjoining part of the posterior surface, but the greater part of the rough surface below the articular facet is related to fat and the synovial membrane of the knee.

Ossification.—The patella is cartilaginous at birth. Ossification, usually from a single centre, begins about the fifth year and is completed about puberty. Separate epiphysial nodules have been found in the lateral margin of the patella. For the development of the patella in relation to the knee joint, see Walmsley, R. (1940).

Structure and Variations.—The patella is composed of spongy tissue enclosed in a shell of compact tissue, which is thickest in front and at the vertical elevation behind. Small *vascular foramina* are present on the anterior surface. The patella may be absent; its absence is said to be hereditary and transmitted by the female. In one recorded case the patella was divided into a large, upper part and a smaller, lower part embedded in the ligamentum patellæ. The facets on the articular surface are modified in people who habitually squat.

Tibia

The **tibia** or shin-bone [*tibia* = shin-bone] comes next in size after the femur and is between a fourth and a fifth of the length of the body. It is the medial and larger of the two bones of the leg, and it can be felt through the skin in all its length. It is a long bone, having **a shaft** and **two ends**. The most outstanding border of the shaft is the **anterior** border; the lower end is the smaller end; and on the **medial** side of the lower end there is a stout, blunt projection called the *medial malleolus*.

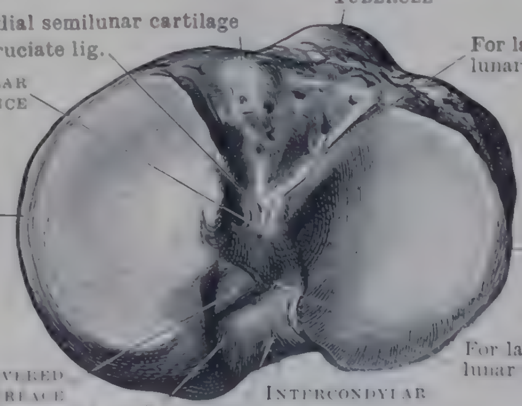

Fig. 266.—Proximal Surface of Right Tibia.

The **upper end** is large and expanded to support the lower end of the femur. Its transverse diameter is the wider and it is bent slightly backwards to overhang the shaft. It includes two imperfectly separated condyles and a tubercle.

The **tubercle** is the low elevation on the front where the upper end joins the anterior border of the shaft; its lower part is rough; its upper part is smooth and rounded and gives attachment to the ligamentum patellæ.

The two **condyles** make up nearly the whole of the upper end; they are separated *posteriorly* by a wide, shallow depression or notch; *anteriorly*, above the tubercle, they are united by a more or less flattened surface concealed behind the ligamentum patellæ. In the **kneeling posture** the body rests on the rough part of the tubercle, the ligamentum patellæ, the front of the two condyles, and the lower part of the patella. The *upper surface* of each condyle is large, oval and smooth; it articulates with the corresponding condyle of the femur; the more central part of the articular area articulates directly with the femur, but the more peripheral part is separated

from the femur by a *semilunar fibro-cartilage.* Between the articular surfaces of the two condyles there is a rough **intercondylar area** which rises near its middle into a prominent **intercondylar eminence.**

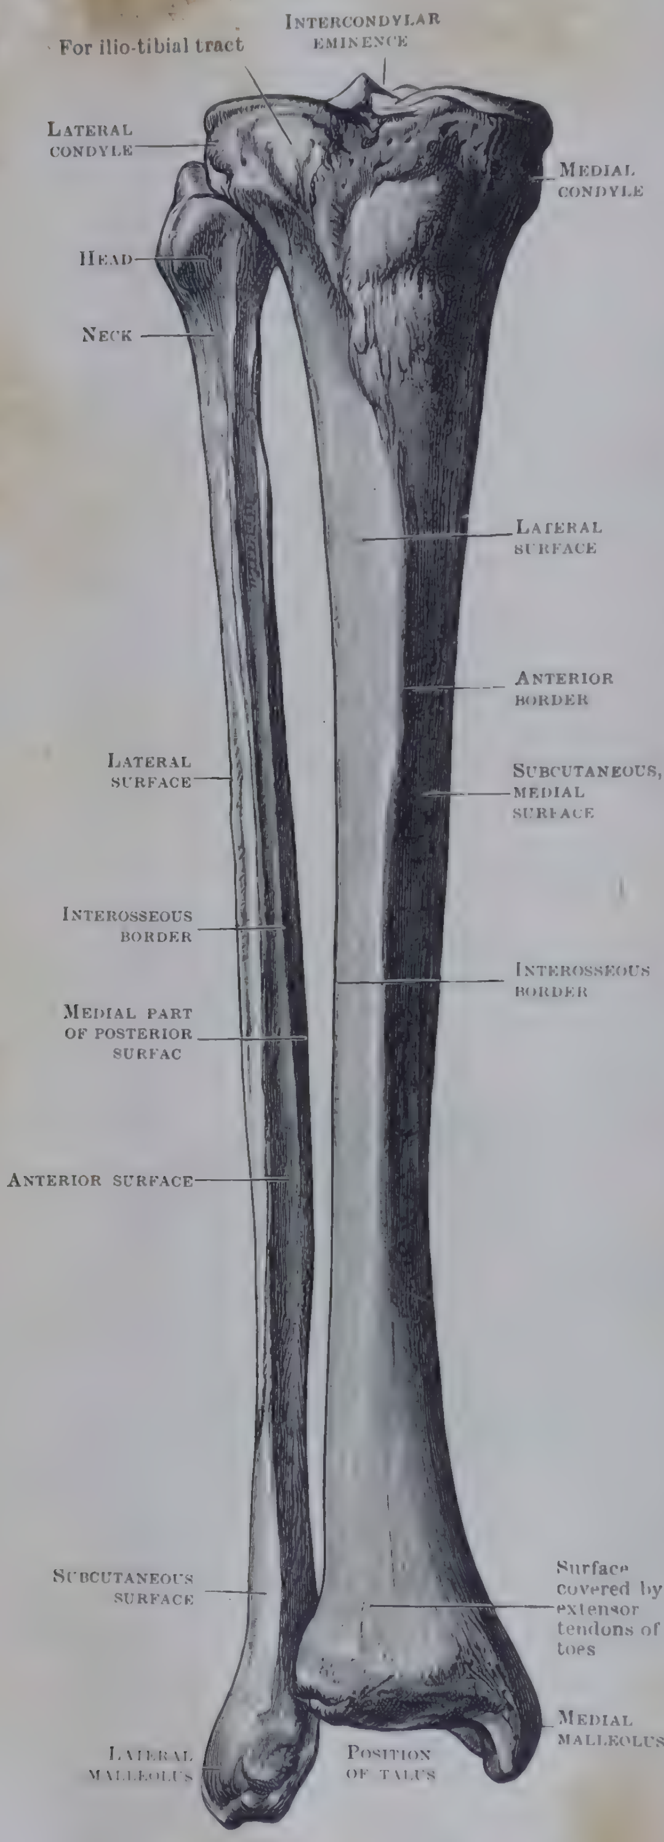

FIG. 267.—RIGHT TIBIA AND FIBULA SEEN FROM IN FRONT.

On the back of the **medial condyle** there is a rough, horizontal groove for the insertion of part of the tendon of the semimembranosus muscle. The **lateral condyle** stands more abruptly away from the shaft than the medial does—so much so that it has a *distal surface.* This distal surface is separated from the lateral surface by a curved ridge to which the fascia of the antero-lateral side of the leg is attached; on the posterior part of the distal surface there is a flat, circular **facet** for articulation with the head of the fibula. On the anterior part of the *lateral surface* there is usually a well-marked impression for the attachment of the posterior part of the *ilio-tibial tract*, a thickened part of the fascia of the thigh. Both the condyles can be felt at the sides of the knee.

The **lower end** of the tibia has five surfaces—anterior, posterior, lateral, medial, and distal.

The **anterior surface** is smooth and rounded, and it can be felt indistinctly through the skin and the tendons that descend from the front of the leg to the foot.

The **medial surface** is subcutaneous, and is continued on to the **medial malleolus**, which is the well-known prominence, both felt and seen, on the medial side of the ankle [*malleollus* = a small hammer]. The distal border of the malleolus is pointed anteriorly and notched posteriorly; it gives attachment to an exceedingly strong fibrous band named, from its shape, the *deltoid ligament* [Δ = the Greek capital letter *delta*]. The lateral surface of the malleolus is smooth and articulates with the medial surface of the talus or ankle-bone.

The **posterior surface** lies deeply under cover of a pad of fat and the tendo calcaneus, the stout sinew felt above the heel. The surface is on the same plane as the back of the malleolus, which can be felt. Where it merges

into the back of the malleolus there is a distinct vertical groove for the tendons of the tibialis posterior and flexor digitorum longus; nearer the lateral side there is an indistinct groove for the tendon of the flexor hallucis longus.

The **lateral surface** is occupied by a wide, triangular depression, the apical part of which extends on to the shaft and is shallow and rough. The basal part is smoother and deeper—being bounded in front and behind by prominent ridges or tubercles. It is called the **fibular notch** because the lower part of the fibula lies in it; the fibula is usually in actual contact with the lower part, but is bound to the upper part by a very short but very thick interosseous ligament.

The **distal surface** is square and smooth, concave from before backwards, slightly convex from side to side, and broader in front than behind; it articulates with and rests upon the upper surface of the talus, the highest bone of the tarsus.

The **shaft** is thinnest about the junction of the middle and lower thirds; it becomes thicker towards the lower end and still more so towards the upper end. It has three borders and three surfaces. The *borders* are anterior, medial, and interosseous; the *surfaces* are posterior, lateral, and medial.

The **anterior border** or shin of the leg is the most prominent of the borders. It begins at the tubercle and extends sinuously to the anterior margin of the medial malleolus; it can be felt from end to end in the living leg. Small notches—the result of accidental impacts—may be felt in it. Its lower third is blunter than the rest of it. The **medial border** is a smooth, blunt margin that extends from near the back of the medial condyle to the back of the medial malleolus; it also can be felt from end to end, but it is best marked in the middle third of the bone. The **interosseous border** is on the lateral side, and is so named because it gives attachment to the interosseous membrane—a strong, fibrous sheet stretched between the tibia and the fibula. It is a

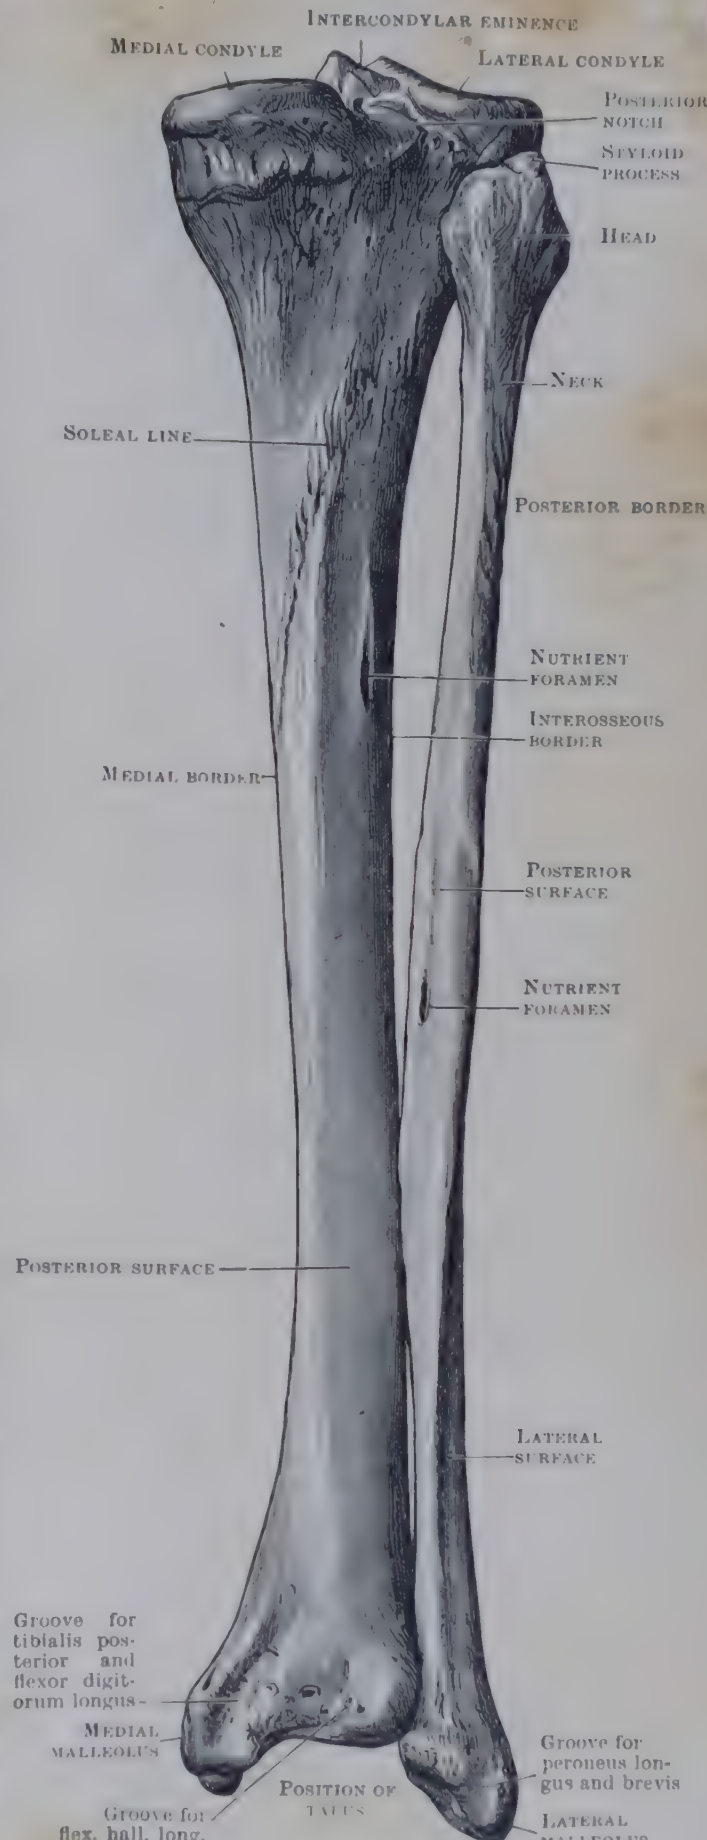

Fig. 268.—Right Tibia and Fibula seen from Behind.

distinct, sharp line, but is not prominent. It extends from the apex of the fibular

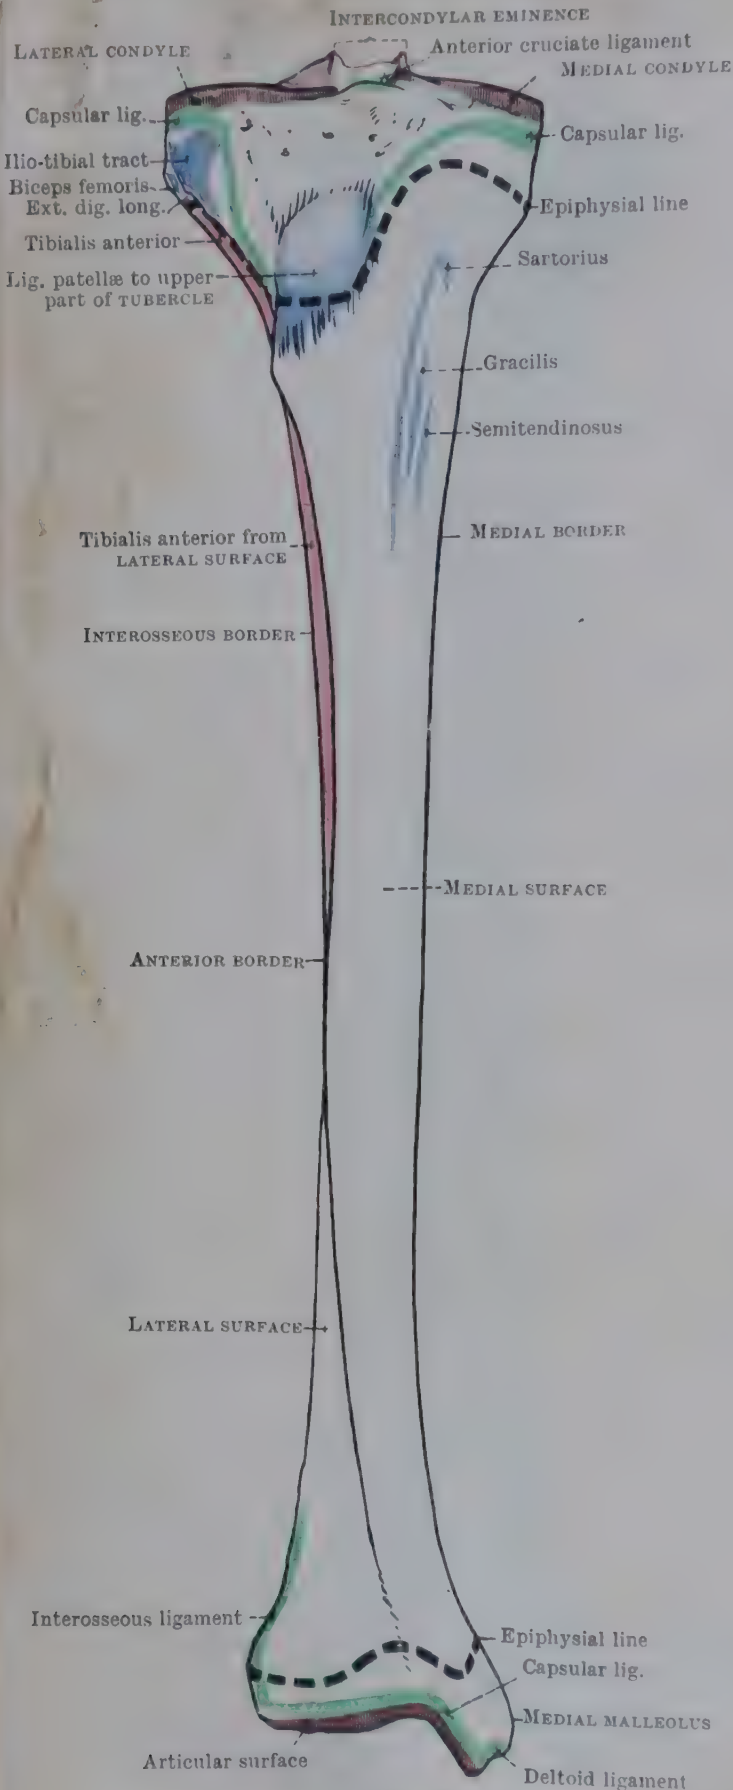

FIG. 269.—ANTERIOR ASPECT OF RIGHT TIBIA.

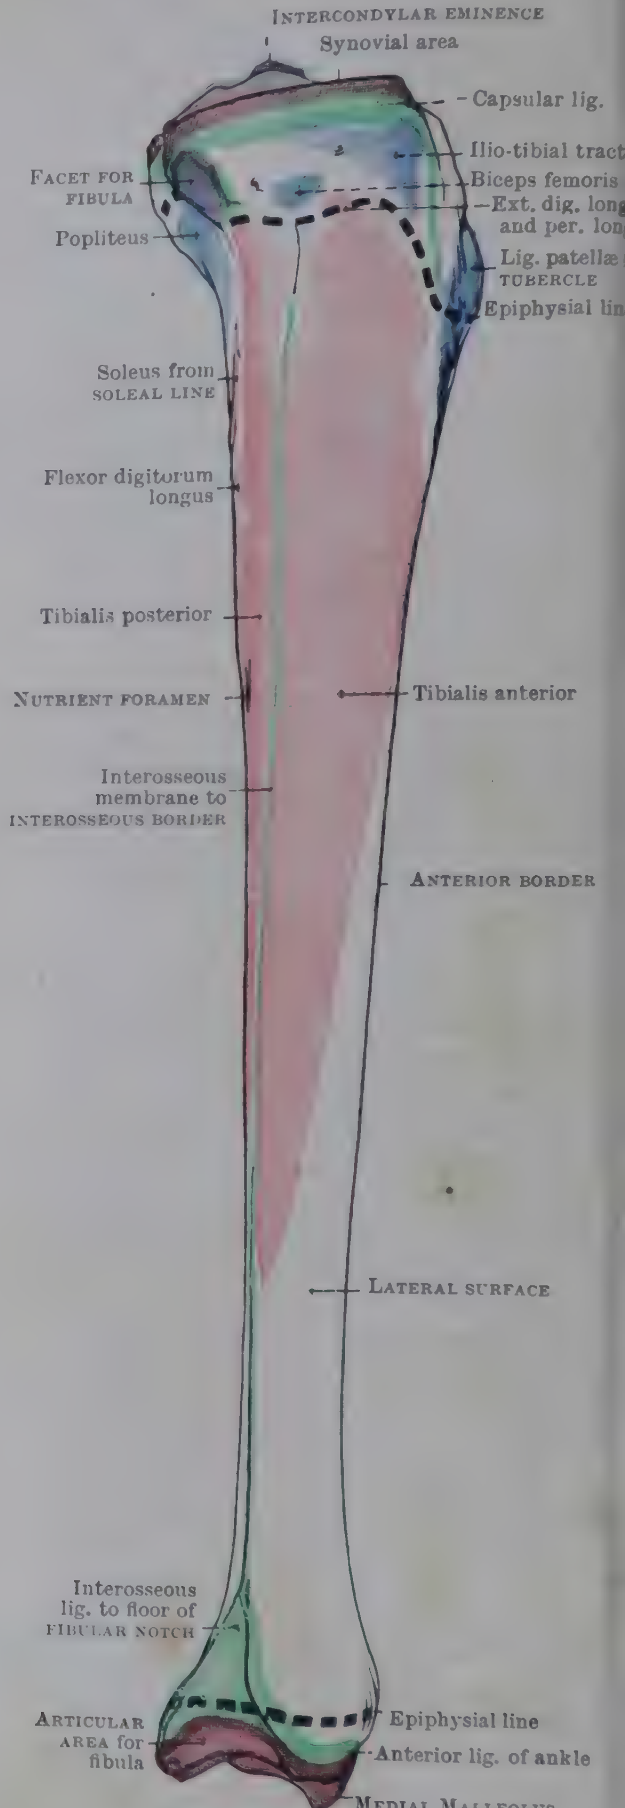

FIG. 270.—LATERAL ASPECT OF RIGHT TIBIA.

notch to the lower part of the lateral condyle some distance in front of the facet for the head of the fibula.

The **medial surface**, between the anterior and medial borders, is smooth and

slightly convex and can be felt through the skin. It is continuous inferiorly with the medial malleolus and its upper part is slightly roughened for the attachment of tendons and ligaments that overlie it. The **lateral surface** is between the anterior and interosseous borders, and, owing to the direction of the lower parts of those borders, it turns forwards to become continuous with the front of the lower end of the tibia. The **posterior surface** is between the medial and interosseous borders; its upper part encroaches on the lateral aspect of the bone owing to the position of the upper part of the interosseous border. The upper third of the posterior surface is crossed by an oblique ridge called the **soleal line** which begins near the facet for the head of the fibula and runs downwards and medially towards the medial border. The line is the chief bony origin of the soleus muscle that lies deeply in the calf; the part of the surface above the line gives insertion to the popliteus muscle which lies in the lower part of the floor of the popliteal fossa. The part of the surface below the soleal line is imperfectly divided into medial and lateral parts by a more or less *vertical line*—which is often ill-defined.

The **nutrient foramen** is near the soleal line and is directed downwards.

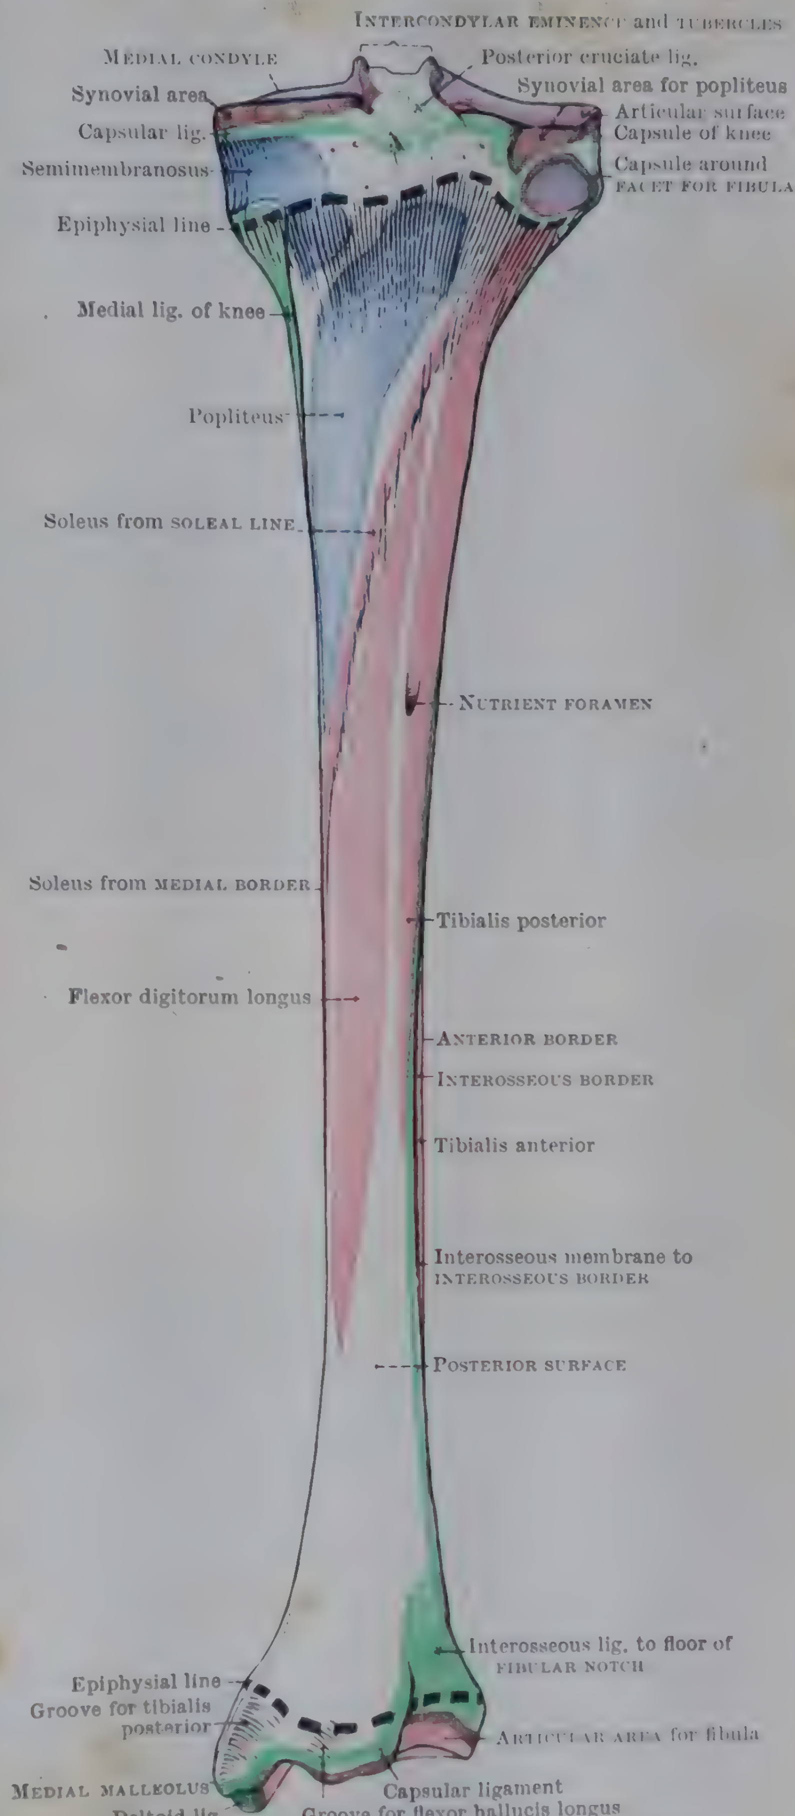

FIG. 271.—POSTERIOR ASPECT OF RIGHT TIBIA.

The articular surface of the **medial condyle** is ovoid, with its long axis antero-posterior; it is concave in each direction. The superior articular surface of the **lateral condyle** is rounder and slightly smaller. It is slightly concave from side to side; from before backwards, its posterior part is convex, but its anterior part varies from slightly convex to slightly concave in different specimens. Its margin is well-defined anteriorly and laterally, but it is rounded off posteriorly—increasing the convexity of the posterior part. The parts of a condylar articular surface that articulate with the semilunar cartilage and with the femur may be indicated by a difference in texture or colour. The sides of

the **intercondylar eminence** stand up prominently as the **intercondylar tubercles**; the articular cartilage extends on to them, and they are separated by a groove that runs obliquely from in front backwards and in a lateral direction. The medial tubercle is the higher and blunter; it sends backwards an oblique ridge that bounds the groove posteriorly and gives attachment to the **posterior horn of the lateral semilunar cartilage.**

On the front of the bone the area above the tubercle, composed of the united anterior surfaces of the two condyles, is covered with fat and is related to the deep infrapatellar bursa, which sometimes also overlaps the upper edge of the tubercle. The **tubercle of the tibia** is divided into two parts—an upper and a lower. The *lower part* is subcutaneous, but is rough; and its upper edge is often raised as a rough ridge that receives the superficial fibres of the ligamentum patellæ; but there may be no ridge, or there may be a depression in place of a ridge. The *upper part* is smooth and rounded, and it is the chief insertion of the ligamentum patellæ; its upper edge is sharply defined and is often bounded by a narrow, shallow, arched groove.

The posterior surface of the **shaft** is variable in contour, but usually its upper part is rounded and its lower part flat. The lower parts of the posterior and lateral surfaces are free from muscular attachments, but are overlain by muscles and tendons.

Attachments. — The capsular ligament of the knee joint is attached to the circumference of the **condyles** a little below the margins of the articular surface; the capsule of the upper tibio-fibular joint to the margins of the **facet for the fibula**; the cruciate ligaments and the horns of the semilunar cartilages to the **intercondylar area** in the following order from before backwards: anterior horn of medial cartilage and anterior cruciate ligament in front of the intercondylar eminence, the horns of the lateral cartilage to the front and back of the eminence, the posterior horn of the medial cartilage and the posterior cruciate ligament behind the eminence. The fascia lata to the sides of both *condyles*; its ilio-tibial tract to the impression on the *lateral condyle*; and the fascia of the leg to the ridge on that condyle. Below that ridge, on the overhanging, distal surface of the condyle, a few fibres of the biceps femoris are inserted in front of the facet for the fibula, and fibres of the peroneus longus, extensor digitorum longus, and tibialis anterior muscles arise. Part of the semimembranosus tendon is inserted into the medial part of the horizontal *groove* on the back of the *medial condyle* and into the rough area below the groove. The ligamentum patellæ is inserted into the smooth, upper part of the **tubercle** of the tibia, and its most superficial fibres run on into the rough part.

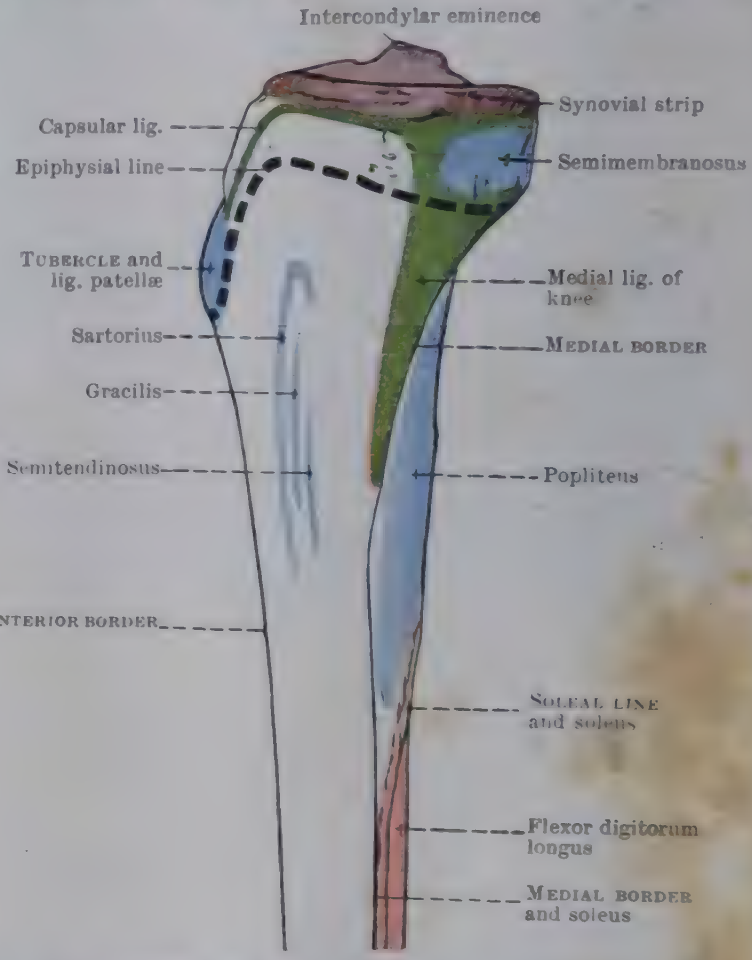

FIG. 272.—MEDIAL ASPECT OF UPPER HALF OF RIGHT TIBIA.

The medial ligament of the knee is attached to a rough patch about two inches long and half an inch wide on the *medial surface of the* **shaft**, immediately in front of the upper part of the medial border. The tendons of the semitendinosus, gracilis, and sartorius, in that order from behind forwards, have linear insertions into the area immediately in front of that rough patch. The tendon of the popliteus, as it emerges from the knee joint, lies in a smooth, shallow, oblique groove on the back of the lateral condyle between the superior and fibular articular surfaces; it then becomes fleshy and widens out to be inserted into the surface above the **soleal line**. Part of the soleus arises from the line and the middle third of the *medial border*; the flexor digitorum longus from the upper two-thirds of the *medial area* of the **posterior surface**; part of the tibialis posterior from the *lateral area*; and the fascia that covers the tibialis posterior is attached to the *vertical line*. The interosseous membrane to the *interosseous border*; the fascia of the leg to the *medial* and *anterior borders*; the superior extensor retinaculum to the lower part of the anterior border. The inferior extensor retinaculum is attached to the *anterior* border of the medial malleolus; the deltoid ligament to the *distal* border; the flexor retinaculum to the *posterior* border. The posterior ligament of the ankle joint and transverse tibio-fibular ligament to the *posterior* border of the **lower end**; the anterior ligament to the *anterior* border. The interosseous tibio-fibular ligament to the floor of the **fibular notch**; the anterior inferior and posterior inferior tibio-fibular ligaments to the anterior and posterior *margins* of the lower part of the notch.

[Facing p. 305

Ossification (Pls. XXIV, p. 297, XXVI).—The **primary** centre appears at the seventh week of intra-uterine life. At birth only the ends are cartilaginous.

The *upper* epiphysial centre appears shortly after birth and sometimes shortly before birth.

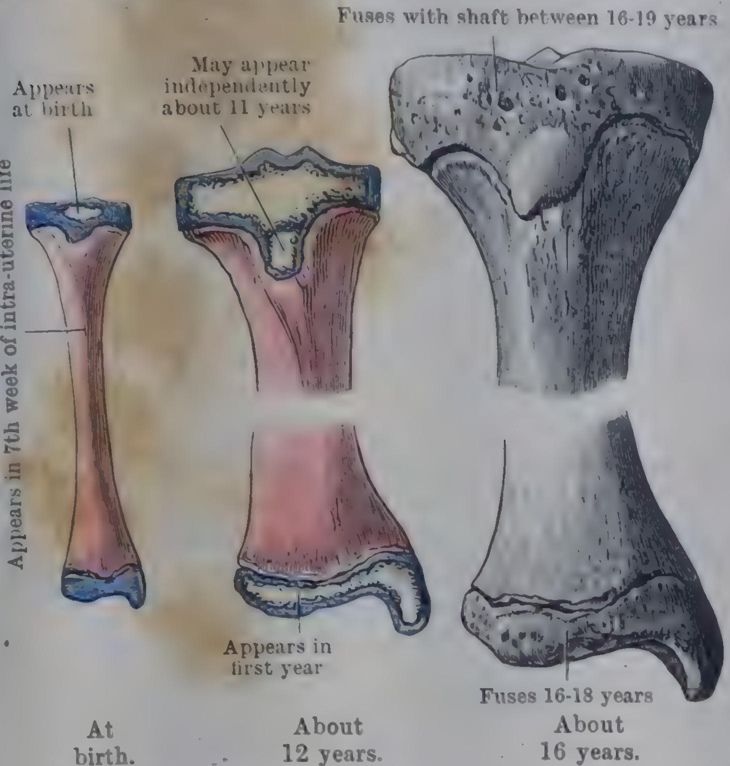

Fig. 273.—Ossification of Tibia.

The *epiphysial line* extends downwards in front to include the greater part of the tubercle. The downward spread of ossification to include the tubercle begins at the end of the tenth year; and that is the last part of the epiphysis to unite with the shaft. The medial malleolus is cartilaginous till the eighth year, when ossification begins to extend into it from the lower epiphysis. Occasionally there are additional epiphysial centres for the tubercle and the medial malleolus.

Structure and Variations.—The structure is like that of the other long bones. The medullary cavity falls short of each end by two or three inches. The cavity is narrow in the middle, for its walls are thickest there. The posterior wall is thicker than the side-walls, and the anterior wall is thicker still, owing to the heaping up of dense bone at the shin. The compact bone is much thicker in the tubercle and the intercondylar eminence than elsewhere at the upper end. The **nutrient canal** extends through the compact bone obliquely for two inches before it reaches the medullary cavity.

Tibiæ that show compression from side to side are called **platyknemic**; the condition is more common in prehistoric and savage people than among modern Europeans. Exaggerated *retroversion* of the upper end is said to be due to the habit that some people have of walking with the

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.

For lower end	6 mo.–1 year	M. 18; F. 16	Outside.

knees slightly bent. The anterior margin of the lower end is often grooved transversely for the attachment of the anterior ligament of the ankle. In people who habitually squat rather than sit there may be a 'pressure' facet on that margin.

Fibula

The **fibula** or splinter-bone is the lateral and smaller bone of the leg. It is almost as long as the tibia, is very slender, and has slightly expanded ends. In some animals it is pointed at one end—hence its name [*fibula* (from *figibula*) = a pin or skewer; the equivalent word in Greek is περόνη (peronē), hence the names *peroneus* and *peroneal* given to muscles, vessels, and nerves related to the fibula].

The fibula has a **shaft** and **two ends**. It gives attachment to muscles and is so covered that it is not easily felt except at the ends. Its lower end assists in the formation of the ankle joint, but its upper end fails to reach the femur and lies 1½ inches behind and below the most prominent part of the lateral condyle of the tibia, articulating with the inferior surface of the condyle. The **upper** end is knob-like; the lower end is compressed from side to side and triangular in outline; on the **medial** side of the lower end there is a large, nearly flat, triangular facet; the **posterior** aspect can be recognized from the fact that there is a pit *behind* the lower part of the facet.

The **upper end** is the *head* of the fibula. The anterior, posterior, lateral, and medial surfaces of the **head** are identified more easily after the surfaces of the shaft

and lower end have been recognized; the medial part of the *proximal surface* bears a *facet* of considerable size for articulation with the lateral condyle of the tibia; a conical projection, the **styloid process**, stands up from the junction of the *lateral* and *posterior* surfaces. The head is felt as a hard knob well back on the lateral side of the leg at the level of the tubercle of the tibia. If the finger is passed round to its posterior surface, a big nerve, called the *lateral popliteal nerve*, can be felt and rolled between the finger and the bone; it is felt most easily when the knee is bent to a right angle to relax the muscles. The part of the shaft immediately adjoining the head is the **neck** of the fibula, and it also can be felt; the nerve inclines downwards and forwards from the back of the head and ends on the lateral side of the neck, and it is most liable to injury there.

The **lower end** is the *lateral malleolus*, the outstanding prominence on the lateral side of the ankle. It articulates with the lateral surface of the lower end of the tibia, and projects downwards beyond the tibia to articulate with the lateral surface of the talus; the talus therefore fits between the two malleoli.

The **lateral malleolus** has four surfaces—lateral, medial, anterior, and posterior. The **lateral surface** is subcutaneous. The **medial surface** bears a large, almost flat, articular *facet*; the malleolus projects so far beyond the tibia that only the upper edge of the facet articulates with the tibia; the remainder articulates with the talus. The pit behind and below the facet is the *malleolar fossa*, and is big enough to accommodate the tip of the little finger. The rough mark on the shaft, immediately above the facet, fits into the fibular notch of the tibia and is bound to its floor by an interosseous ligament. The **anterior surface** is narrow from side to side, convex from above downwards, and slightly roughened. The **posterior surface** is wider and flatter than the anterior; the width of its lower part is greatly reduced, owing to the malleolar fossa; the tendon of the peroneus brevis lies on it and often grooves it longitudinally, and the tendon of the peroneus longus lies on that of the brevis.

The **shaft** of the fibula, though slender, is strongly marked by grooves and ridges which vary in size according to the strength of the muscles and fascial sheets which have been attached to them. It has three borders and three surfaces, one of which—the posterior surface—is divided into two by an outstanding medial crest resembling a border. In addition, there is a smooth **triangular subcutaneous area** which is the upward continuation of the lateral surface of the malleolus on to the lower part of the shaft. This triangular area is continuous at its apex with the anterior border of the shaft and, since it also indicates the lateral side and inferior end, it provides sufficient information to place the bone in its proper position as well as leading to identification of all its parts. The area is about two inches in length and, along with the malleolus, is easily identified through the skin.

The **anterior border** of the shaft runs from the apex of the triangular subcutaneous area up to the neck as a sharp, even line. The **lateral surface**, for the peroneal muscles, lies lateral to the anterior border and is prolonged downwards behind the triangular area to become continuous with the posterior surface of the malleolus. It is limited posteriorly by the **posterior border** which runs from the medial margin of the posterior surface of the malleolus up to the neck of the bone, usually as a distinct edge. The **anterior surface**, for extensor muscles and peroneus tertius, lies medial to the anterior border and is very narrow, or even linear, at its upper part It usually widens to about a quarter of an inch towards its lower end. The anterior surface is in front of the interosseous membrane and so is limited medially by the **interosseous border**. This border gives attachment to the membrane but is never strongly marked and approaches close to the anterior border in its upper part. Its lower end is easier to find and runs into the rough triangular patch for the interosseous ligament, situated above the medial surface of the malleolus. The remainder of the shaft, between the posterior and interosseous borders, is named **posterior surface** because it is behind the interosseous membrane. It is divided by a prominent *medial crest* into a flat or slightly convex area, for the flexor hallucis and soleus muscles, situated lateral to the crest and a concave area between the crest and the interosseous border, for tibialis posterior muscle. The area for tibialis posterior is frequently divided by an oblique ridge beginning at the interosseous border near the neck and running downwards and backwards. It gives attachment to a fascial septum in the muscle and may be mistaken for part of the medial crest. The medial crest begins at the neck and runs down the shaft to join the interosseous border three or four inches above the lower end. It is here that the crest is most easily identified and in many fibulæ it is the most prominent ridge on the bone. Below the crest the posterior surface inclines on to the medial aspect of the bone behind the interosseous membrane.

The **nutrient foramen** is usually on the posterior surface, about the junction of the upper and middle thirds, and is directed downwards ; it may be near the lower third.

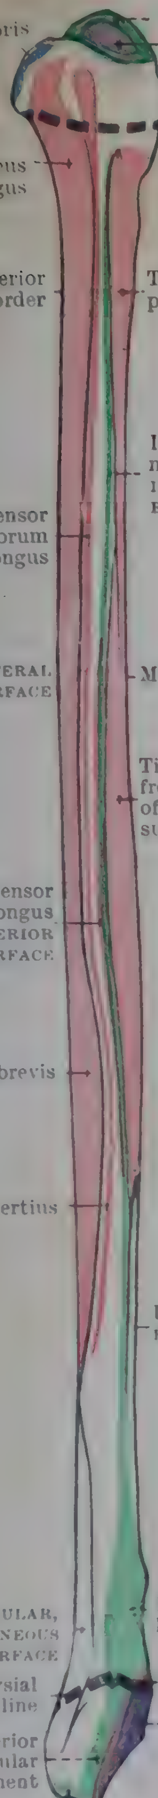

Fig. 274.—Anterior Aspect of Right Fibula.

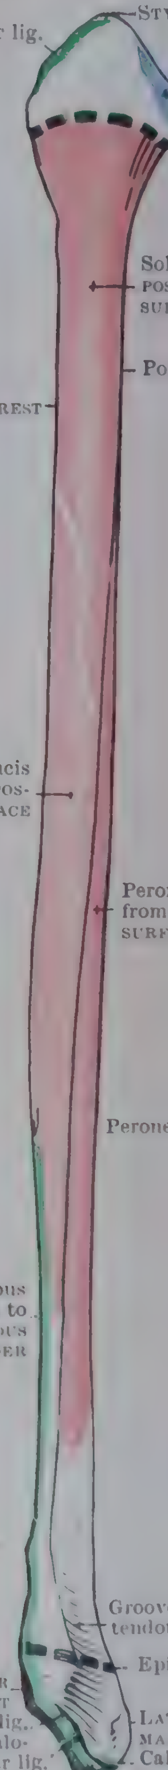

Fig. 275.—Posterior Aspect of Right Fibula.

Attachments.—The tendon of the biceps is inserted into the **head**—the main slip on the lateral side of the styloid process, and a small slip farther forwards. The lateral ligament of the

knee is attached to the head between the slips of the biceps tendon; the capsular ligament of the superior tibio-fibular joint to the margins of the *facet*; the deep fascia to the *lateral side* of the

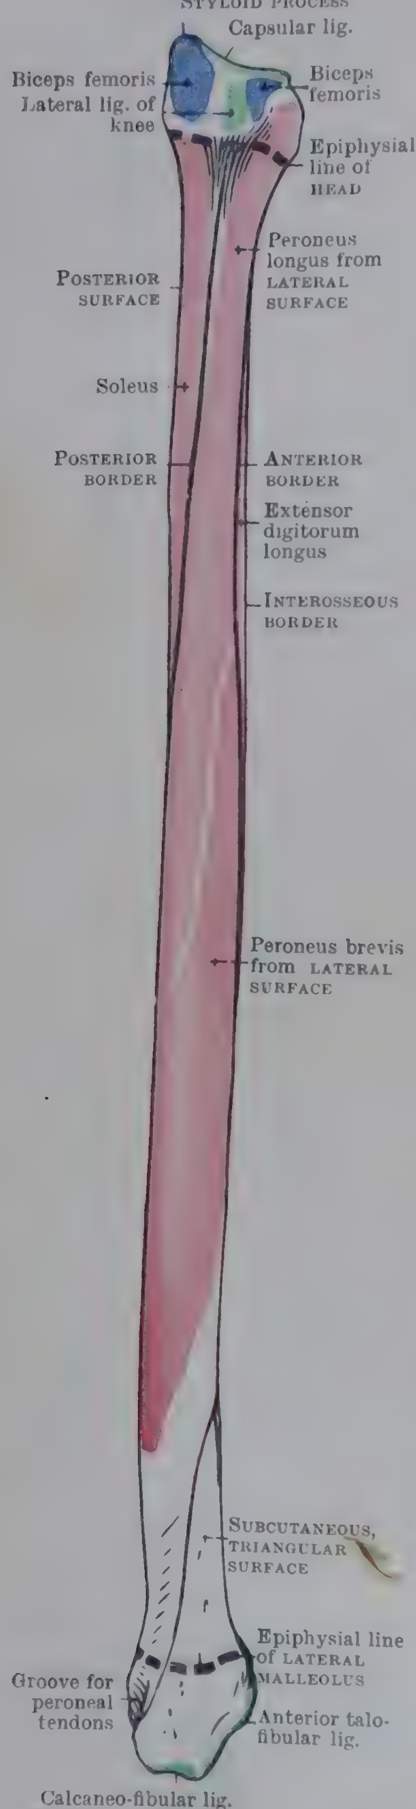

FIG. 276.—LATERAL ASPECT OF RIGHT FIBULA.

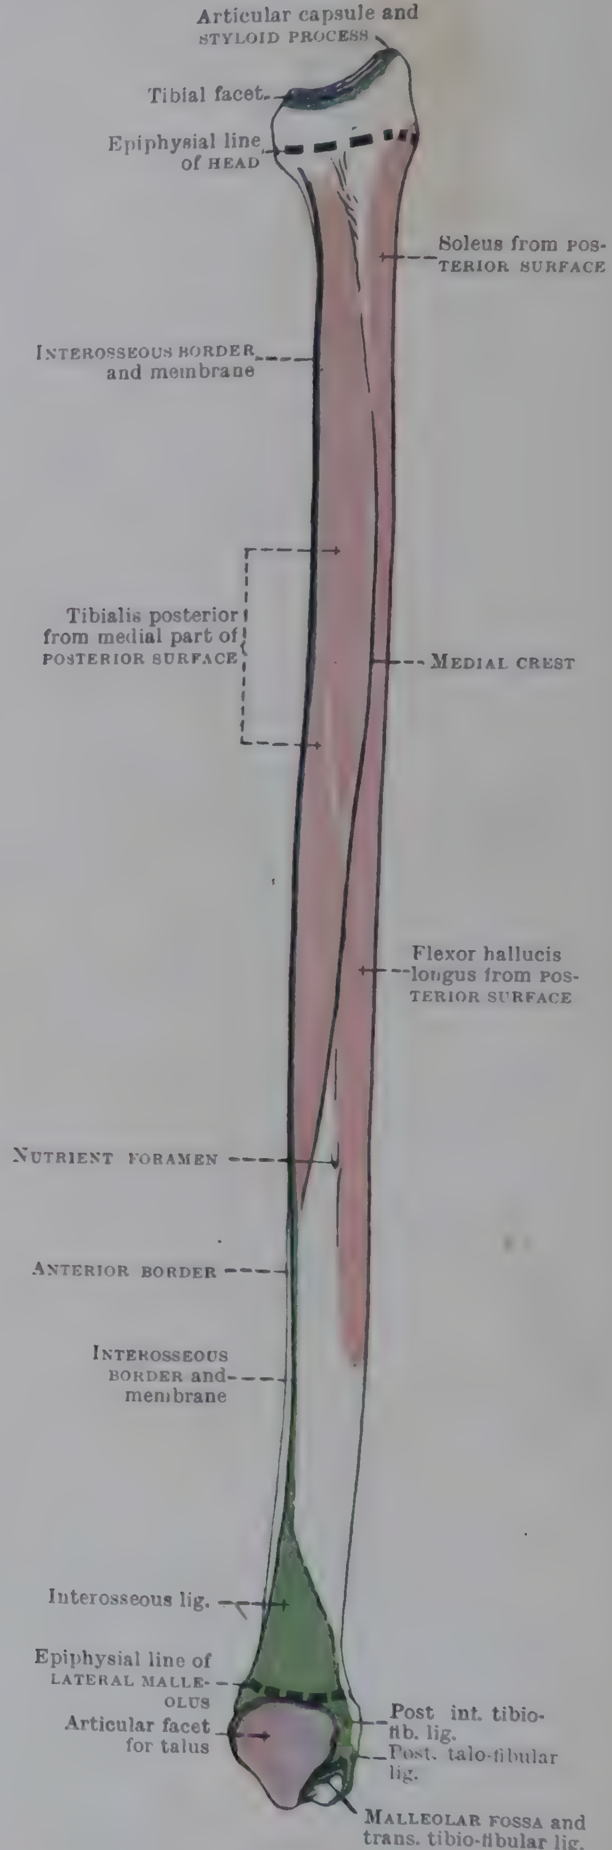

FIG. 277.—MEDIAL ASPECT OF RIGHT FIBULA.

head. The muscles that arise from the upper part of the shaft take origin also from the adjoining surfaces of the head.

The peroneus longus arises from the head and the upper two-thirds of the *lateral surface* of the **shaft**; the peroneus brevis from the lower two-thirds, overlapping the longus anteriorly in the middle third. Part of the tibialis posterior from the head and the part of the *posterior surface* between the medial crest and the interosseous border; part of soleus from the head and the upper third of the remainder of the surface, and the flexor hallucis longus from the lower two-thirds. The extensor digitorum longus from the head and the upper two-thirds of the *anterior surface*; the peroneus tertius from the lower third; and, medial to those two, the extensor hallucis longus from the middle three-fifths. The interosseous membrane is attached to the *interosseous border*; the fascia over the tibialis posterior to the *medial crest*; the posterior intermuscular septum to the *posterior border*; the anterior intermuscular septum to the greater part of the *anterior border*; the deep fascia of the leg to the *margins of the subcutaneous surface* (including the superior extensor retinaculum attached to its anterior margin); the interosseous ligament to the rough area above the facet at the lower end.

The anterior inferior and posterior inferior tibio-fibular ligaments are attached to the **lateral malleolus** at the anterior and posterior margins of its articular facet; the anterior talo-fibular ligament to the *anterior surface* of the malleolus near its tip; the calcaneo-fibular ligament to the *tip*; the posterior talo-fibular ligament and the transverse tibio-fibular ligament to the floor of the **malleolar fossa**; the superior peroneal retinaculum to the margins of the *posterior surface* of the malleolus.

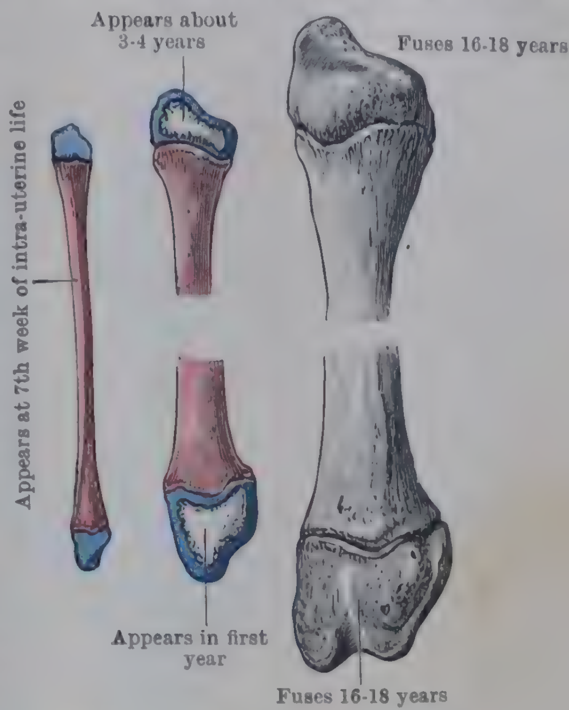

Fig. 278.—Ossification of Fibula.

Ossification (Pls. XXIV, p. 297, XXVI, p. 305).—The **primary** centre appears at the seventh week of intra-uterine life. Only the ends are cartilaginous at birth.

At the third month of intra-uterine life the fibula is nearly half as thick as the tibia, and its lower end is either at the same level as the tibial malleolus or only a very little lower. At birth it is still, compared with the tibia, much thicker relatively than in the adult; its lower end has not yet reached the adult level and does not do so until ossification has begun in it. The fibular malleolus reaches lower than the tibial in only a few vertebrates besides Man, *e.g.*, elephant, leopard, walrus; and Man vies with the Elephant in that respect. Its importance in the construction of the ankle joint accounts for its downward extension, and probably accounts also for ossification beginning in it sooner than in the upper end.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For lower end	**M.** 1 yr. **F.** 1 yr.	**M.** 18; **F.** 16	Medial part inside, lateral part outside.
For upper end	**M.** 3-4 yr. **F.** 3 yr.	**M.** 18; **F.** 16	Outside.

Structure and Variations.—The structure is like that of other long bones. The medullary canal extends from the neck to a point about three inches from the tip of the malleolus; its lateral wall is thicker than the medial. The *nutrient canal* is one inch in length.

The fibula is occasionally absent or incompletely developed. The facet on the head may be double or may be absent.

Tarsus

The term **tarsus** originally included nearly the whole foot [ταρσός (tarsos) = the part of the foot between the toes and the heel], but it is now applied only to the posterior half of the foot, the skeleton of which consists of seven tarsal bones.

The **tarsal bones** are closely bound together by ligaments. They are arranged in two groups—a posterior group consisting of two bones related vertically to each other, the **talus** on top and the **calcaneum** or "heel-bone" below it. The anterior group is more or less horizontal and comprises five bones; four are placed side by side—three **cuneiform** bones and, lateral to them, the **cuboid** bone. The fifth is the **navicular** which is placed between the talus and the three cuneiforms (Fig. 279).

All the tarsal bones are conveniently described as having six surfaces—anterior, posterior, superior, inferior, lateral, and medial.

Sufficient knowledge of the characters of the individual bones is necessary to give a clear understanding of the structure and mechanism of the foot.

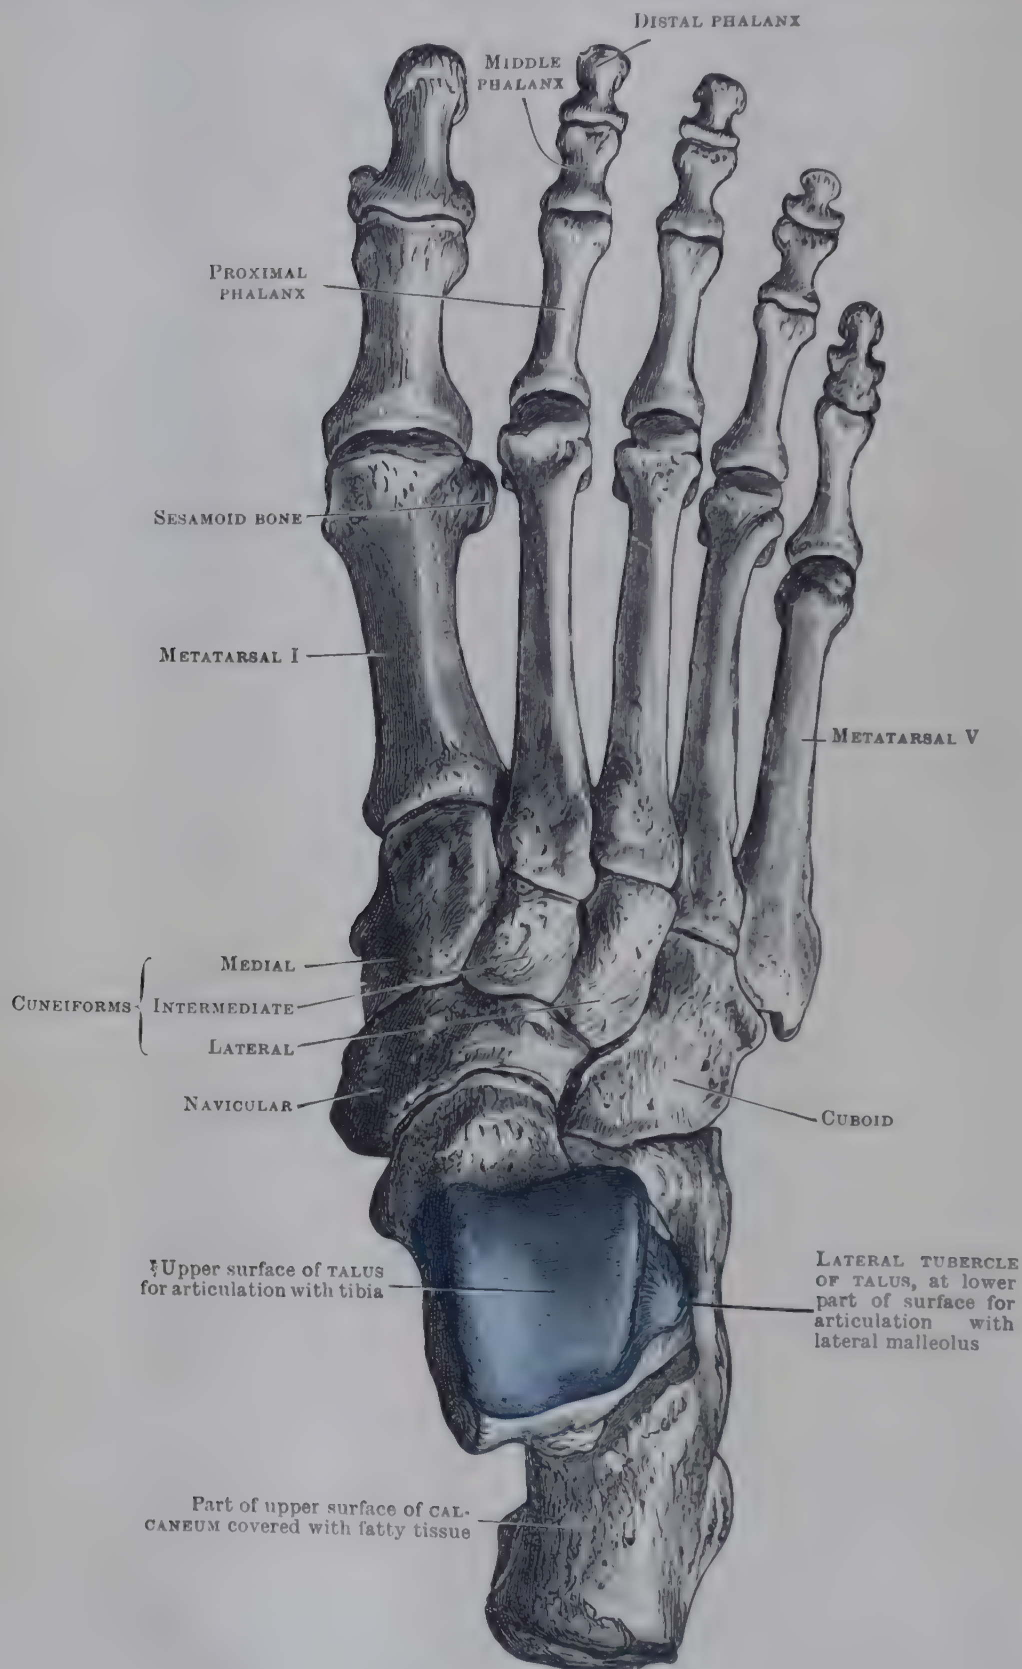

Fig. 279.—Upper or Dorsal Surface of Bones of Right Foot.

Calcaneum

The **calcaneum** is the heel-bone [*calcaneum* (allied to calx) = the heel]. It is the largest of the tarsal bones, being nearly three inches in length and about half of that in thickness.

The *anterior* and *posterior surfaces* are the ends of the bone. The anterior surface is smooth and concavo-convex, to articulate with the cuboid bone: the posterior surface is rough, and the tendo calcaneus is inserted into a specially roughened strip across the middle of the surface.

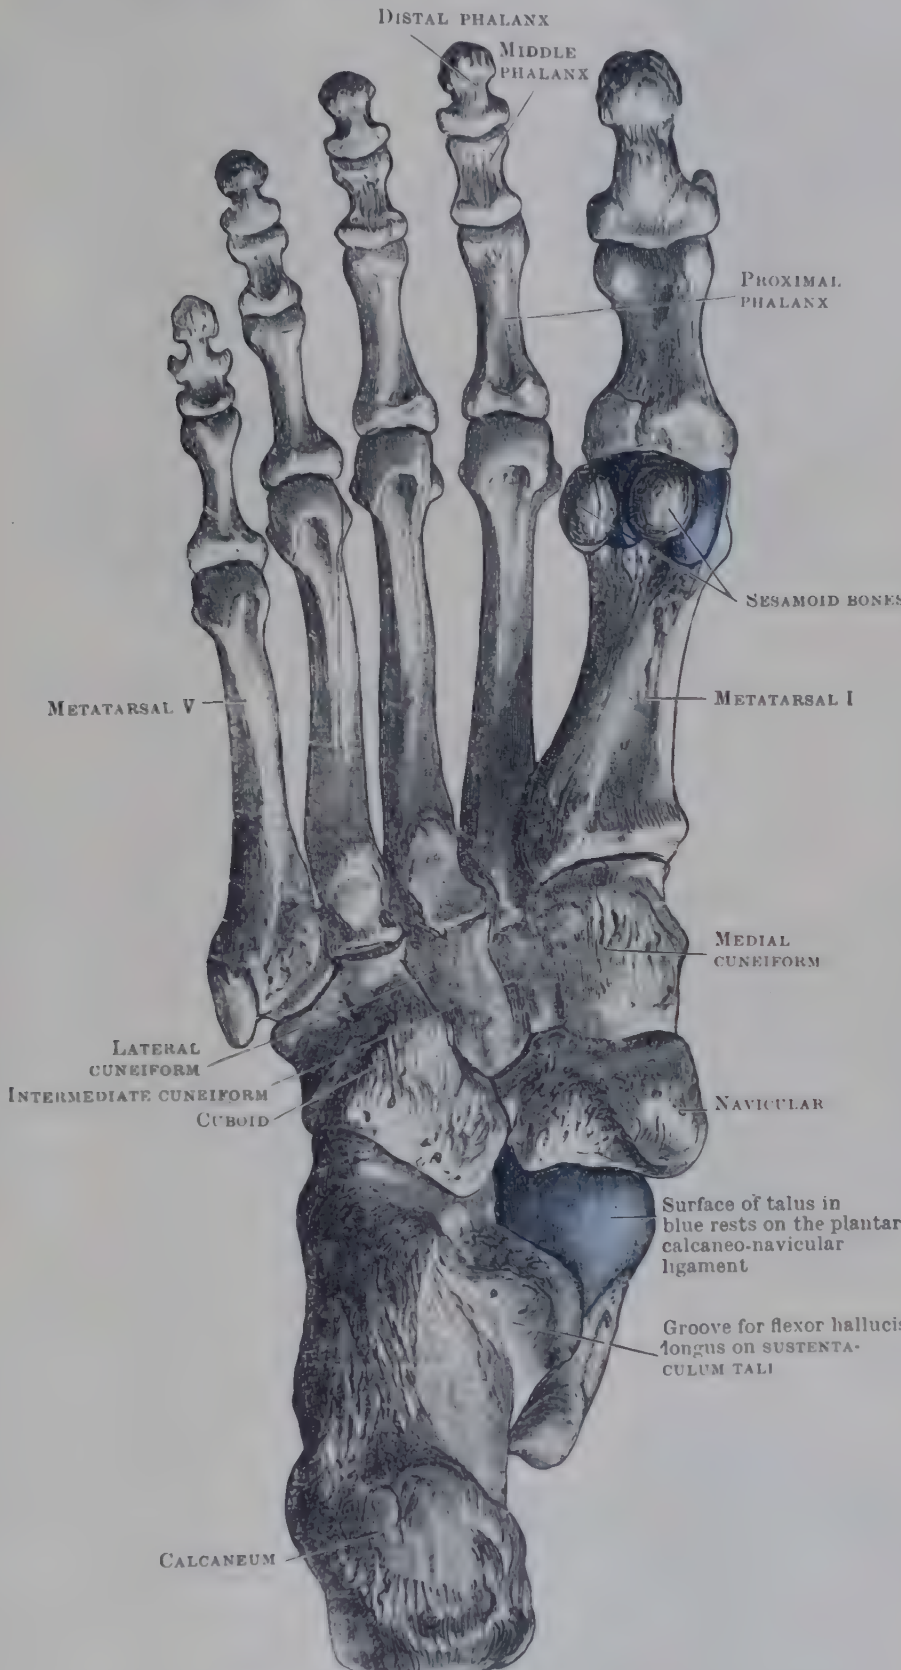

FIG. 280.—LOWER OR PLANTAR SURFACE OF BONES OF RIGHT FOOT.

The *superior surface* is distinguished from the others because it has a large, oval facet about its middle for articulation with the body of the talus. In front of the facet there is a groove for the attachment of an interosseous ligament between the talus and calcaneum (p. 394). In front of the lateral part of that groove there is

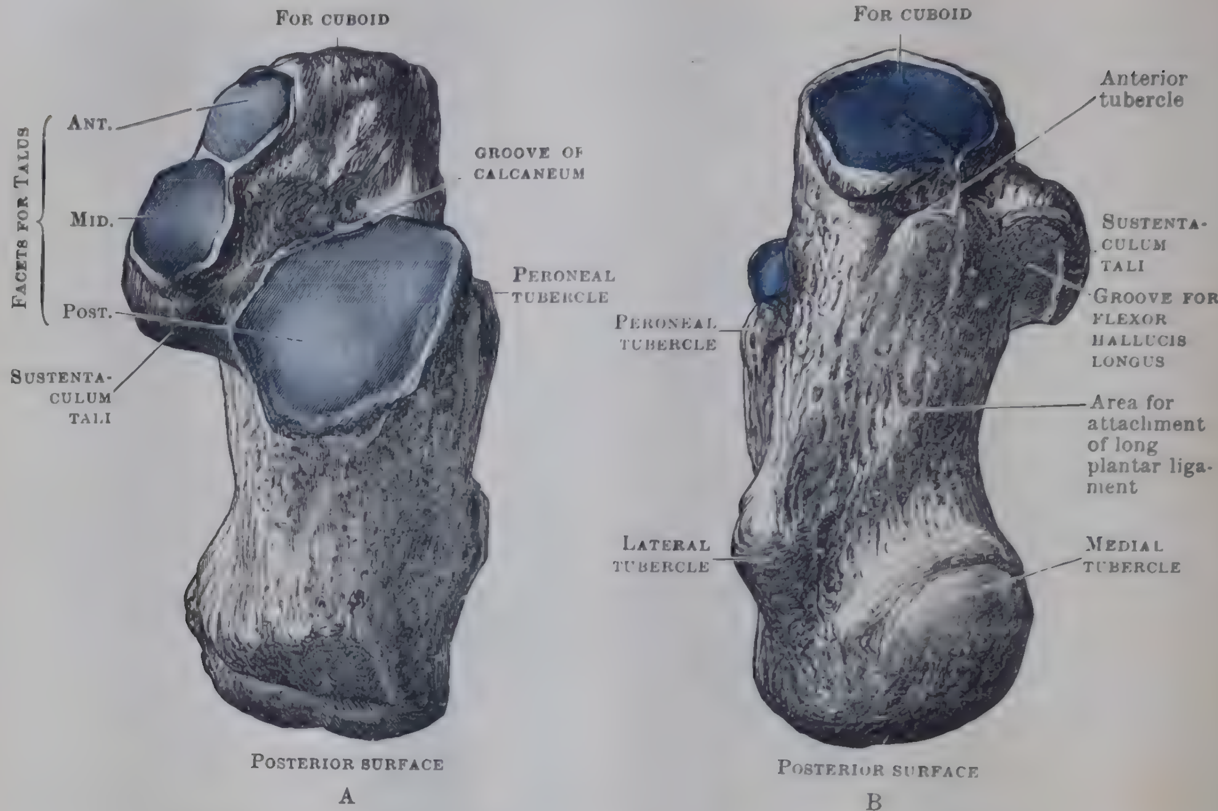

Fig. 281.—Right Calcaneum. A, seen from above; B, seen from below.

a rough, fairly flat, quadrilateral area, and at the anterior and medial corner of the area there is usually a small facet for articulation with the head of the talus. In front of and medial to the medial part of the groove, there is a projecting shelf of bone called the **sustentaculum tali** because part of the talus rests on it; the upper surface of the sustentaculum is smooth for articulation with the talus; its lower surface is grooved by the tendon of the flexor hallucis longus as it runs forwards into the sole of the foot. The medial border of the sustentaculum is thick and rough and can be felt in the living body as an ill-defined bony resistance a finger's breadth below the medial malleolus. The tendon of the flexor digitorum longus muscle lies on the medial border of the sustentaculum.

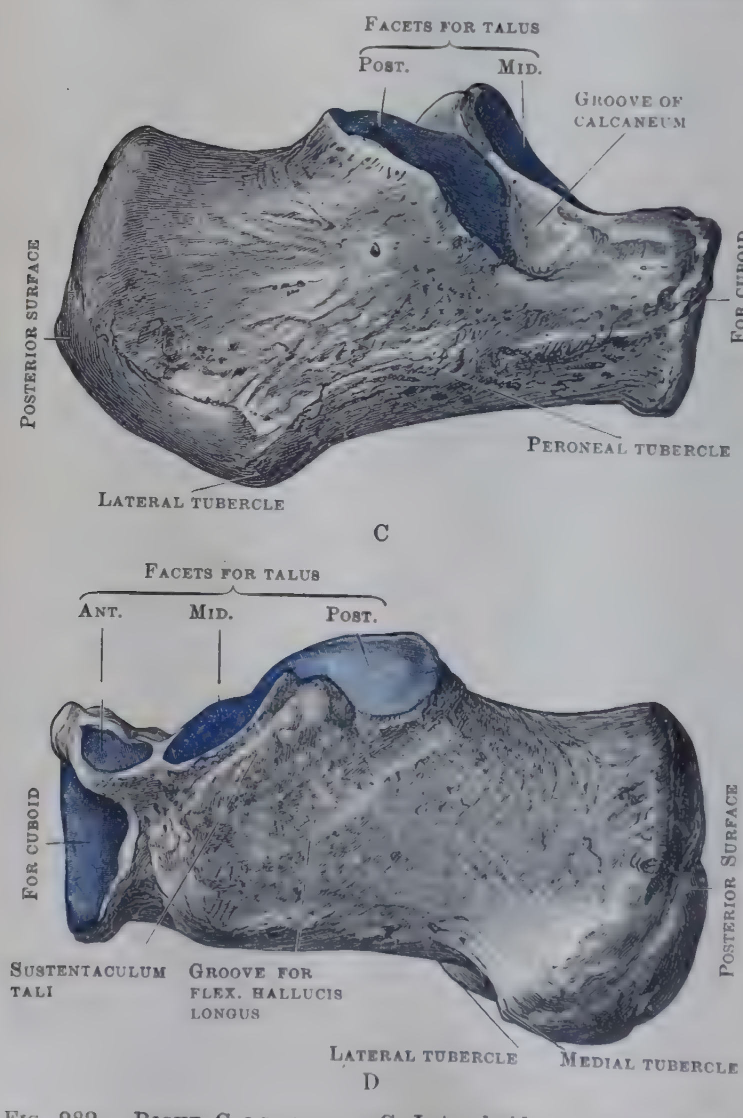

Fig. 282.—Right Calcaneum. C, Lateral side; D, Medial side.

The *inferior surface* is rough. At its anterior part there is a low, rounded eminence called the **anterior tubercle** of the calcaneum. At its most posterior part there are two blunt, rounded prominences called the **lateral** and **medial tubercles** of the calcaneum; the medial tubercle is the larger of the two. When the

calcaneum is laid on the table it rests on the three tubercles. When the sole is on the ground the long axis of the calcaneum is directed forwards, upwards and slightly sidewards; the bone rests on the backs of the lateral and medial tubercles, *i.e.*, on the lower, sloping part of the posterior surface; and the anterior part of the bone is raised up from the ground.

The *medial surface* is markedly concave owing to the projection of the medial tubercle and the sustentaculum. The *lateral surface* is slightly convex and is rough. On the anterior half of the surface, in some specimens, there is a small but well-marked **peroneal tubercle**. The tendons of the peroneus longus and brevis cross the surface obliquely—the longus below the tubercle, the brevis above it—and produce shallow grooves on the bone. Except for the strips covered by those two tendons, the whole of the lateral surface is subcutaneous and can be felt in the living foot.

The **anterior surface** is concave from above downwards and convex sideways; its margins are sharp, except medially. The **posterior surface** widens from above downwards; the upper of its three areas is crescentic in outline; the intermediate is rough for tendo calcaneus insertion; the lower has a striated appearance. The wide, saddle-shaped area behind the large facet on the **superior surface** is covered with the fatty, fibrous tissue that lies deep to the tendo calcaneus; and it varies in length with the degree of projection of the heel. The **inferior surface** is slightly concave from behind forwards and is convex from side to side. The *anterior tubercle* fades away posteriorly, but ends abruptly in front near the anterior margin, and it is separated from that margin by a shallow groove or notch. The **lateral surface** is widest at the posterior end; and its anterior third is much narrower than the rest of it. The *peroneal tubercle* is variable in position, but is usually a little below the lateral end of the rough groove of the upper surface. The wide groove or concavity that occupies the **medial surface** is oblique from above downwards and forwards; it is bridged across by the flexor retinaculum which converts it into a tunnel. The margin of the *sustentaculum tali* is sometimes grooved by the tendon of the flexor digitorum longus.

Attachments.—The tendo calcaneus is inserted into the rough strip across the middle of the *posterior surface* and is separated from the upper part of the surface by a *bursa*; the lower part of the surface is covered with the fatty pad on which the heel rests. The calcaneo-fibular ligament is attached to the middle of the *lateral surface*; the inferior peroneal retinaculum to the margins of the grooves which lodge the peroneal tendons. The flexor retinaculum and the plantar aponeurosis are attached to the **medial tubercle**, and parts of the abductor hallucis and flexor digitorum brevis arise from it; the abductor digiti minimi from both **medial and lateral tubercles**. The short plantar ligament is attached to the **anterior tubercle** and the groove in front of it; the long plantar ligament to the wide area on the *inferior surface* behind the anterior tubercle; the lateral head of the flexor accessorius arises from the lateral edge of that area, and the medial head from the *medial surface*. The deltoid ligament and the plantar calcaneo-navicular ligament are attached to the medial margin of the **sustentaculum tali**, and a slip from the tendon of the tibialis posterior is inserted into it.

The following structures, after they leave the back of the leg and turn forwards into the sole of the foot, are related to the sustentaculum tali: the tendon of the tibialis posterior lies above it, between it and the medial malleolus; the tendon of the flexor hallucis longus lies on its lower surface; the tendon of the flexor digitorum longus lies along its medial margin; the posterior tibial vessels and nerve lie between the tendons of the flexor digitorum and flexor hallucis.

The capsular ligament of the talo-calcanean joint is attached to the margins of the large, oval *facet* on the *upper surface*; the groove in front of the facet gives attachment to the interosseous talo-calcanean ligament; the rough flat area in front of the lateral end of the groove gives attachment to the stem of the bifurcated ligament, the stem of the inferior extensor retinaculum, and some fibres of origin of the extensor digitorum brevis (Fig. 347, p. 394): and the dorsal calcaneo-cuboid ligament is attached to the upper and lateral margins of the *anterior surface*.

Structure.—For the architectural features of the calcaneum, see p. 108, and Pl. II, p. 104.

Talus

The **talus**, ankle-bone or witch-bone, is next to the calcaneum in size, and it has large, smooth articular facets on several of its surfaces. It rests on the upper surface of the calcaneum, directly below the lower end of the tibia: it is held between the two malleoli, and with them and the lower end of the tibia it forms the *ankle joint* [*talus* = the ankle-bone].

The bulkier part of the talus is the *body*; the smooth and rounded end is the anterior part of the bone and is called the *head*; the rough, slightly constricted part between the head and the body is the *neck*.

The *superior surface* of the **body** is a large face for articulation with the lower end of the tibia. It is convex from before backwards, slightly concave from side

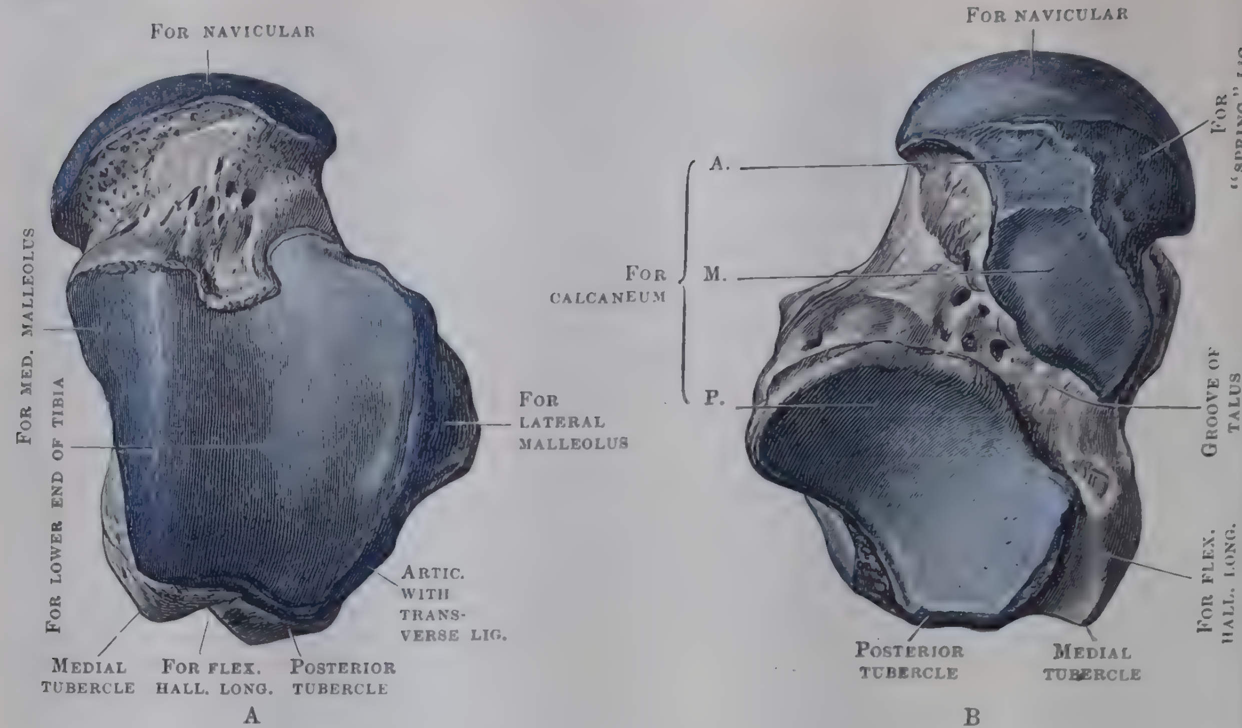

Fig. 283.—Right Talus. A, Upper surface; B, Lower surface.

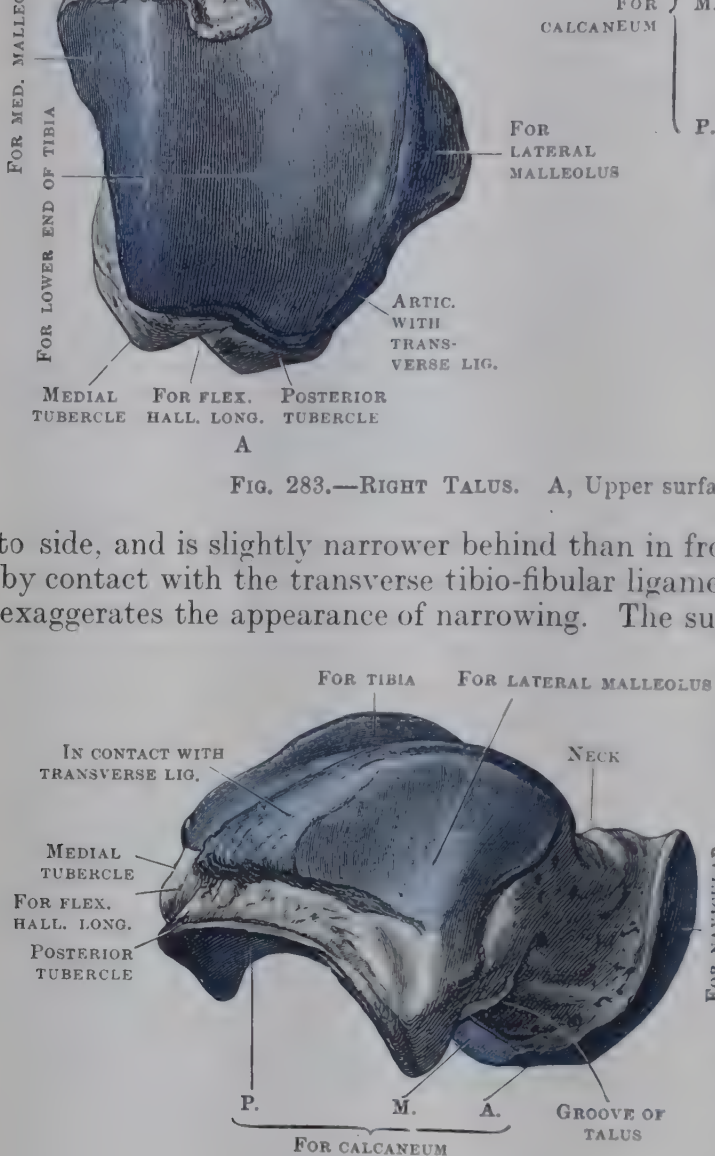
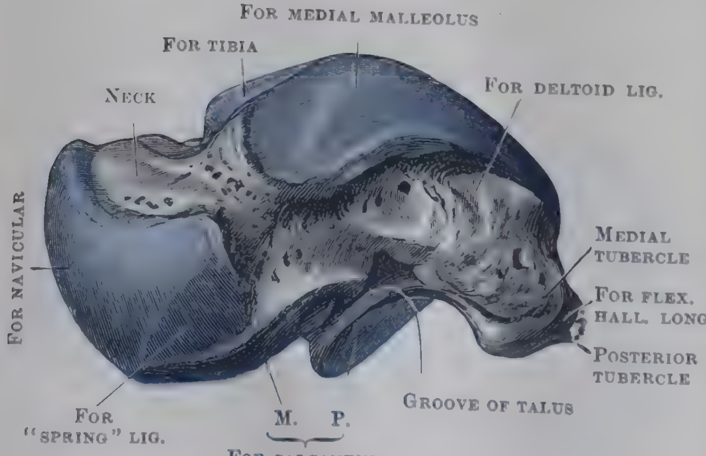
to side, and is slightly narrower behind than in front. The lateral border is bevelled by contact with the transverse tibio-fibular ligament to form a triangular area which exaggerates the appearance of narrowing. The superior and lateral surfaces and the articular part of the medial surface are sometimes, together, called the **trochlea** of the talus. The *inferior surface* has two facets with a deep groove between them. The one farther back is large, concave, and oval, with the long axis oblique, and it articulates with the large, oval facet on the upper surface of the calcaneum. The one in front is on body, neck, and head; it articulates with the sustentaculum tali and with the facet on the anterior part of the upper surface of the calcaneum; it varies in its extent, and the part on the head may be separate from the rest.

The *medial surface* can be distinguished from the lateral surface because it is nearly all rough and is flush with the medial side of the neck. Near the upper margin there is a comma-shaped facet for articulation with the medial malleolus.

The *lateral surface* stands away from the neck, and it is nearly all occupied by a large facet for articulation with the lateral malleolus. The posterior part of the facet is united to the upper surface by the triangular facet mentioned above.



Lateral side.



Medial side.

Fig. 284.—Right Talus.

The *posterior surface* is very small. It is crossed by a fairly broad, oblique groove that lodges the tendon of the flexor hallucis longus. When the talus and calcaneum are placed together properly, that groove is continuous with the groove for the same tendon on the lower surface of the sustentaculum tali. The projection on the lateral side of the groove is the **posterior tubercle** of the talus, and the rough prominence on the medial side is the **medial tubercle**.

The *anterior surface* is the convex, smooth surface of the **head**; it articulates with the navicular bone. The facet on the lower surface of the head for articulation with the anterior part of the upper surface of the calcaneum is usually continuous with the facet that articulates with the sustentaculum tali. The lower part of the medial side of the head articulates, not with a bone but with the plantar calcaneo-navicular or "spring" ligament, which stretches between the sustentaculum tali and the plantar surface of the navicular bone; a faint ridge often marks off that area from the rest of the articular surface of the head.

When the talus and calcaneum are placed together, the grooves which give attachment to the interosseous ligament (p. 394) form a tunnel called the **canalis tarsi** which expands at its antero-lateral end to form the **sinus tarsi** (Wood Jones, 1944). The head of the talus looks in a medial direction as well as forwards. The articular facet on the lateral surface of the body is concave from above downwards; at its lower angle the bone projects laterally to form the **lateral tubercle**. On the medial surface, below the tail of the articular comma, there may be a circular or oval impression for the attachment of part of the deltoid ligament.

Inversion is the movement whereby the medial border of the foot is lifted up, the lateral border is depressed, and the sole looks towards the median plane. **Eversion** is the reverse movement whereby the lateral border of the foot is lifted up. Movement at the ankle joint is almost entirely flexion and extension, taking place between the tibio-fibular socket and the body of the talus, and the anterior part of the body is uncovered by the tibia in full extension. Inversion and eversion are movements of the rest of the foot below the talus and round the head of the talus, which is partially uncovered in full inversion (p. 398). When the foot is extended so that it is almost in line with the leg, and is inverted, the head of the talus can be both felt and seen as a distinct prominence about an inch in front of and below the ankle joint, and the body of the talus also may be felt near the lateral malleolus.

Attachments.—The anterior ligament of the ankle joint and the dorsal talo-navicular ligament are attached to the *upper surface* of the **neck**; the anterior talo-fibular ligament to the *lateral surface*; a part of the deltoid ligament to the *medial surface* of both neck and **body**; the capsular ligament of the talo-calcanean joint to the margins of the large, oval facet on the *lower surface* of the body; the interosseous ligament to the floor of the *groove* in front of that facet; the posterior ligament of the ankle joint to the upper part of the *posterior surface*; the posterior talo-fibular ligament to the **posterior tubercle**. No muscle or tendon is attached to the talus.

Cuboid Bone

The **cuboid** bone may be picked out from the other smaller tarsal bones because of its more cubical shape and the ridge and groove on its inferior surface. It lies in the lateral margin of the foot in front of the calcaneum.

The *anterior* and *posterior surfaces* can be distinguished from the others because they are both wholly articular. The posterior surface is concavo-convex, slopes from behind forwards and sidewards, and articulates with the calcaneum. The anterior surface is nearly flat; it slopes backwards from medial to lateral side, but its slope is not so great as that of the posterior surface; a faint vertical ridge divides it into two parts which articulate with the bases of the fourth and fifth metatarsal bones.

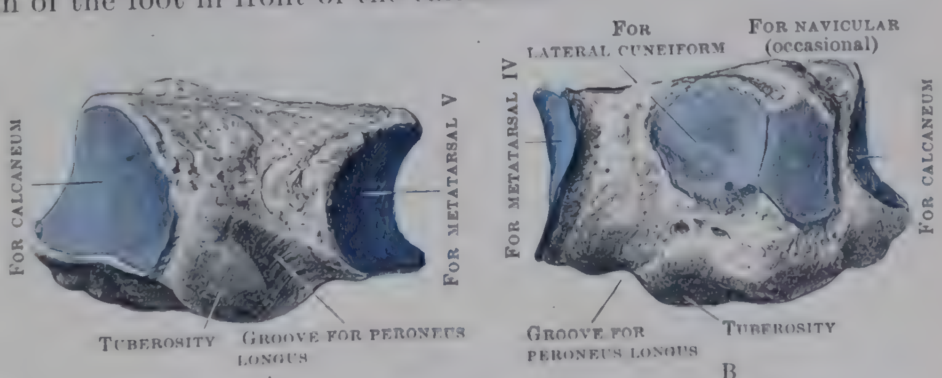


FIG. 285.—RIGHT CUBOID BONE. A, Lateral Side; B, Medial Side.

The *superior surface* is distinguished from the others because it is nearly flat and is rough—having no articular facet. Owing to the slope of the dorsum of the foot from medial to lateral border, the upper surface of the cuboid is flush, not with the upper surface of the calcaneum but with the lateral surface when the bones are placed together properly. The *inferior surface* is rough and uneven. Close to its anterior margin it is crossed by a fairly deep groove which lodges the tendon of the peroneus longus as it crosses the sole of the foot; the posterior boundary of the groove is a broad, prominent ridge, the lateral end of which is called the **tuberosity.**

The *lateral surface* is the smallest of all the surfaces, owing to the slope of the other surfaces, and it looks downwards as well as in a lateral direction. It is occupied by the tuberosity and the lateral end of the groove seen on the plantar surface. On the antero-lateral aspect of the tuberosity there is often a smooth facet produced by contact with a sesamoid bone or cartilage which lies in the substance of the peroneus longus tendon as the tendon turns into the sole. The *medial surface* is large and rather uneven; about its middle there is a facet for articulation with the lateral cuneiform bone; and, behind that facet and continuous with it, there may be another, smaller facet for articulation with the navicular bone.

The long peroneal tendon traverses the whole length of the groove on the lateral and lower surfaces; and the groove is lined throughout with the synovial sheath of the tendon. The facet for the peroneal sesamoid is, however, not in line with the groove. The tendon, as it enters the groove, expands, so that the part of it which contains the sesamoid articulates with the facet while its upper edge lies in the groove. The sesamoid glides obliquely on the facet during the movements of eversion and inversion; during inversion the tendon is partly drawn off the facet and then occupies the lateral end of the groove more completely.

Attachments.—Dorsal, plantar, and interosseous ligaments that bind the **cuboid** to neighbouring bones are attached to the rough parts of its surfaces. The long plantar ligament is attached to both *lips* of the **groove** on the *plantar surface* and holds the peroneus longus tendon in place. A slip from the tendon of the tibialis posterior is inserted into the medial part of the groove; and a slip of the flexor hallucis brevis arises from the medial part of the area behind the ridge.

Navicular Bone

The **navicular bone** is readily identified because one of its two large surfaces is markedly concave—hence its name, from a fancied resemblance to a boat. It lies in the medial side of the foot in front of the talus; and it is compressed from before backwards.

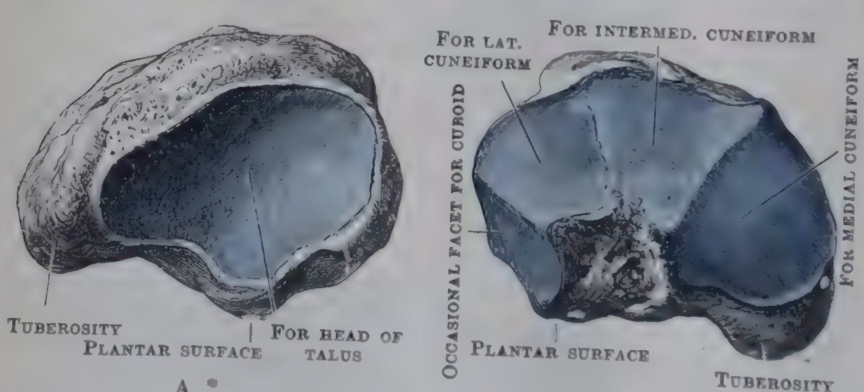

Fig. 286.—Right Navicular Bone.
A, Posterior aspect; B, Anterior aspect.

The *posterior surface* is the large, smooth, concave surface, and it articulates with the head of the talus. The *anterior surface* also is smooth, but it is slightly convex, and is mapped out by faint ridges into three areas for articulation with the three cuneiform bones. The *superior surface* is rough and is convex in its longer measurement. The *inferior surface* also is rough, but it is much smaller than the dorsal surface and is very uneven.

The *medial surface* is modified into a rough projection called the **tuberosity** of the navicular bone. This tuberosity is an important landmark and can be felt on the medial side of the foot about an inch below and in front of the medial malleolus. When shoes are worn the tuberosity is felt at the edge of the shoe. Close to the tuberosity, on the plantar surface, there is a shallow, oblique groove that lodges the smaller, deeper part of the tendon of the tibialis posterior as it

runs forwards in the sole. The *lateral* surface is not marked off from the superior surface by any definite line; it is small and usually rough, but it may be faceted to articulate with the cuboid bone.

Attachments.—Dorsal and plantar ligaments are attached to the rough parts and bind the **navicular** bone to adjacent bones. The most important is the plantar calcaneo-navicular ligament (or "spring" ligament), which stretches from its *plantar surface* to the sustentaculum tali. The anterior fibres of the deltoid ligament are attached to the **tuberosity**, which receives also a great part of the tendon of the tibialis posterior.

Cuneiform Bones

The three **cuneiform** bones are wedge-shaped [*cuneus* = a wedge]. They lie side by side in front of the navicular bone and link it with the medial three metatarsal bones. Their anterior and posterior surfaces are occupied by smooth articular facets. The medial cuneiform is the largest and most important; the intermediate one is the smallest and is the most definitely wedge-shaped.

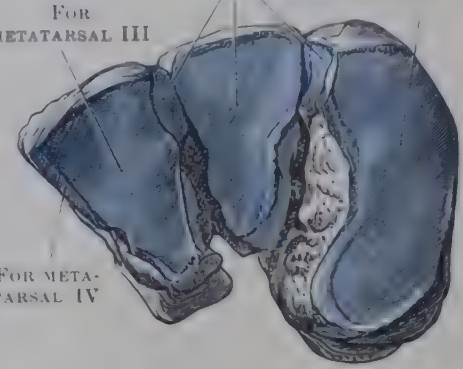

Fig. 287.—Anterior aspect of Cuneiform Bones of Right Foot.

The **medial cuneiform** lies in the medial side of the foot and is the bone felt in front of the tuberosity of the navicular bone. The *anterior surface* is kidney-shaped in outline, the concave edge being its lateral margin; it articulates with the base of the first metatarsal bone. The *posterior surface* is concave and pear-shaped, with the stalk of the pear upwards; it articulates with the navicular bone. The *lateral surface* is uneven and slightly concave; it has facets near its posterior and upper margins for articulation with the intermediate cuneiform and with the medial side of the base of the second metatarsal bone. The *medial surface* is the largest of the surfaces and is rough, and, in conformity with the shape of the medial side of the foot, it is convex from above downwards. At the most anterior and lowest part there is a smooth impression, resembling a facet, for the insertion of the tendon of the tibialis anterior, under which a bursa may lie. The *inferior surface* is rough and is the base of the wedge. The *superior surface* is reduced to a border—the edge of the wedge—between the lateral and medial surfaces, and it slopes downwards and backwards, because the posterior surface is smaller than the anterior.

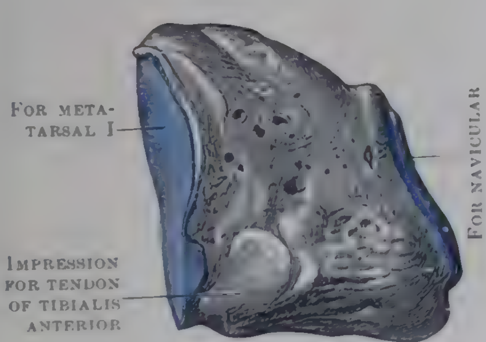

Fig. 288.—Right Medial Cuneiform (Medial Side).

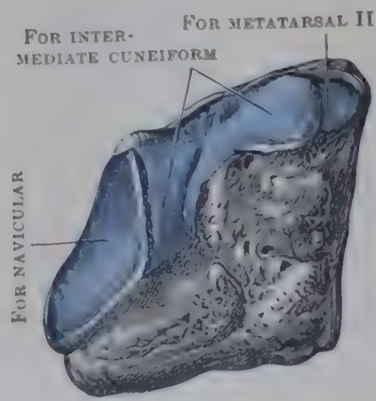

Fig. 289.—Right Medial Cuneiform (Lateral Side).

The **intermediate cuneiform** is the smallest of the tarsal bones. Its *superior surface* is square in outline, rough and slightly convex, and is the base of the wedge. The *inferior surface* is reduced to a rough border between the medial and lateral surfaces, and is the edge of the wedge. The *anterior* and *posterior surfaces* are triangular in outline: the anterior is slightly convex and articulates with the base of the second metatarsal bone; the posterior is slightly concave and articulates with the navicular bone. The *medial surface* has a facet along its upper border and another along its posterior border, both for articulation with the medial

cuneiform and usually confluent to form a single L-shaped facet. The rest of the surface is rough. The *lateral surface* has a facet along its posterior border for articulation with the lateral cuneiform, and the rest of it is rough. The facet along the upper border distinguishes the medial surface from the lateral surface; the facets along the posterior borders enable one to distinguish the posterior surface from the anterior, if that has not been done already.

The **lateral cuneiform** is larger than the intermediate cuneiform—if both specimens are from the same skeleton. If they are not, a large intermediate cuneiform can be identified by its square superior surface.

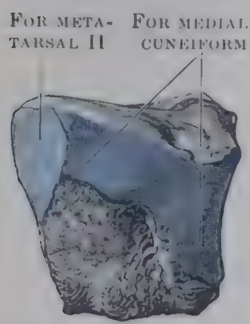

Fig. 290. — Right Intermediate Cuneiform (Medial Side).

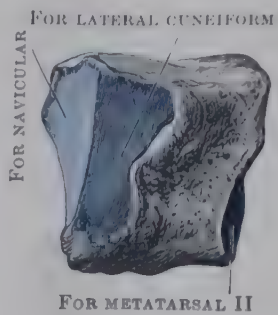

Fig. 291. — Right Intermediate Cuneiform (Lateral Side).

The *superior surface* of a lateral cuneiform is oblong in outline, rough and nearly flat, and is the base of the wedge; its anterior part turns medially, so that its long axis is slightly bent and its lateral border is angulated. The *inferior surface* is reduced to a rough, thick border between the medial and lateral surfaces, and is the edge of the wedge. The *anterior surface* is covered with a facet for articulation with the base of the third metatarsal bone, and is nearly triangular in outline. The upper and larger part of the *posterior surface* is covered with a quadrangular facet for articulation with the navicular bone, and the small, lower part is rough. The *medial surface* has a narrow facet along its posterior border for articulation with the intermediate cuneiform, and usually two small facets along its anterior border for articulation with the lateral side of the base of the second metatarsal bone; the rest of the surface is rough. The *lateral surface* is usually wider from before backwards than the medial surface; and it has a small facet at its anterior border for articulation with the medial side of the base of the fourth metatarsal bone. It has also a large facet in its upper posterior corner; that facet distinguishes the lateral surface from the medial surface, distinguishes the lateral cuneiform from the intermediate, and enables one to identify the posterior surface, for it lies close to the posterior border; it articulates with the cuboid bone. The rest of the lateral surface is rough.

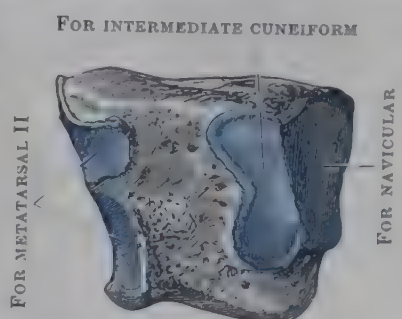

Fig. 292.—Right Lateral Cuneiform (Medial Side).

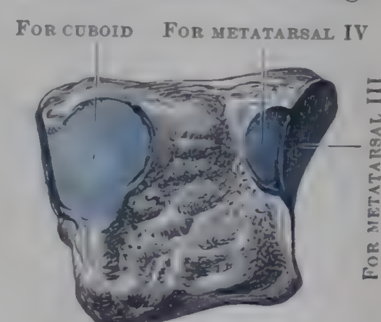

Fig. 293.—Right Lateral Cuneiform (Lateral Side).

When the three cuneiform bones are fitted together, their posterior surfaces are nearly flush, for they all articulate with the front of the navicular bone. The intermediate cuneiform is shorter than the other two; a gap is left, therefore, between the medial and the lateral and in front of the intermediate one. (See Fig. 279.) The base of the second metatarsal bone fits into the gap. This metatarsal bone, therefore, articulates posteriorly with the intermediate cuneiform, and at the sides with the medial and the lateral—an arrangement which increases the stability of the foot, but adds to the difficulty of amputating the foot at the tarso-metatarsal joints. The intermediate and lateral cuneiform bones are placed edge downwards and are of less depth than the first; the plantar surfaces of the cuboid bone and the medial cuneiform are therefore not far apart.

Attachments.—The three **cuneiform** bones are united to one another and to adjacent bones by dorsal, plantar, and interosseous ligaments. A large part of the tendon of the tibialis posterior is inserted into the posterior part of the *inferior surface* of the **medial** cuneiform, and it sends slips to the inferior surfaces of the **other two**. The greater part of the tendon of the tibialis anterior is inserted into an impression situated low down and far forward on the *medial surface* of the **medial** cuneiform, and the smaller part of the peroneus longus tendon is inserted into an impression at

the corresponding point on its *lateral surface.* The medial cuneiform, therefore, receives parts of the tendons of the tibialis anterior, tibialis posterior, and peroneus longus, while the intermediate and lateral cuneiform bones get only slips from the tibialis posterior.

Metatarsus

The **metatarsus** is in front of the tarsus and is the skeleton of the anterior or distal half of the foot proper [μετά (meta) = next after]. It consists of five separate **metatarsal bones**—one corresponding to each toe. They are named by number—*first*, *second*, etc., beginning with the one for the big toe. Each metatarsal is a miniature long bone, having a **shaft** and **two ends**. They are slightly concave lengthwise on the inferior or plantar surface; the rounded end is the **anterior** or distal end and is called the *head*; the **posterior** end is larger and forms the *base*.

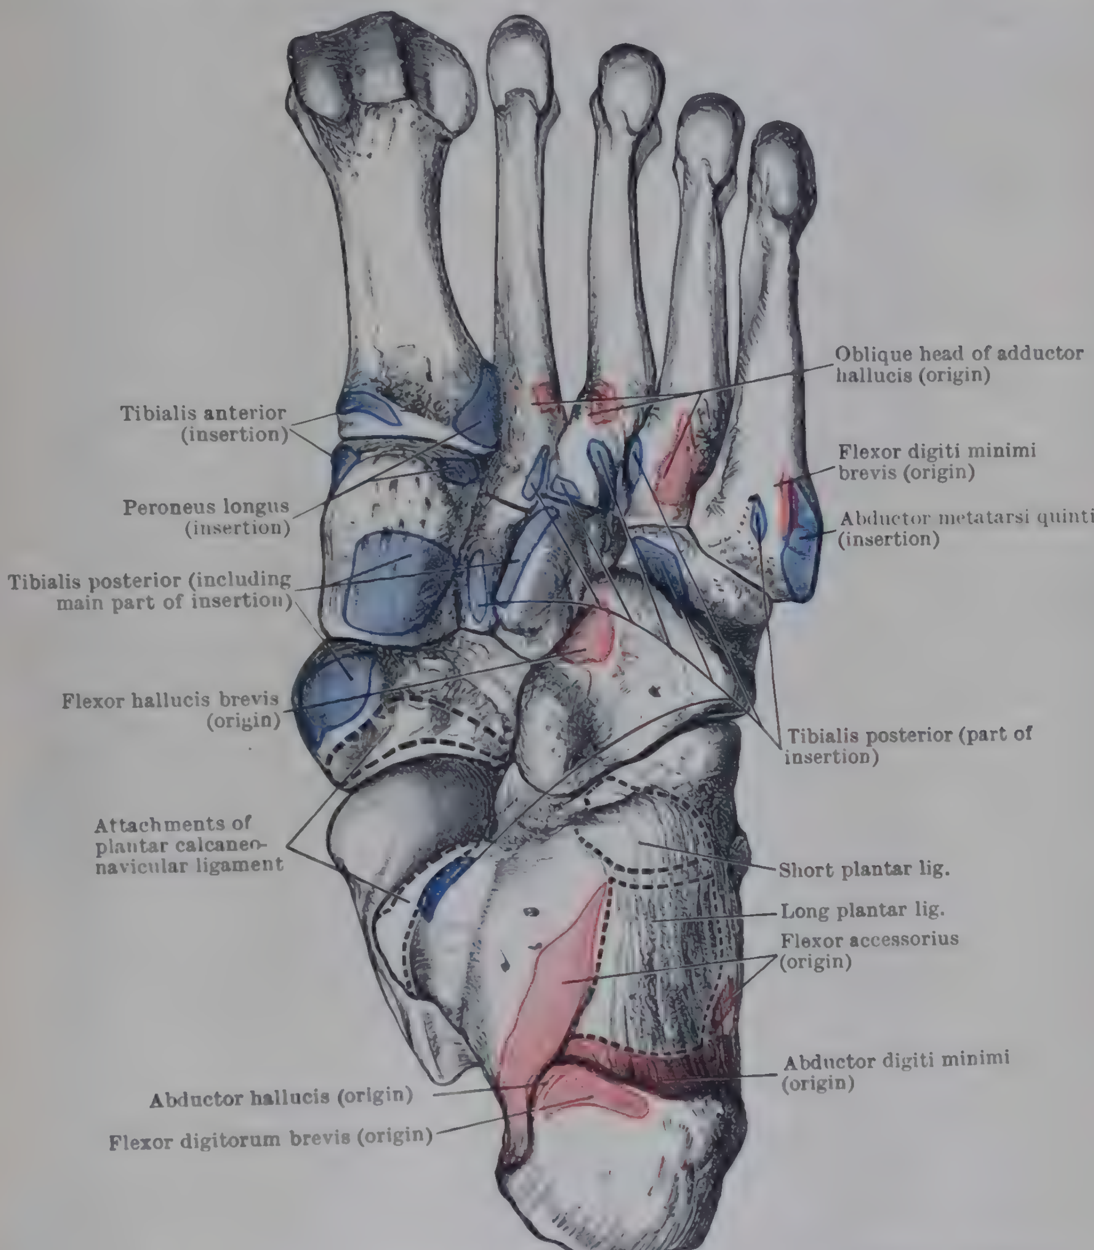

Fig. 294.—Muscle Attachments to Left Tarsus and Metatarsus (Plantar Aspect).

The corresponding bones of the hand are *metacarpal bones*. The metatarsal bones are more flattened from side to side than the metacarpals and, except in the case of the first, the shaft tapers to a narrow head. A metacarpal has on its dorsal surface a long, flat, triangular area, the base of which is at the wide, rounded head of the bone. Metatarsal bones have no such area. The metatarsals are about three inches long, and they are rather longer than the metacarpals if the bones are from

the same skeleton. The first metatarsal and metacarpal bones each have their own special characters.

The bases of the metatarsal bones are firmly bound to the tarsus by ligaments, and their *posterior surfaces* articulate with the tarsus, forming *tarso-metatarsal joints.* The bases of the lateral four are tightly bound to each other and articulate *side by side,* forming *intermetatarsal joints*; the base of the first sometimes articulates with that of the second but is usually free.

FIG. 295.—RIGHT FIRST METATARSAL BONE (Plantar Aspect).

The **heads** articulate with the proximal row of phalanges, forming *metatarso-phalangeal joints.* The sides of the heads have grooves and tubercles for the attachment of the collateral ligaments of these joints. The articular part extends much farther on to the plantar surface than on to the dorsum, because when the toe is *flexed* (*i.e.,* moved towards the sole) the base of the phalanx articulates with the plantar surface of the head of the metatarsal; when the toe is *extended* it is in a straight line with the metatarsal, and the base of the phalanx articulates with the distal surface of the head. *Dorsiflexion* or *hyperextension* is the movement of bending the toe upwards out of line with the metatarsal; the degree to which it is possible varies in different people but is never great, and the articular surface of the head extends, therefore, very little on to the dorsum.

The **first metatarsal bone** can be felt in all its length in the medial side of the foot. Its **base**—looked at end-on—is kidney-shaped, with the long axis vertical, and the notched or concave side is the *lateral* side. It articulates with the medial cuneiform bone. The **head** is slightly compressed from above downwards, and it has two well-marked grooves on its lower or *plantar* surface for articulation with two sesamoid bones. The **shaft** is three-sided with dorsal, plantar, and lateral surfaces which can be identified by reference to the head and base.

The **fifth metatarsal bone** is easily distinguished from the others because it is compressed from above downwards, has a relatively small **head**, and has a large **tubercle** on the *lateral* side of the **base**. The bone can be felt in its whole length in the lateral border of the foot, and the tubercle makes the prominence—seen as well as felt—about midway between the heel and the little toe. The posterior surface of the base articulates with the cuboid.

A line drawn from the base of the first metatarsal to the tubercle of the fifth slants backwards, and corresponds fairly closely to the position of the tarso-metatarsal joints. These joints and the posterior surfaces of the bases of the lateral four metatarsals therefore slope backwards from medial to lateral side; consequently, the lateral surface of a metatarsal is longer than the medial surface and can be distinguished at a glance.

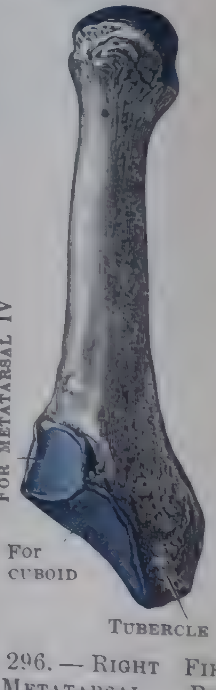

FIG. 296.—RIGHT FIFTH METATARSAL BONE (Dorsal Aspect).

The **second** and **third metatarsal bones** are very much alike. They are compressed from side to side in all their length; the posterior surface of the base is nearly triangular in outline and articulates with a cuneiform bone. But they can be distinguished if the *lateral* surface of the base is examined: the lateral surface of the **second** has two facets—an upper and a lower—separated by a horizontal groove, and one or both of the facets are double; for the base of the second metatarsal fits in between the lateral and medial cuneiform bones, articulating with them, and the lateral surface articulates also with the base of the third metatarsal.

The **head** and **shaft** of the **fourth metatarsal bone** resemble those of the second and third, but the base is more irregular, is more cuboidal in shape, and its posterior surface, which

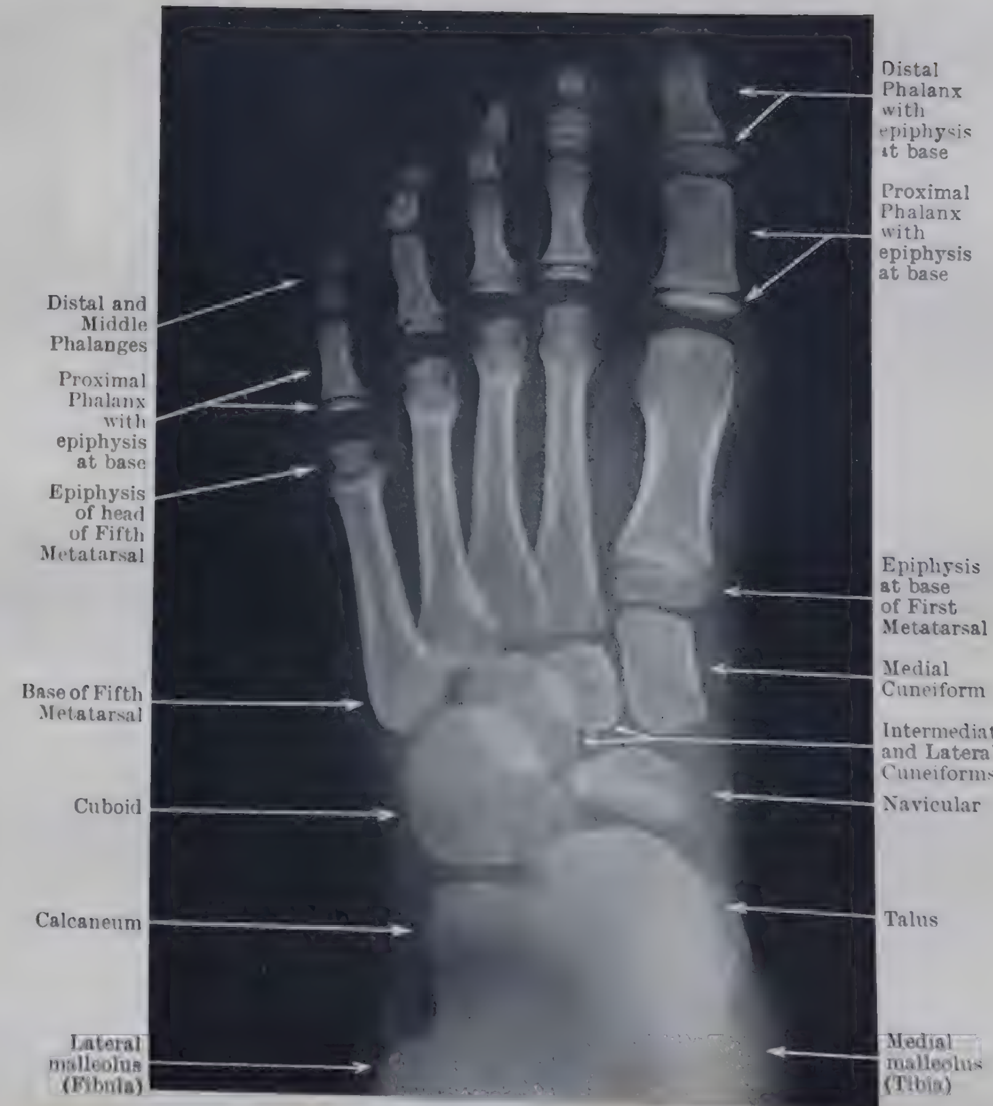

FIG. 2.—RADIOGRAPH OF FOOT OF BOY AGED 7. (Dr. J. Duncan White.)

Cf. Plate XVIII, Fig. 2, noting that the Tarsus is more advanced in ossification than the Carpus, but that the Phalanges of the Toes are less advanced than those of the Fingers.

[Facing p. 321]

articulates with the cuboid, is more nearly square in outline. The *lateral surface* of the **base** has a large facet bounded by an oblique groove; in that respect it resembles the lateral surface of the third, but the medial surfaces are quite different: the *medial surface* of the **third** has two small facets, an upper and a lower; the *medial surface* of the **fourth** has a large facet which is usually divided, for it articulates not only with the base of the third metatarsal but also with the lateral surface of the lateral cuneiform bone.

The articular surface of the head is bounded, on the sides and superiorly, by a groove—better marked in the smaller metatarsals than in the first. On each side the upper part of the groove is bounded posteriorly by a smooth tubercle. The edge of the plantar part of the articular surface is notched in the middle. The boundaries of the notch end posteriorly as pointed tubercles. The groove on the first for the medial sesamoid is usually the wider (Fig. 294.)

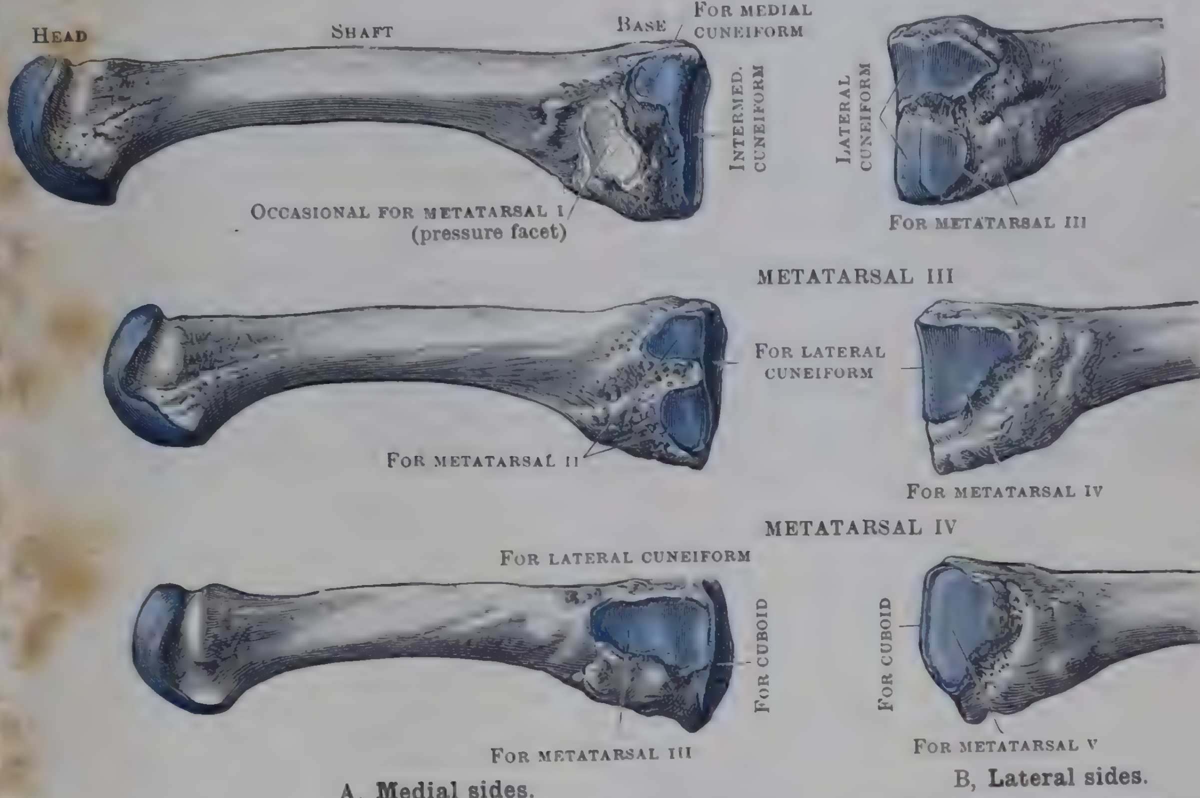

FIG. 297.—VIEW OF BASES AND SHAFTS OF SECOND, THIRD, AND FOURTH METATARSAL BONES OF RIGHT FOOT. NOTE THAT THE SECOND IS THE LONGEST.

Attachments.—In the case of *each metatarsal*, collateral ligaments pass from the sides of the **head** to the sides of the base of the proximal phalanx, and the plantar ligament closes in the metatarso-phalangeal joint below, being attached loosely to the plantar surface of the metatarsal immediately behind the head, and firmly to the plantar surface of the base of the phalanx; the extensor tendon either takes the place of a dorsal ligament or is fused with it. Dorsal, plantar, and interosseous ligaments bind the **bases** to one another and to the tarsus.

Slips of the long plantar ligament are attached to the plantar surfaces of the **bases** of the *second, third*, and *fourth* metatarsals; slips of the tibialis posterior tendon are inserted into these bases, and the oblique head of the adductor hallucis arises from them. One head of a dorsal interosseous muscle arises from each side of the **shaft** of each of these three bones, and the first and second plantar interosseous muscles arise respectively from the third and fourth.

The smaller part of the tendon of the tibialis anterior is inserted into an impression on the medial side of the **base** of the *first* metatarsal bone near the sole, and the greater part of the peroneus longus tendon into a smooth impression on the prominent, lowest part of the lateral side; one head of the first dorsal interosseous muscle arises from the lateral surface of the **shaft**.

The peroneus brevis and tertius are inserted into the dorsum of the **base** of the *fifth* metatarsal; part of the flexor digiti minimi brevis arises from the plantar surface. The abductor metatarsi quinti (when present) and a strong band of the plantar fascia are inserted into the *tubercle*. The third plantar interosseous muscle arises from the plantar surface of the **shaft**, and one head of the fourth dorsal interosseous from the medial surface.

Phalanges of Toes

Each **phalanx** is a miniature long bone, possessing a **shaft** and **two ends** [φάλαγξ (phalanx) = a round log or roller]; the **proximal** or posterior end is the larger end and is the *base*; the **distal** end is the *head*. The proximal phalanx of a

toe is about the same length as the middle phalanx of a finger, but it can be picked out from among phalanges of fingers because its base is larger, and its shaft is relatively more attenuated; the proximal phalanx of the big toe, on the contrary, is thicker than any other phalanx. The middle and distal phalanges of the toes are so short that they cannot be mistaken either for the proximal phalanges of toes or for the phalanges of fingers.

The **proximal phalanx** of a toe is a little more than an inch in length, and it is slightly concave lengthwise on its inferior or *plantar surface.* The **base** is expanded and is concave on its proximal surface for articulation with the head of the metatarsal. The **shaft** is thin—being compressed from side to side near the base, and from above downwards near the head. The **head** is pulley-shaped and articulates with the base of the middle phalanx; the articular part extends on to the plantar surface but scarcely at all on to the dorsum, for dorsiflexion is a limited movement, while flexion is free, and the middle joint of the toes in many people who have worn boots since infancy is in a permanent position of flexion.

Fig. 298.—Phalanges of a Toe (Plantar Aspect).

The **middle phalanx** is very short—usually less than half an inch in length—and it may be a mere nodule of bone. The **base** articulates with the head of the proximal phalanx and is therefore the reverse of a pulley: it has two concave smooth areas with a low, vertical, smooth ridge between them. The **shaft** is convex on its dorsal surface and either flat or concave on its plantar surface; but it may be difficult to distinguish the surfaces if the phalanx is stunted. The articular part of the **head** is a shallow pulley, and as it extends some distance on to the plantar surface it is a guide to the surfaces.

The **distal phalanx** also is very small. The **base** articulates with the head of the middle phalanx and is relatively expanded. The **shaft** is constricted; the **head** is expanded and is very rough on its plantar surface.

The **big toe** has only two phalanges. The **proximal** resembles the proximal phalanx of the other toes and the **distal** resembles the distal; but they are much larger in every way than the phalanges of other toes. In an adult big toe the medial side of the base of a phalanx is larger than the lateral side, and the big toe inclines therefore towards the other toes; the inclination is not an abnormality due to wearing pointed boots, but it may be exaggerated by the use of boots that do not fit.

Owing to the slant of the joints between the tarsus and metatarsus and to the fact that the toes are progressively shorter from the second to the fifth, the nail of the little toe is about the level of the root of the big toe. The root of the little toe or fifth metatarso-phalangeal joint is the yielding prominence on the lateral border of the widest part of the foot; it usually bulges out the side of the shoe a little in front of the middle, and, being so far back, it is apt to be mistaken for the base of the metatarsal bone if the foot is shod.

Attachments.—The plantar and the collateral ligaments of the metatarso-phalangeal joints and interphalangeal joints are attached to the **bases** and the **heads**; the fibrous flexor sheaths are attached to the margins of the **shafts** of the proximal and middle phalanges and to the base of the distal phalanx in front of the insertion of the long flexor tendon.

The abductor hallucis is inserted into the medial side of the **base** of the **proximal phalanx** of the *big toe*; the adductor hallucis into the lateral side; the flexor hallucis brevis into both sides; the medial tendon of the extensor digitorum brevis into the dorsum. The flexor brevis and abductor digiti minimi are inserted into the lateral side of the base of the proximal phalanx of the *little toe.*

The **base** of the **distal phalanx** of the *big toe* receives the insertion of the tendons of the long flexor and extensor on the plantar and dorsal surfaces respectively. A tendon of the flexor digitorum brevis is inserted into the margins of the **shafts** of the **middle phalanx** of each of the *other toes*, and a slip of the extensor expansion into the dorsum of its base. The **base** of each **distal phalanx** gives insertion to a tendon of the flexor digitorum longus on its plantar surface, and to the rest of the extensor expansion on its dorsal surface.

Columns of the Foot.—The bones of the foot as a whole can be separated into two columns. The **lateral column** consists of the calcaneum, the cuboid, the fourth and fifth metatarsal bones, and the phalanges of the corresponding digits. The **medial column** consists of the talus, the navicular, the three cuneiform bones, the medial three metatarsal bones, and the phalanges of the corresponding digits.

Arches of the Foot.—The bones of the tarsus and metatarsus are arranged in the form of a half-dome with longitudinal and transverse arches; the foot therefore

rests posteriorly on the lower part of the back of the calcaneum, anteriorly on the heads of the metatarsal bones, and at the lateral border slightly on the fifth metatarsal bone, while at the medial border it is raised well away from the ground.

The dome and its arches conform to the shape of the bones with which the framework of the foot is built, and they are maintained by the ligaments that bind the bones together and by the muscles, tendons, and fasciæ of the foot. Their chief supports are the muscles, particularly the tendons of the tibialis posterior and peroneus longus which cross the sole obliquely from opposite sides.

The advantages given by the arches of the foot are that the weight of the body is distributed over the foot (compare the use of arches above windows in the wall of a big building), sufficient rigidity and strength are provided to allow the foot to be used as a lever, and a space is provided in which the soft parts of the sole of the foot may lie free from pressure. The arches are modified by the presence of joints which allow a small range of movement, controlled by the muscles and limited in range by ligaments. This control of the joints by the muscles provides elasticity and spring to the foot and serves to absorb shocks such as are received in running or jumping.

If, for any reason, the muscles and tendons become inefficient, the strain of upholding the arches under the weight of the body may become too much for the ligaments; they stretch, and the arches sink down gradually till a condition of flat-foot or splay-foot is established, the bones altering in shape to fit each other in their modified positions in the flattened arch.

See also the Section on JOINTS, in which the arches are described more fully.

Ossification of Bones of Foot (Pls. XXVI, p. 305, XXVIII, p. 321).—**Tarsus.** Each tarsal bone has one *primary* centre.

	Calcaneum.	Talus.	Cuboid.	Lateral Cuneiform.	Navicular.	Intermed. Cuneiform.	Medial Cuneiform.
Primary centre appears at	6th month	8th month	Birth or soon after	1st year	3rd year	M. 4 yr. F. 3 yr.	M. 4 yr. F. 3 yr.

The centres for the navicular may be double (or even multiple) at first, but they rapidly fuse. The calcaneum alone has a *secondary* centre. The part of the bone that bears the medial and lateral tubercles is ossified from it; it appears at 8 in girls and 10 in boys, and the epiphysis unites at 15 and 18 respectively. Ossification of all the tarsal bones is completed after puberty. Part of the posterior tubercle of the talus may have a separate centre, and that portion of it may develop as an independent bone called the *os trigonum*.

Metatarsus.—A *primary* centre for each metatarsal appears in the ninth week of intra-uterine life. They are well ossified at birth. A *secondary* centre for each appears as follows, that for the first being a few months earlier than the others :—

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For *base* of first	M. 3 yr.; F. 2 yr.	M. 18; F. 15	Outside.
For *head* of others	M. 3 yr.; F. 2 yr.	M. 18; F. 15	Outside.

Epiphyses have been seen in the bases of the lateral metatarsals instead of in the heads.

Phalanges.—Each has a *primary* centre for shaft and head, and a secondary centre for the base.

Primary Centre for	Distal Phalanx.	Proximal Phalanx.	Middle Phalanx.
Appears	At end of 3rd month	At end of 4th month	6th month—birth

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphysial Line to Capsule of Neighbouring Joint.
For base	M. 3 yr. F. 2 „	M. 18 F. 15	Outside.

Structure and Variations.—The *tarsal* bones have the structure of short bones; their non-articular surfaces are pierced by numerous *nutrient vessels.* The *metatarsal* bones and the *phalanges* have the structure of long bones. The medullary cavity is relatively narrow, and may be absent in the distal two phalanges. The *nutrient foramen* of a metatarsal is on or near the plantar surface; it is directed towards the head in the first, towards the base in the others. In the phalanges, when it is present, it is on the plantar surface and is directed towards the base.

The **calcaneum** occasionally articulates with the navicular. The sustentaculum tali may be a separate bone, and so may be the peroneal tubercle. The articular surface for the medial malleolus on the **talus** extends on to the neck in an infant. Occasionally in an adult talus there is a small facet for the tibia on the medial part of the upper surface of the neck, probably due to the

Fig. 299.—Radiograph of the Hand at Birth.

The metacarpus and phalanges are well ossified, but the carpus is still entirely cartilaginous. (Compare with Fig. 300, and see also Pls. XVIII, p. 273, and XXVIII, p. 321.)

Fig. 300.—Radiograph of the Foot at Birth.

Calcaneum and talus are well ossified; the cuboid is quite distinct, and in this instance the lateral cuneiform is already beginning to ossify.

ankle joint being often in a state of extreme flexion. The *os trigonum*, when present, may be quite separate, or joined to the body of the talus by cartilage. An ossicle may be present between the talus and dorsal surface of navicular, and another on the dorsum between the talus, calcaneum, navicular, and cuboid. The tuberosity of the **navicular** is sometimes a separate bone. The metatarsal articular surface of the **medial cuneiform bone** may be divided into a dorsal and a plantar part, and the whole bone may be so divided; in both cases there is similar division of the tarsal surface of the first metatarsal. In rare cases a little separate ossicle is found between the posterior parts of the dorsal surfaces of the medial and intermediate cuneiform bones. Division of the **cuboid** has been recorded; in rare cases there is a very small facet for the lower part of the **head** of the talus on the medial side of the projecting angle of its posterior surface. The tubercle of the **fifth metatarsal** may be separate (*os Vesalianum*); as also the part of the base of the **first** into which the peroneus longus is inserted. A separate ossicle may be found between the bases of the first and second metatarsals. Fusion of **phalanges** is not uncommon, especially in the little toe. For an account of accessory bones of the foot, with bibliography, see Trolle (1948).

Sesamoid Bones

Sesamoid bones are embedded in tendons, but there is usually one surface free and smooth for articulation. The largest sesamoid bone is the **patella**. The *flexor hallucis brevis* has two little sesamoid bones in its tendons of insertion. They are about the size of half of a marrowfat pea, and, being compressed and oval, should not be mistaken for the pisiform bone. They play against the grooves on the plantar

surface of the head of the first metatarsal bone, and they add to the size and firm consistence of the medial part of the ball of the foot; the medial sesamoid may be divided transversely, and sometimes there is a minute nodule between the two. Occasionally there are minute sesamoid bones at the *other metatarso-phalangeal joints* and at the *interphalangeal joint* of the big toe and other interphalangeal joints. A sesamoid bone or cartilage is usually present in the tendon of the *peroneus longus* as it crosses the lateral side of the cuboid bone to enter the sole. The tendon of the *tibialis posterior* is thickened at the point where it glides over the spring ligament; the thickening has sometimes the character of a sesamoid cartilage. More seldom, a sesamoid bone is present--in the *tibialis anterior* near its insertion; in the *psoas major* as it passes over the pubic bone; in the lateral head of the *gastrocnemius* as it crosses the lateral condyle of the femur; and in the *gluteus maximus* as it overlies the greater trochanter.

DEVELOPMENT AND MORPHOLOGY OF THE LIMBS

The limbs appear in the Human embryo in the fourth week as small buds on the sides of the body near the cephalic and caudal ends of the trunk (Fig. 72). They are derived from a slight longitudinal ridge which lies ventral to the paraxial mesoderm and, since they appear opposite several segments of the body, each of them receives branches from a corresponding number of spinal nerves. The spinal nerves that contribute fibres to the upper limb are the lower five cervical and the upper two thoracic; and the lower limb contains branches from the last thoracic nerve, the five lumbar nerves, and the upper four sacral nerves. The buds arise from the ventro-lateral part of the trunk, and the nerves of a limb are accordingly derived from the *anterior primary rami* of the spinal nerves.

Each bud has two surfaces and two borders. At first the surfaces look ventrally and dorsally; the ventral aspect corresponds to the flexor surface of the adult limb, and the dorsal aspect to the extensor surface; the borders of each bud look headward and tailward, and are named **pre-axial and post-axial.** (Figs. 118-121, pp. 99, 100.)

During the second month slight constrictions appear in the elongating buds at positions that correspond to the elbow and the wrist, the knee and the ankle; and grooves appear on the dorsal surfaces of the extremities of the buds—indicating the division into digits. At the same time, the central or axial mesoderm of the bud condenses and passes through a pro-cartilage stage and then chondrifies to form the cartilage-models of the limb-bones. Chondrification begins in the roots of the limbs and spreads towards the digits, leaving unchondrified intervals where joints are to be formed. The cartilage developed along the pre-axial border of the forearm becomes the radius, and the pre-axial digit becomes the thumb; in the leg and foot the pre-axial cartilage and digit become the tibia and the big toe; similarly, the ulna and little finger, the fibula and little toe are developed at the post-axial borders.

During the third month the embryo—now called the *fœtus*—begins to assume the "fœtal position" (Fig. 121) with flexion at all the joints, notably those of the limbs. The wrist and the elbow are flexed and the upper arm is bent tailwards along the side of the thorax; the ankle is flexed and the foot is turned medially, the knee is flexed and the thigh is inclined headwards along the abdomen. At the same time the upper and lower limbs begin to be rotated around their long axes.

Rotation of the limbs.—The extensor surface of a limb-bud is on its dorsal aspect. As the limb grows, it bends so as to project ventrally and, in addition, the *upper limb* is rotated through about 90° so that the extensor surface of the elbow faces backwards and the *lower limb* undergoes a similar rotation in the opposite direction to make the extensor surface of the knee face forwards. The distal part of the upper limb requires an additional twist, equivalent to pronation of the forearm and hand, to bring its extremity into the adult position. In Man, to gain the erect posture, the limbs swing tailwards from the quadrupedal position to lie parallel to the long axis of the body; the rotation of the forearm and hand does not require to be so complete as in the fore-limb of a quadruped, and the final rotation of the foot which brings the ball of the great toe to the ground is not completed until after birth, when the weight of the body is taken on the foot as the child learns to walk. Rotation of the limbs takes place at least partly at the shoulder and hip joints and possibly in the shafts of the bones. No rotation of the limb-girdles is seen during development.

Homologies.—The homology between the limb-bones of Man and those of other animals, and the serial homology between the bones of the two limbs in Man, are fairly clear except in the limb-girdles, and the carpus and tarsus (p. 327).

Limb-Girdles.—The homologies of the parts of the girdles have become obscured owing to the structural alterations that have occurred in order to adapt the two limbs to their different functions. Even in four-footed animals the functions of the fore-limbs and hind-limbs are not quite the same, though both are used for support and locomotion; the fore-limb is at the same time adapted for *pull* and the hind-limb for *push*; the pelvic girdle is therefore more consolidated than the shoulder-girdle. The modifications from the primitive type are more varied

and more profound in the shoulder-girdle, and they began so long ago in phylogenetic development that in Man there is no evidence in ontogenetic development of how they came about.

The primitive, fundamental limb-girdle is a curved bar of cartilage embedded in the muscular substance of the side of the trunk at right angles to the long axis of the trunk. The cartilage is divisible into a dorsal part and a ventral part by means of an articulation of the middle of its lateral surface with the cartilage of the free portion of the limb.

In the pelvic girdle the *dorsal part* forms the ilium and the *ventral part* is divided into cephalic and caudal bars which become the pubis and ischium respectively. In the shoulder-girdle the

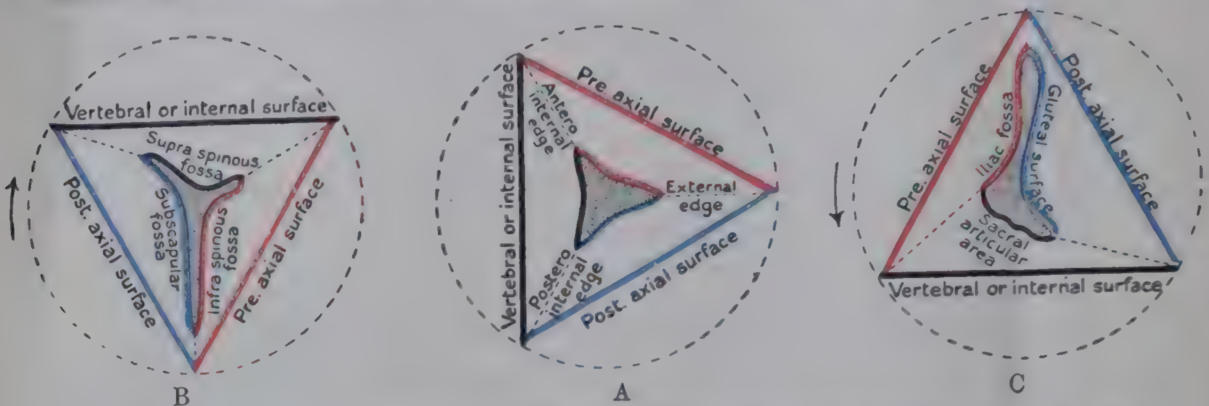

FIG. 301.—DIAGRAM OF HOMOLOGOUS PARTS OF SCAPULA AND ILIUM, ACCORDING TO FLOWER.

A : Ideal type ; three-sided rod. B : Scapula rotated forward through a quarter of a circle (90°), and the primitive medial or vertebral surface is now directed forwards. C : Ilium rotated backwards through a quarter of a circle and the primitive medial surface is now directed backwards.

dorsal part forms the blade of the scapula but the *ventral part* varies considerably in different vertebrates and homologies are difficult to establish. In Man it forms the upper part of the glenoid cavity and the coracoid process of the scapula. The suprasternal ossification (which may be separate as a suprasternal bone in Man) probably represents an epicoracoid element while the cephalic bar of the ventral part, the precoracoid of lower forms, seems to have been replaced, at least in part, by the membranous element of the clavicle. The exceptionally early ossification of the clavicle spreads from centres at each end before the cartilage has fully formed

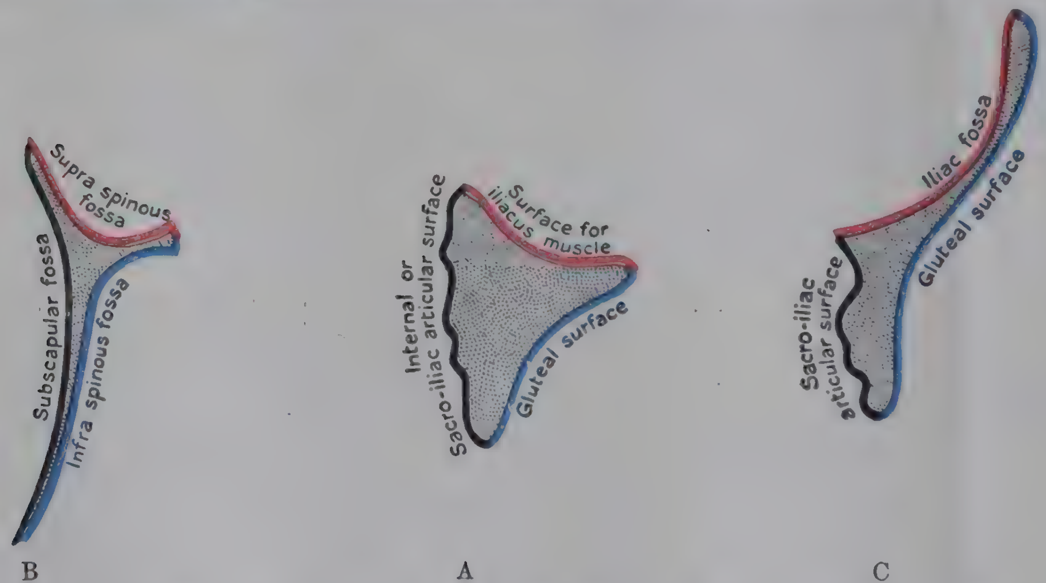

FIG. 302.—DIAGRAM OF HOMOLOGOUS PARTS OF SCAPULA AND ILIUM, ACCORDING TO HUMPHRY.

A : Primitive rod-like ilium of kangaroo, prismatic on section. B : Scapula. C : Ilium. The corresponding surfaces are similarly coloured.

and there is evidence that the middle third of the clavicle is membrane bone. Keith (1948) reviews these problems and provides references.

The limbs are usually regarded as being serially homologous, the pre-axial structures on the radial side of the upper limb corresponding to the pre-axial structures on the tibial side of the lower limb. Post-axial structures such as the ulna and fibula are similarly equivalent and the little toe corresponds to the little finger. In making comparisons due allowance has to be made for rotation of the knee and elbow in opposite directions during development so that the posterior surface of the shaft and the lateral epicondyle of the humerus correspond to the anterior surface and medial epicondyle of the femur. The olecranon is analogous to but not homologous with the patella.

The homologies of the carpal and tarsal bones are not so clear; they are given in the following table, together with the more generalized type from which they are evolved:—

Type.	Hand.	Foot.
Radiale (Tibiale)	= Scaphoid (body)	= Talus.
Intermedium	= Lunate	= Absent, or Os trigonum (?).
Ulnare (Fibulare)	= Triquetrum	= Calcaneum.
Centrale	= Absent, or fused with Scaphoid	= Navicular, less its tuberosity.
Carpale (Tarsale), i.	= Trapezium	= Medial Cuneiform.
Carpale (Tarsale), ii.	= Trapezoid	= Intermediate Cuneiform.
Carpale (Tarsale), iii.	= Capitate	= Lateral Cuneiform.
Carpale (Tarsale), iv. } Carpale (Tarsale), v. }	= Hamate	= Cuboid, plus the peroneal sesamoid.

The pisiform is omitted from the table, since it is now generally regarded as being a vestige of an additional digit placed post-axial to the little finger (digitus post-minimus). Its homologue in the foot is by some considered to be fused with the calcaneum. The peroneal sesamoid probably corresponds to the hook (sometimes an independent ossicle) of the hamate bone. Similarly, on the pre-axial border of the hand and foot, vestiges of a suppressed digit (prepollex and prehallux) may occasionally be met with. The tuberosity of the navicular bone of the foot may be the homologue of the pre-axial sesamoid in the hand, which probably fuses with the scaphoid to form its tubercle. The frequent occurrence of an increase in the number of digits seems to indicate that phylogenetically the number of digits was greater than at present and included a prepollex or prehallux, and a digitus post-minimus.

The view that the limbs are serially homologous has been widely held since the time of Flower (1870) and Huxley (1871); but it has also been argued that the limbs are, as Humphry (1858) phrased it, " placed at opposite ends of the trunk and the opposed surfaces of their upper segments have, consequently, been made to correspond with one another ". This " mirror image " idea has been supported by others, particularly by Drennan (1927) who superimposed an upper limb of one side of the body on the lower limb of the other side. Pre-axial structures of the one limb then correspond to post-axial structures of the other. Serial homology has the advantage that it agrees largely with the functional arrangement of the limbs for progression in one direction. In the scheme originally put forward by Flower the limb-girdles were assumed to rotate through 90° (Fig. 301). Humphry assumed that they were not involved in the rotation of the limbs (Fig. 302).

In Man the lower limbs have been specialized for the whole office of support and locomotion. The upper limbs have undertaken more varied functions, including that of prehension. The lower limbs are increased in strength and length and are constructed for stability; mobility is the aim achieved in the upper limb. The elements of the lower limb-girdle are welded into one bone which is firmly jointed to its fellow and to the backbone, and, with the adoption of the erect attitude, it assumes the special human characteristic of wide expansion of the ilia to support the abdominal viscera.

In order to be free and movable, the shoulder-girdle is not built into the wall of the body cavity. The scapula is only loosely connected with the axial skeleton by muscles; the clavicle is joined to the sternum by a freely movable joint; and, further, these two constituents of the girdle are not fused with each other but are connected by a movable joint. To obtain greater freedom and range of movement, the upper limb, including the ventral part of the scapula, becomes farther removed from the trunk, and the scapula loses the support received through the union of the coracoid element with the sternum, as in birds, reptiles, and, to some extent, in the lowest mammals. As a substitute for that support the clavicle is evolved as a new element; in its most specialized form, as in Man, it gives strength and stability to the girdle and keeps the upper limb removed from the trunk so that the movements are unhampered. Being itself a movable fulcrum, it enlarges the range of movement and, in particular, it facilitates abduction of the arm.

The head of the humerus articulates with a shallow cavity and is connected with the scapula by a lax capsule; in the femur, the presence of a long neck set at an angle to the shaft removes the limb from the trunk and enables the limb to have a wide range of movement, although the head of the femur articulates with a deep cup and is held firmly in place by a strong capsule.

The power of pronation and supination combined with the free movement permissible at the wrist joint give the upper limb a varied mobility which the lower limb does not possess. This is to a limited extent compensated for by the possibility of slight rotation at the knee joint, slight sideways movement at the ankle joint in full extension, and a considerable range of inversion and eversion of the sole of the foot. The knee and hip joints are particularly stable in full extension.

The hand, as a prehensile organ, has its phalanges increased in length and the carpus reduced; the opposability of the first metacarpal enables the hand to grasp cylindrical objects firmly, and the opposable fifth metacarpal enables it to grasp spherical objects. In the foot, strength and stability are required; the tarsal bones are large, and, having to sustain the weight of the body, the tarsus and metatarsus are built in the form of an arch; the foot does not have the prehensile function which it discharges in Apes, and therefore the digits are short and none of them is opposable.

MEASUREMENTS AND INDICES EMPLOYED IN PHYSICAL ANTHROPOLOGY

Craniometry

Craniology is the study of the skull, and it includes the consideration of the differences in the skull in the various groups of Mankind. Accurate measurements are required for the estimation of the differences, and the name *craniometry* is given to the methods of measurement.

Capacity of the Cranium.—The size of the skull varies considerably in the different races of Man. Apart from individual differences and the proportion of head-size to body-weight, the size is generally greater in the more highly civilized races than in the lower types. The size of the head is closely correlated with the size of the brain; and an estimate of the size of the brain can be formed from the dimensions of the cranial cavity. To determine the capacity of the cavity, fill it with some suitable material and then measure the cubage of the amount of material required. Various materials have been employed, each of which has its advantage. Liquids would be the most accurate, but the foramina make them useless, without special precautions. In practice, seeds, glass beads, and leaden shot have been found to be sufficiently serviceable.

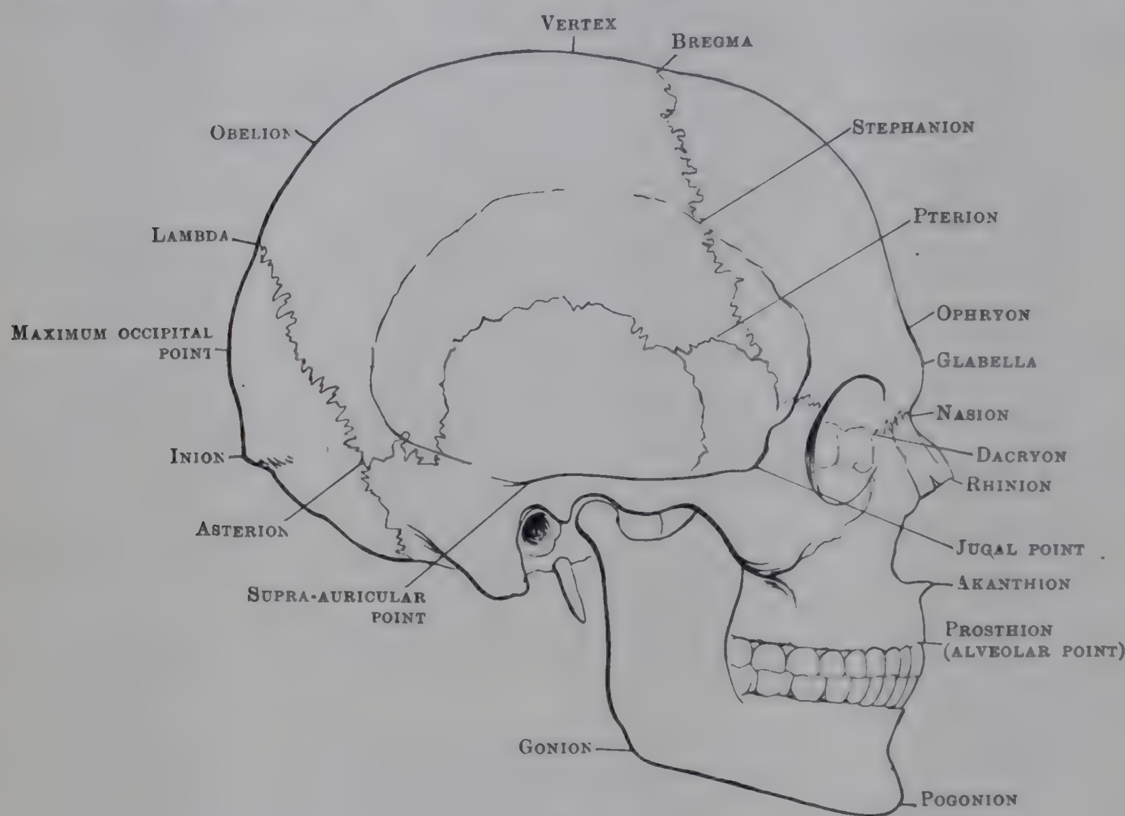

Fig. 303.

There is a wide range of variation in the capacity of different crania, but, owing to the varying thickness of bone and size of sinuses, the capacity is not directly proportional to the size of the skull as a whole. For purposes of classification and comparison, skulls are grouped according to their **cranial capacity** into the following varieties:—

- **Microcephalic skulls** are those with a capacity below 1350 c.c., and they include the skulls of Andamanese, Veddahs, Australians, Bushmen, Tasmanians, etc.; [μικρός (micros) = small; κεφαλή (cephalē) = head].
- **Mesocephalic skulls** range from 1350 c.c. to 1450 c.c., and they are found among the following races: American Indians, Chinese, and some African Negroes; [μέσος (mesos) = middle].
- **Megacephalic skulls** are those with a capacity over 1450 c.c. They are most commonly met with in the more highly civilised races: Mixed Europeans, Japanese, etc.; [μέγας (megas) = big].

Form of the Cranium.—The shape, as well as the size, has been used as a means of classifying skulls; but, in the past, undue emphasis may have been laid on differences in shape. These differences are expressed by the comparison of measurements between given points. The more important points from which measurements are taken are indicated in Fig. 303.

The measurements of the length of the skull may be taken between a variety of points—the nasion, the glabella, or the ophryon in front, and the inion or the maximum occipital point behind; or the maximum length alone may be taken without reference to any fixed points. In all cases, the measurement used should be stated. The widest part of the skull is very variable in position; note whether it occurs above or below the parieto-squamosal suture. The width of the skull may also be measured from one asterion to the other (**bi-asterionic width**) or from one stephanion to the other (**bi-stephanic width**). The height measurement usually taken is the distance from the basion to the bregma.

The relation of the breadth to the length of the skull is expressed by the **cephalic index**, which gives the proportion of the maximum breadth to the maximum length of the skull, assuming the length equal 100, or—

$$\frac{\text{Max. breadth} \times 100}{\text{Max. length}} = \textbf{Cephalic index.}$$

The results are classified into three groups :—

1. **Dolichocephalic,** with an index below 75 : Australians, Kaffirs, Zulus, Eskimos, Fijians.
2. **Mesaticephalic,** ranging from 75 to 80 : Europeans (mixed), Chinese, Polynesians (mixed).
3. **Brachycephalic,** with an index over 80 : Malays, Burmese, American Indians, Andamanese ; [βραχύς (brachys)=short ; δολιχός (dolichos)=long].

For other cranial indices and for measurements and indices of other parts of the skeleton, the reader is referred to previous editions of this text-book and to the special works of Martin (1928), Wilder (1920), Hrdlička (1920) and Drennan (1937).

ARTHROLOGY

by Robert Walmsley, M.D., F.R.S.E.
Bute Professor of Anatomy, University of St. Andrews

Arthrology[1] is that branch of Anatomy which deals with the manner in which the individual bones of the skeleton are joined together. These **joints** or **articulations** between the bones vary in structure and function: some are immovable; others permit movement of varying extent and complexity. The chief kinds of joints have also developmental differences, with some relation to the different modes of origin of the conjoined bones.

To begin with, the skeleton in any region exists as a continuous thickening of mesoderm. Where next a cartilaginous phase intervenes, the cartilaginous precursors of the bones may still be continuous, as in the cartilaginous base of the skull, or may remain separate as in the limbs and be joined by zones of persisting membranous tissue. When ossification occurs, the bones are all formed separately, and therefore joints are found between their contiguous parts. Bones formed in membrane are connected by the intervening membranous tissue, and so become united by fibrous joints; bones formed in cartilage are connected either by cartilage or by membranous tissue according to the continuous or discrete formation of the preceding cartilages. The membranous connexion between bones formed from separate cartilages may persist and give rise to a fibrous joint, or may become chondrified and give rise to a cartilaginous joint; but usually the connecting membranous tissue forms a cellular disc called a *primitive joint-plate* in which further changes occur. The central part of the joint-plate is absorbed so that a cavity appears within it, whereas the peripheral part of the joint-plate along with the surrounding mesoderm form a fibrous sleeve with a specialized lining that connects the contiguous bones and bounds the joint-cavity that now exists between them.

Classification of Joints.—Bones are ultimately joined, therefore, in one of three ways:—

(1) By **fibrous joints**, where the bones have arisen in membrane or where they were preceded by discrete cartilaginous models and the primitive membranous connexion has persisted.

(2) By **cartilaginous joints**, either of a primary type where the uniting cartilage is the remains of a preceding continuous cartilaginous formation, or of a secondary type where the membranous tissue between bones ossifying from discrete cartilages is subsequently chondrified.

(3) By a more elaborate type of joint having a cavity between the bone-ends surrounded by fibrous ligaments lined with a specialized membrane. This lining membrane produces a fluid called *synovia* which passes into the joint-cavity, and is therefore itself called the *synovial membrane*. As the synovial fluid and membrane are characteristic of joints of this type, these are called **synovial joints**.

These three kinds of joints will now be considered in detail and the varieties of each described.

[1] For general works of reference, with bibliographies to date, see Bryce (1915) and Fick (1904–11).

FIBROUS JOINTS

Fibrous joints are of two types—suture and syndesmosis.

Suture.—A suture is a type of fibrous joint found only in the skull, in which a very thin layer of white fibrous tissue, called the *sutural ligament*, unites the opposed bone surfaces (Fig. 304); the union between the bones is so close that no movement can take place at the joint. Externally the sutural ligament is continuous with the periosteum and internally it is continuous with the outer layer of the dura mater (p. 997).

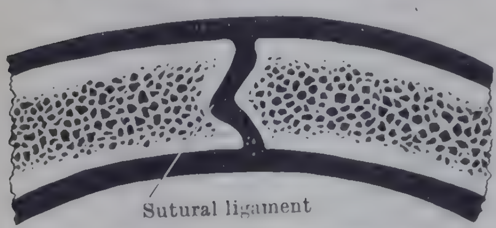

FIG. 304.—VERTICAL SECTION THROUGH A SUTURE (Sagittal).

Obliteration of the sutures usually begins between the ages of thirty and forty when the sutural ligaments become ossified, a process called *synostosis*. The process of obliteration begins on the deep aspect of the ligament and slowly extends to its superficial part; complete obliteration of the sutures does not occur until an advanced age (p. 211).

Varieties of Suture.—Different varieties of suture are named from the ways in which the opposed parts of the bones are fitted to one another. Sutures between bones joined edge to edge are commonly strengthened by toothed projections from the one bone fitting between similar processes on the other; such a suture is called **serrate** when the projections are pointed like the teeth of a saw (Fig. 305), or **denticulate** when the projections broaden towards their free ends like human teeth, and the bones are dovetailed together. In a **limbous** suture, serrate or dentate edges of the opposed bones alternately overlap one another in addition. Where plane overlapping bevelled edges of bone are united, a **squamous** suture is formed. When relatively flat surfaces of bone are joined together, as in the joint between the maxilla and the vertical plate of the palatine bone, a **flat** suture results. In a **wedge-and-groove** suture a crest on one bone fits into a groove on another, as the rostrum of the sphenoid fits into the groove between the alæ of the vomer. A **peg-and-socket** suture resembles the union between the fang of a tooth and its socket; but the only example in the skeletal system is the insertion of the styloid process in the temporal bone.

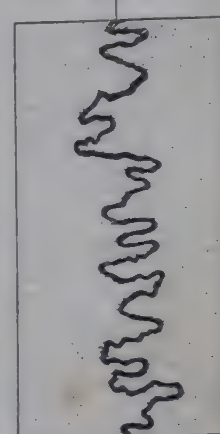

FIG. 305.—SURFACE VIEW OF SERRATE SUTURE (Sagittal). Cf. Fig. 153, p. 153.

Syndesmosis.—A **syndesmosis** is a fibrous joint in which the uniting fibrous tissue, much greater in amount than in a suture, forms an interosseous membrane or ligament. The inferior tibio-fibular joint is a syndesmosis where the bones are joined by an interosseous ligament; the attachment of the shaft of the radius to that of the ulna may be regarded as an example of syndesmosis in which an interosseous membrane unites the bones. Movement may be permitted at a syndesmosis by the flexibility of an interosseous membrane or the stretching or twisting of an interosseous ligament. This last occurs to an extremely small extent unless the ligament is composed largely of elastic fibrous tissue, as in the case of the ligamenta flava between the laminæ of adjacent vertebræ.

CARTILAGINOUS JOINTS

In a **cartilaginous joint** the bones are united by an intervening plate of cartilage. The sides of the plate are directly fused to the joint-surfaces of the two bones, and the perichondrium clothing its periphery is continuous with the periosteum covering the bones. As already indicated, cartilaginous joints are of two types, primary and secondary, which differ in development, structure, and function.

Primary Cartilaginous Joint.—The cartilage of the **primary** type of joint (Fig. 306) is a remnant of the continuous cartilaginous mass in which the articulating bones are formed, and it retains its original hyaline nature. This is the most rigid kind of cartilage; hence no movement is permitted at this type of joint unless, as in the solitary example of the union between the first rib and

the sternum, the uniting cartilage is a bar long enough to allow an appreciable degree of bending or twisting. The primary cartilaginous joints are intimately related to the mode of growth of the bones concerned (p. 116), and most of them

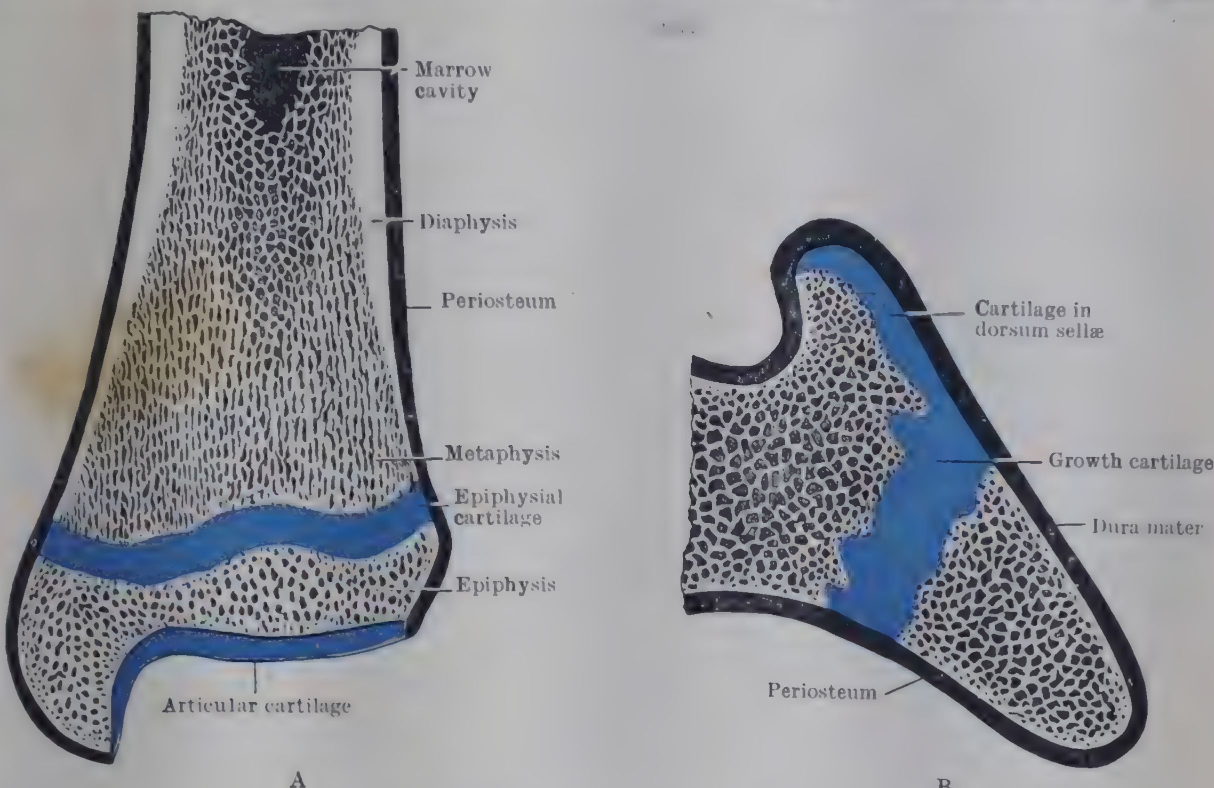

FIG 306.—PRIMARY CARTILAGINOUS JOINTS.

A. Diagrammatic section of joint between diaphysis and epiphysis of growing long bone.
B. Median section of joint between occipital and sphenoid bones in child aged one year.

become obliterated by synostosis before the age of twenty-five; only two pairs of joints escape this fate—the petro-basilar and the first sterno-costal.

Secondary Cartilaginous Joint.—The **secondary** type of cartilaginous joint is more specialized, occurs only in the median plane and persists throughout life. In its early stages of development it is represented by a plate of cellular membranous tissue between separate cartilaginous rudiments (Fig. 307), but later this plate differentiates into fibro-cartilage. When the cartilaginous rudiment undergoes a bony change, a thin lamina of the cartilage adjoining the fibro-cartilage remains unossified and persists as a lamina of hyaline cartilage between the bone and the fibro-cartilage (Fig. 313). Such a joint is that between the bodies of adjacent vertebræ. Fibro-cartilage is less rigid than hyaline cartilage: a slight amount of bending or twisting of the one bone upon the other may therefore take place at this type of joint, the amount depending on the thickness of the fibro-cartilaginous plate and the degree to which fibrous tissue is formed in it. In some such joints the centre of the fibro-cartilaginous plate is

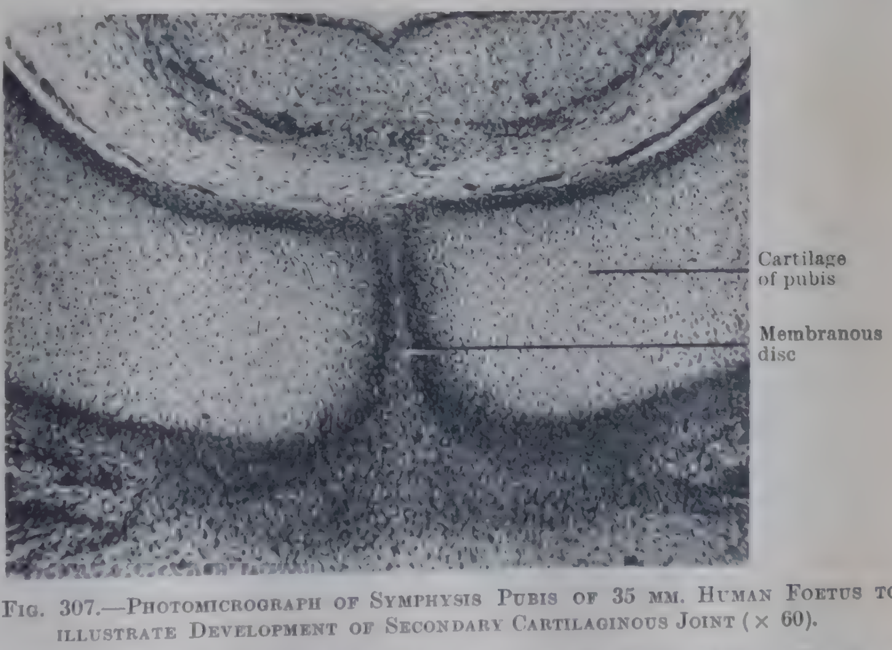

FIG. 307.—PHOTOMICROGRAPH OF SYMPHYSIS PUBIS OF 35 MM. HUMAN FOETUS TO ILLUSTRATE DEVELOPMENT OF SECONDARY CARTILAGINOUS JOINT (× 60).

modified either by the formation of an irregular slit-like cavity, as in the pubic symphysis, or by the presence of a core of soft, pulpy tissue, as in an intervertebral disc: these modifications increase the amount of movement. In fibro-cartilaginous joints additional strength is secured by the presence of ligaments around the joint.

SYNOVIAL JOINTS

The **synovial joint** (Fig. 308) is the most highly evolved type of joint: it is specialized to permit free movement. In accordance with the function of free movement the joint-surfaces of the articulating bones are separated by a **joint-cavity** and each is provided with a special, smooth bearing surface of hyaline cartilage. The bones are connected by flexible ligaments that are attached chiefly round about the bone-ends and these form the **capsular ligament.** The capsular ligament is lined with **synovial membrane** which bounds the joint-cavity and produces the synovial fluid within the cavity.[1]

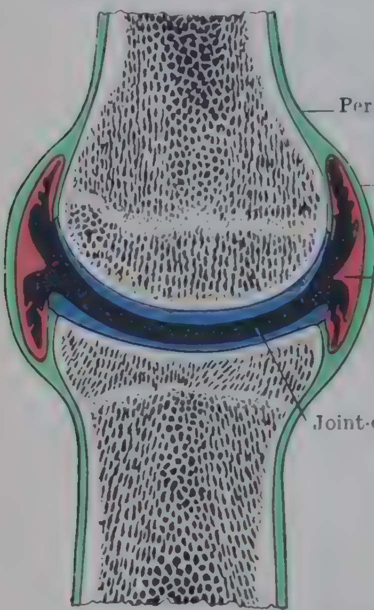

Fig. 308.—Diagram of a Synovial Joint.
Articular cartilage, *blue*; synovial membrane, *pink*; capsular ligament and periosteum, *green*.

The part of a bone that enters into the formation of a synovial joint—usually enlarged or expanded in the case of the extremity of a long bone—is composed of spongy bone with a thin superficial layer of particularly dense bone. The *articular surface* is that area of the bone which comes into contact during movement with the other bone of the joint, and it is covered with a layer of hyaline cartilage called the **articular cartilage.** This presents a firm, perfectly smooth, free surface, devoid of perichondrium. By its slight elasticity the articular cartilage lessens jarring shocks at the joint. It has no nerves and is, therefore, insensitive. It is avascular, and is nourished to some extent by permeation of fluid from the vascular ring in the synovial membrane at its periphery (p. 340), but principally by the synovial fluid itself (Strangeways, 1920). The appreciation of the difference in the nourishment of the peripheral and central portions of the articular cartilage is of fundamental importance in joint-pathology. The periphery of the cartilage is adequately nourished from the adjacent vessels and is liable to overgrowth changes, whereas the central part is less well nourished and is prone to degenerative changes.

The connecting structures of the synovial joint are the *articular ligaments.* These are arranged in various ways, but are always composed of dense white fibrous tissue which, by its flexibility, permits movement at the joint, but by its great tensile strength resists disruption. Every synovial joint is provided with a **capsular ligament**. This usually takes the form of a sleeve, each end of which is firmly attached in a continuous line around the articular extremity of one of the bones at a variable distance from the edge of the articular cartilage. Where more than two bones enter into the formation of the joint the capsular ligament has the form of a more irregular sac with openings tightly filled by the articulating parts of the bones. If the articular end of a bone is ossified from an epiphysial centre, the epiphysial line bears no constant relation to the line of capsular attachment in different joints: the epiphysial line may be intracapsular or extracapsular in position, or partly the one and partly the other. Small apertures in the capsular ligament give passage to nerves and vessels; there may be larger openings through which synovial pouches protrude. The capsular ligament may be strengthened or even replaced, in part, by adjacent muscle tendons or their expansions. The fibres

[1] The conventional term 'joint-cavity' is inexact. There is normally no real 'cavity', but only a solution of continuity between surfaces in contact.

of the ligament may form a dense feltwork; but where, during movement, any recurring strain must be resisted, the fibres there become arranged in parallel bundles in the line of the straining force; such specialized portions of the capsular ligament are usually thickened and distinguished by special names. Besides the capsular ligament with its possible special bands, other ligaments, standing apart from it, may unite the bones. These **accessory ligaments** may be extracapsular, like the costo-clavicular and coraco-clavicular ligaments of the clavicular joints, or intracapsular, like the cruciate ligaments of the knee joint.

Inside some synovial joints, pads of fibro-cartilage lie between the articular surfaces and blend peripherally with the capsular ligament. Such a fibro-cartilage may form a complete **articular disc** attached to the capsule all round, so as to divide the joint-cavity into two separate compartments (Fig. 309); the mandibular and sterno-clavicular joints are made bi-cameral in this way. Or the intra-articular fibro-cartilage may be wedge-shaped as in the acromio-clavicular joint, or crescentic as in the knee joint, with a free edge projecting into the joint cavity. Though articular discs may add their resilience to that of the articular cartilages in cushioning the bone-ends their principal function, according to MacConaill (1932), is to assist in maintaining a layer of synovial fluid between articular surfaces (see p. 388). In the sterno-clavicular joint the articular disc is so attached to the bones as well as to the capsule that it plays the part of an intra-capsular ligament also.

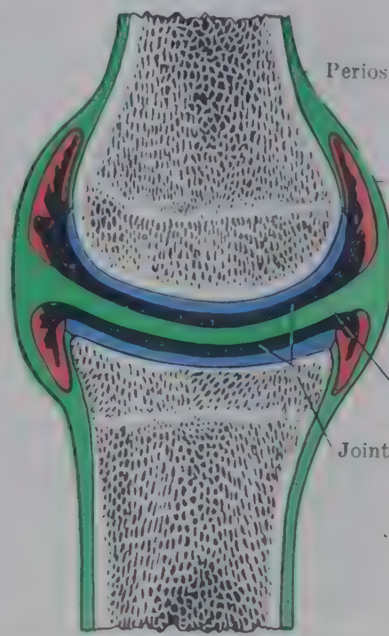

FIG. 309.—DIAGRAM OF A SYNOVIAL JOINT WITH ARTICULAR DISC DIVIDING THE JOINT-CAVITY INTO TWO COMPARTMENTS.

Articular cartilage, *blue*; synovial membrane, *pink*; capsular ligament, articular disc and periosteum, *green*.

The **synovial membrane** is one of the most important and most characteristic features of a synovial joint. It is a specialized stratum of delicate connective tissue—highly vascular, and velvety in appearance in the living—which lines the capsular ligament, and, with it, forms the capsule of the joint. At the attachments of the capsular ligament the synovial membrane is reflected on to the bones to clothe them as far as the edge of the articular cartilage. Thus, all intra-capsular bony surfaces are covered with hyaline cartilage on the articular areas and with synovial membrane on the non-articular areas. The transition between the two coverings is fairly abrupt; the junction goes obliquely from the free surface so that the membrane slightly overruns the bevelled edge of the cartilage. Often a redundant fold of the membrane from just beyond the junction overlaps the cartilage in addition. A varying amount of fatty or areolar tissue may intervene between the membrane and the ligament or bone which it covers. The fatty tissue, when large in amount, bulges the synovial membrane towards the joint-cavity, forming soft and highly compressible pads or folds; these serve to fill up irregularities of the intra-articular surfaces, such as the fossæ at the lower end of the humerus, but permit projections on the other moving member of the articulation to occupy the fossæ in certain positions of the joint; in some such cases the subsynovial fatty tissue is then partially extruded through little gaps in the attachment of the capsular ligament. The synovial membrane is also folded over intracapsular tendons, ligaments, or cartilages, which usually are thus excluded from the joint-cavity. But it must be remembered that although the synovial stratum can be traced continuously over most intra-capsular surfaces except those covered with articular cartilage, it is not everywhere recognizable as a definite lining membrane. Where fibro-cartilages or ligaments within a joint are exposed to fairly continuous pressure, the synovial membrane over them is so thinned out that it is unrecognizable as a layer separate from the proper tissue of the cartilage

or ligament itself. Thus, the semilunar cartilages in the knee joint, under constant pressure between the articulating bones, have no synovial covering (Fig. 310); nor has that part of the deep surface of the capsular ligament of the hip joint which is exposed to constant pressure of the head of the femur.

Microscopically, synovial membrane is composed of a collagenous ground-work, showing delicate fibres and containing connective tissue cells of several kinds. Its thickness and cell-content vary in different situations: it is thickest where separated from underlying ligaments by a layer of areolar tissue, is very thin when covering fatty pads, and, as already described, thins out to disappearance in areas under pressure. The more mobile parts of the synovial membrane have numerous elastic fibres which prevent nipping of the membrane by the articular surfaces during movement of the joint (Davies, 1945). Towards its free surface the cells become rather flattened, but there is not a complete lining of mesothelial cells. From the surface, *synovial villi* may project into the joint-cavity, each a tuft, sessile or pedunculated, of the fibrous ground-work with cells embedded in it and arranged irregularly around its surface. *Synovial folds* are projections on a larger scale, involving a folding of the whole thickness of the membrane (Fig. 311); secondary folds may arise from primary ones, and for localized collections of these folds, covered in turn with villi, the term **synovial fringes** is apt. The folds and villi greatly increase the free surface of the synovial membrane, and this, in conjunction with the rich vascular and lymphatic supply of the membrane, accounts for the rapidity with which toxic absorption occurs in acutely infected joints.

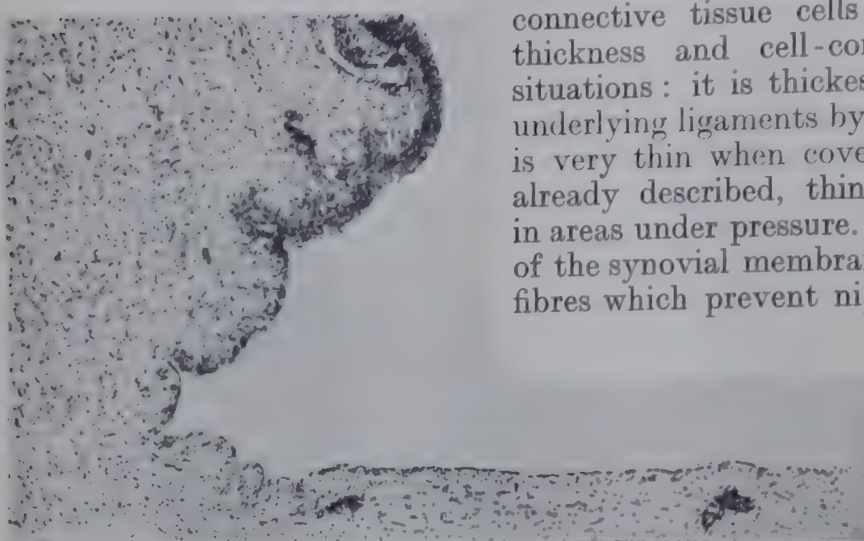

Fig. 310.—Section from Human Knee Joint.

The section is at the angle between the *semilunar cartilage* (below) and the *capsular ligament* (on left). Note that the *synovial membrane* forms a folded lining over the ligament but disappears on the surface of the cartilage. (Photomicrograph × 50.)

The **synovial fluid** is a clear, slightly yellow, glairy fluid deriving its name from its likeness in appearance and consistence to white of egg (for details regarding viscosity and volume see Davies, 1944). It is, in amount, sufficient only to cover with a thin film all surfaces within the joint—less than half a cubic centimetre in the knee joint. The synovial fluid is now regarded as a dialysate of blood-plasma to which there is an addition of mucin (Bauer, Ropes and Wayne, 1940). The actual source of the mucin, which is largely responsible for the viscid nature of the fluid, is still in doubt, but it is probably a secretion of the synovial cells. The function of the fluid is threefold: it serves to lubricate the joint-surfaces; it appears to be the main source of nourishment for the articular cartilage; and the cells it contains—constantly migrating from the synovial membrane, circulating in the fluid and entering the membrane again—remove by phagocytic action micro-organisms and the debris of wear and tear in the joint (Coggeshall, Warres & Bauer, 1940).

It will be clear that the synovial cavity of the joint, bounded by synovial membrane and articular cartilage, is completely closed. Where an opening in the ligamentous layer of the capsule allows the synovial layer to protrude, the imperforate continuity of the synovial layer is always maintained. But the synovial cavity is not completely closed in a histological sense: the synovial membrane, unlike the pleura or the peritoneum of the coelomic cavities, has no complete epithelial lining as a barrier between the cavity of the joint and the tissue-spaces around. The cavity is itself, in effect, an enormously enlarged tissue-space; that is how it was developed. This has a bearing on the rapid absorption which can take place from an acutely infected joint-cavity.

Bursæ.—Closely akin to synovial membrane are the walls of certain closed

sacs, known as **synovial bursæ**, that are found in many situations in the body. The bursæ contain fluid resembling synovia, and they serve to facilitate the play of one structure upon another. **Subcutaneous bursæ** are found between the skin and underlying bony prominences such as the olecranon and the patella. **Subfascial bursæ** are similarly placed beneath the deep fascia. **Subtendinous bursæ** are found where one tendon overlies another tendon or a projection of bone; the walls of such a bursa in the neighbourhood of a joint may be continuous

FIG. 311.—SYNOVIAL FOLDS FROM HUMAN KNEE JOINT.

The *capsular ligament* (just appearing at base of photograph) is separated from the *synovial membrane* by loose areolar tissue. Note numerous blood-vessels in the synovial membrane. (Photomicrograph × 100.)

with the synovial membrane of the joint through an aperture in the capsular ligament.

Of the same nature are the **synovial sheaths** that surround tendons running in osteo-fascial tunnels, as in the case of the tendons passing behind the flexor retinaculum at the wrist and of the flexor tendons lying on the front of the fingers. The synovial layer lines the tunnel and is also reflected round the tendon that lies within it.

Development of a Synovial Joint.—After the cartilaginous precursors of the bones have been formed, their ends are separated from each other by a disc of very cellular mesenchyme that is called the **primitive joint-plate** (Fig. 312 A). There are no sharp lines of demarcation between the ends of the cartilages and the joint-plate, and indeed the cells of the joint-plate that are adjacent to a cartilage are to be regarded as a chondrogenetic layer that is associated with the growth in length of the cartilage (for this, and other details of joint-development, see Haines, 1947). As development proceeds, a process of differentiation occurs within the joint-plate and the two chondrogenetic layers become separated from each other by an intermediate stratum of loose tissue in which the cells are relatively scanty (Fig. 312 B). The intermediate stratum of loose tissue later undergoes liquefaction so that a **joint-cavity** appears between the ends of the cartilages; the cartilages in turn lose the chondrogenetic layers over the articular surfaces though a thin fibrillar layer may persist over them until birth. The mesenchymatous tissue that surrounds the joint-plate differentiates into a dense outer layer that forms the **capsular ligament**, and an inner loose layer that forms the **synovial membrane**. The synovial layer is invaded by extensions of the joint-cavity so that the typical relationship of joint-cavity to synovial membrane is established. *Intra-articular ligaments* and *fibro-cartilages* arise from thickenings that project inwards from the wall of the primitive joint cavity. A complete *articular disc* arises from a transverse mesenchymatous septum between double cavities which appear in the joint-plate. *Extra-capsular ligaments* may arise independently of the joint-plate, from separate membranous bands.

Morphology of Ligaments.—Certain articular ligaments and fibro-cartilages, whether or not arising ontogenetically after the common manner just described, have been credited with interesting phylogenetic histories, sometimes in different versions. Thus, a muscle tendon that originally stretches over a joint to the farther bone may acquire a new attachment on the

nearer bone, leaving the original terminal portion of the tendon to become a ligament fixed to both bones. Or the altered functioning of a joint in phylogeny may cause an earlier ligament or cartilage to be married into changed relations in the later type of joint. In the knee joint the medial and lateral ligaments are examples of stranded tendons, and the attachment of the lateral semilunar cartilage to the posterior cruciate ligament is a reminder of the different mechanism of an earlier vertebrate knee.

Such morphological points will be mentioned with the structures concerned, but it must be remembered that they are of interest rather than importance from the standpoint of present function.

Blood- and Lymph-Vessels. — A synovial joint is freely supplied by branches of the main arteries that are adjacent to it. These branches perforate the capsular ligament and break up within the synovial membrane into capillaries which form a rich and intricate network. Many of the capillaries are extremely close to the free surface of the synovial membrane and this accounts for the frequency with which haemorrhage occurs into the joint-cavity after even minor trauma (Davis, 1945). Adjacent to the peripheral margin of the articular cartilage the larger vessels of the synovial membrane branch and anastomose to form a vascular circle, the *circulus articuli vasculosus* of William Hunter (1743), and it is the terminal branches of this circle that overlie the margin of the cartilage and provide it with nourishment (p. 336).

The *lymphatic vessels* form a plexus within the synovial membrane, and from it efferent vessels pass towards the flexor aspect of the limb.

Nerve-Supply. The capsular ligament and synovial membrane are both supplied with nerves. The correlation that exists between the nerves of a joint and the nerves to the overlying tissues is expressed in Hilton's Law (John Hilton, 1863), viz.: "The same trunks of nerves, whose branches supply the groups of muscles moving a joint, furnish also a distribution of nerves to the skin over the insertions of the same muscles; and the interior of the joint receives its nerves from the same source." The nerves in the capsular ligament terminate in free endings and end-organs and probably transmit pain and proprioceptive impulses. In the synovial membrane all nerves, according to Gardner (1944), terminate in relation to blood-vessels and it is considered that many of these are vasomotor nerves.

Joint-Approximation Forces.—It is useful to consider the factors concerned in maintaining the integrity of the union between the bones in synovial joints, in which, for the sake of a joint-cavity to assist free movement, structural continuity of the united bones is given up. Two minor factors common to all such joints are the **force of cohesion** and **atmospheric pressure**—the cohesion because of the smooth joint-surfaces in contact with each other except for an intervening capillary layer of fluid, and the pressure because the atmosphere is excluded from the closed synovial cavity. A third factor of very different value in different joints is **interlocking of the coapted bones**; this is well marked in the hip joint, but is completely absent in plane joints.

The most important factors are the **strength of the articular ligaments** and the **tension of the muscles** around the joint. These two act together in varying proportions; in, for example, the shoulder joint, with its relatively lax capsule, the ligamentous factor is small, whereas in the hip joint, with well developed ligamentous bands in its capsule, it is of more importance. But it must be emphasized that white fibrous tissue ligaments cannot resist continuous strains without lengthening permanently, so that they must ever be supported by the contractile tension of muscle. Whether at rest or in contraction, the muscles around a joint are ever exerting by their active tonicity a force of joint-approximation. Their efforts may be relieved considerably by suitably disposed ligaments, but no ligament will for long resist stretching under constant strain if unaided by muscular tension. Thus, in flat-foot deformity, while the displacement of bones is permitted by over-stretched ligaments, this in turn is due to diminished support from muscles deficient in tone. In the knee joint, where the capsular ligament is largely formed of tendinous expansions from muscles acting on the joint, a beautiful example is seen of close structural and functional co-operation of muscle and ligament.

Limitation of Movement.—Four factors are concerned in the limitation of movement at synovial joints: the apposition of soft parts, the locking of the articulating bones, the tightness of ligaments, and the tension of fully stretched muscles. **Apposition of soft parts** obviously limits movements in such examples as flexion of the elbow when the front of the forearm is pressed against the front of the upper arm, and flexion of the knee when the back of the leg meets the back of the thigh. **Locking of the bones** probably occurs only exceptionally; thus, in the elbow joint, in a few cases pressure facets at the sides of the olecranon fossa of the humerus indicate that extension must have been limited by actual contact of the olecranon with the humerus, but in the majority of cases tension of the muscles and ligaments in front of the joint is the limiting factor. The **tension of ligaments** is an important factor in the limitation of movement. The various parts of a capsular ligament are tense in only certain positions of a joint and they are concerned, therefore, not only in the final limitation of a movement but also in directing the movement of the articular surfaces on each other. In the hip and knee joints the major ligaments are lax in flexion and tense in extension. Furthermore, it is in the position of extension at these joints that the articular surfaces are in fullest contact with each other. Tense ligaments and maximal contact of the articular surfaces are the essential features of a 'locked' joint, and it is when a joint is 'locked' that it is most stable and best adapted for weight-bearing. At many joints **muscular tension** reinforces the restraint on movement imposed by the ligaments, if it does not actually check movement before the ligaments are fully stretched. This effect of the muscles is called their *passive insufficiency* or *ligamentous action*. A good example of limitation of movement purely by muscular tension is the check imposed on flexion of

the hip by the tension of the hamstrings while the knee is fully extended; flexion of the knee lessens the tension of these muscles, and further flexion of the hip can then take place. The effect of muscles in limiting movement in the ordinary person can be appreciated when one considers the greater range of movement possessed by acrobats, who by constant practice conserve or even increase the full extensibility of muscle possessed by all in early life. Admittedly in such cases ligaments and articular surfaces also are modified to allow the extreme movements; but that muscles normally exert a restraint on movement beyond that exercised by ligaments is shown by the extreme movements sometimes produced in the convulsions of tetanus or epileptic fits, when the safeguarding muscular restraint operating in ordinary voluntary action is withdrawn.

Classification of Synovial Joints

Synovial joints may be subdivided for further consideration in terms of the shape of the articulating surfaces and the movements performed at the joint; these two factors being related can be used together in a system of classification. From the point of view of form only, a distinction can be made between **homomorphic** and **heteromorphic** joints. The articular surfaces in a homomorphic joint are similar in conformation; those in a heteromorphic joint are dissimilar. Combining further consideration of shape with an analysis of movement, we distinguish *plane* and *saddle* joints of homomorphic pattern, and *hinge, pivot, ball-and-socket, condyloid* and *ellipsoid* joints in the heteromorphic division.

Plane Joint.—In a typical plane joint the opposed surfaces are flat, and are equal in extent; but in many cases the term is a relative one, as the surfaces are slightly curved. Such curvature, however, is never sufficient to bring the joint into one of the other subdivisions, and has little influence on the movement. This is a simple **gliding**, in any direction, or twisting, of the one bone on the other within the narrow limits permitted by a slight laxity of the capsular ligament. Such joints are found between some of the carpal and tarsal bones, and between the articular processes of adjacent vertebræ.

Saddle Joint.—Here the concavo-convex articular surface of the one bone is reciprocally homomorphic with the convexo-concave surface of the other. Movements are permitted around two principal axes at right angles to each other, and to a less extent around intermediate axes. The only good example is the carpo-metacarpal joint of the thumb.

Hinge Joint.—In this, the articulating surfaces are arranged to permit movement around only one axis—and that a transverse one—as in the hinge of the lid of a box. The elbow and interphalangeal joints are good examples. Usually the articulating bones are in line in the normal anatomical position; movement around the transverse axis causing the bones to become increasingly angulated is termed **flexion**, while movement in the reverse direction is called **extension**. In cases where the normal position is angular, as at the ankle joint, suitably modified terms may describe the movements with less ambiguity, as *dorsi-flexion* and *plantar-flexion* in the example quoted. Two features in the disposition of the ligaments are common to all hinge joints. In the first place, the capsular ligament must be of sufficient length in front and behind to permit movement; of these parts one will be taut and the other lax in full flexion or full extension. In the second place, strong ligaments are placed at the sides of the joint, one end of each ligament being attached in the axis of the hinge; some parts of these ligaments therefore can be taut in all positions of the joint without restricting its movement.

Pivot Joint.—Here also movement can take place around only one axis, but a vertical one, as in the hinge of a gate. A more or less cylindrical articular surface **rotates** within a ring formed partly by bone, partly by ligament, as in the superior radio-ulnar joint; or, conversely, the ring may rotate around the cylindrical surface, as in the joint between the odontoid process and the anterior arch and transverse ligament of the atlas.

Ball-and-Socket Joint.—Here, as for example in the hip and shoulder joints, a " ball " formed by a spheroidal surface on the one bone rotates in a " socket " provided by a concavity in the other. This is the most completely movable form of joint, for movement can take place around an almost infinite number of axes passing through the centre of the 'ball'. For descriptive convenience three principal axes at right angles to one another are specially considered. Around a transverse axis, movements of **flexion** and **extension** take place as in a hinge joint. Movements sideways around an antero-posterior axis are named **abduction** in the case of a limb raised laterally, away from the median plane of the body, and **adduction** when the limb is brought towards or across the median

(2) Incudo malleolar joint

plane. Around a vertical axis in the centre-line of the limb, the limb **rotates, medially or laterally.** **Circumduction** is a composite movement around a number of axes whereby the limb describes the side of a cone, the apex of which corresponds to the centre of the 'ball'. The stability of such a joint depends on the depth of the 'socket', but greater depth of socket proportionately limits movement.

Condyloid Joint.—In this variety the articular surfaces are of the ball-and-socket type; but, owing to the disposition of the ligaments and muscles, the movement of active rotation around a vertical axis is absent. **Flexion** and **extension, abduction** and **adduction**, and **circumduction** take place. The metacarpo-phalangeal joints of the fingers (but not of the thumb) are condyloid joints.

Ellipsoid Joint.—This is a further modification of the ball-and-socket joint: the articular surfaces, instead of being spheroidal are ellipsoidal, as in the radiocarpal joint. The curvature in the long axis of the joint-surfaces has a greater radius than in the short axis. Movement takes place around two principal axes at right angles, corresponding to the greatest and least diameters of the joint, and to a slight extent around intermediate axes. Circumduction also is allowed, but the ellipsoidal surfaces prevent rotation.

JOINTS OF TRUNK AND HEAD

INTERVERTEBRAL JOINTS

The joints between the free vertebræ are arranged on a common plan, with the exception of the specialized joints between the atlas and axis. The bodies of adjacent vertebræ are joined together and also the vertebral arches, but on each

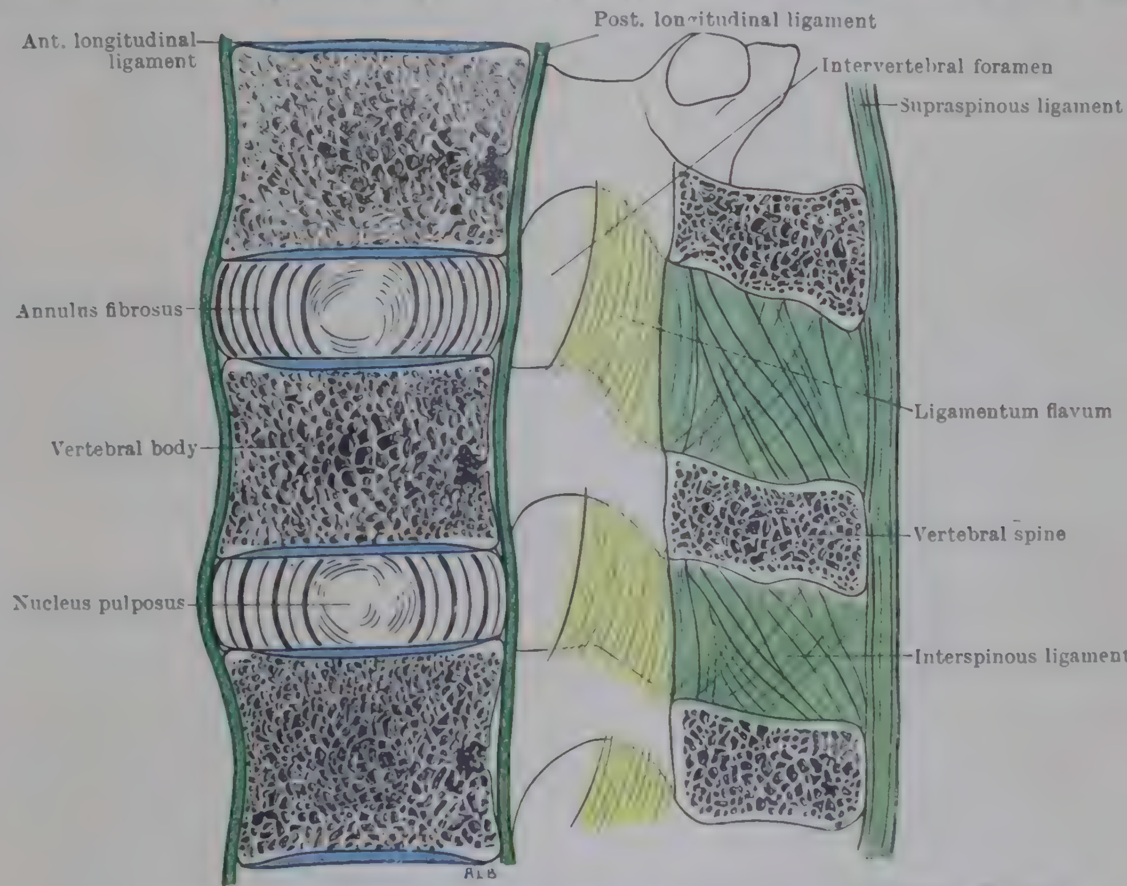

Fig. 313.—Median Section through Part of Lumbar Region of Vertebral Column.
Articular cartilage, *blue*; ligaments, *green* and *yellow* (lig. flava).

side, between these connexions, the pedicles remain free, being separated by the intervertebral foramina (Fig. 313).

Joints between Vertebral Bodies.—These joints are cartilaginous joints of the secondary type; for the bodies are united mainly by *fibro-cartilages*, though these are supplemented by *longitudinal ligaments*.

Intervertebral Discs.—The under surface of one body is united to the upper surface of the succeeding body by a fibro-cartilaginous **intervertebral disc** (Fig. 313). The peripheral part of this disc is called the *annulus fibrosus*, and is composed of fibro-cartilage so densely fibrous that the cartilaginous element is

appreciated with difficulty in microscopical section. The fibres run obliquely between the two vertebræ and are arranged in concentric rings, the fibres in successive rings having opposite obliquities. The central part of the disc, which is soft and gelatinous is called the *nucleus pulposus*. On each surface of the disc, above and below, there is a thin plate of hyaline cartilage, in the marginal part of which the annular epiphysis of the vertebral body develops. The surface of the vertebra with which the cartilage plate is in contact is perforated by numerous small foramina that are most apparent in the zone adjacent to the annular epiphysis. After the thirtieth year the discs are avascular and are nourished by fluid that traverses the foramina from the interior of the vertebrae and passes by diffusion through the cartilage plates. The discs between the cervical vertebræ do not extend quite to the lateral edges of the vertebral bodies, where, between the lipped edge of the body below and the bevelled edge of the one above, there is a small synovial joint. The discs account for nearly one-fourth of the length of the vertebral column but show considerable difference in their thickness in different regions, being thinnest in the upper thoracic region and thickest in the lumbar region. The discs are also slightly wedge-shaped, in conformity with the curvature of the vertebral column in their neighbourhood; this is particularly marked in the cervical and lumbar regions, where the anterior convexities are due chiefly to the greater thickness of the discs in front than behind. It is of considerable practical importance to note that the intervertebral disc forms one of the anterior boundaries of the intervertebral foramen (Fig. 313), and that the spinal nerves, as they pass through the foramina, lie directly behind the corresponding discs.

The nucleus pulposus is customarily described as a white glistening body that is composed of fibro-cartilaginous tissue embedded in a gelatinous matrix, but from the time of its first appearance in the foetus it undergoes a continuous structural change until late adult life. It was formerly believed to be derived from the notochord but this has been shown by Keyes and Compere (1932), and others, not to be strictly correct. Early in foetal life the notochordal cells in each intervertebral region proliferate rapidly but later undergo a mucoid degenerative process which results in the formation of a gelatinous nucleus pulposus. As the notochordal cells degenerate the nucleus is gradually invaded by the surrounding fibro-cartilaginous tissue. In young subjects the nucleus is still largely formed of gelatinous tissue and hence has a translucent appearance that contrasts sharply with the fibro-cartilaginous annulus fibrosus. With increase in age the gelatinous tissue is gradually replaced by fibro-cartilage until in old age the nucleus can no longer be recognized as a separate structure. Coincident with these changes in the structure of the nucleus pulposus, Puschel (1930) has shown that there is a progressive decrease in its water content, which at birth is 88 per cent but at seventy-two years is only 70 per cent.

The nucleus pulposus forms a variable proportion of the intervertebral disc in the different vertebral regions, but is always situated nearer its posterior than its anterior surface. It is normally under considerable pressure and, when the disc of a young or middle-aged subject is cut across, it protrudes above the level of the annulus fibrosus. The nucleus pulposus may be regarded as a water-cushion associated with equalizing the distribution of pressure between vertebræ, and the absorption of mechanical shocks that are constantly being transmitted along the vertebral column. For further information on the structure and function consult Beadle (1931) and Bradford & Spurling (1945).

Longitudinal Ligaments.—The **anterior** and **posterior longitudinal ligaments** also help to unite the bodies of the vertebræ. The **anterior ligament** (Fig. 321) is a broad band of some thickness that runs up and down the front of the column over the anterior surfaces of the vertebral bodies. It is narrowest at its upper end, where it has a pointed attachment to the anterior tubercle of the atlas; it becomes wider as it descends, and ends below by spreading on to the pelvic surface of the sacrum. It is firmly attached to the intervertebral discs and adjacent parts of the vertebral bodies; the superficial fibres pass over several vertebræ, the deepest join adjacent bones. The **posterior longitudinal ligament** (Fig. 314) is constructed on a similar plan. It is placed on the back of the vertebral bodies, in the anterior wall of the vertebral canal. Unlike the anterior ligament, it is broader above than below. Its upper end is continued into the membrana tectoria, which covers the odontoid process and its ligaments and is attached to the occipital bone. Opposite the bodies of the thoracic and lumbar vertebræ the posterior ligament narrows markedly, but remains broader opposite

the intervertebral discs, so that each edge presents a series of pointed dentations. Its narrow, lower end passes on to the anterior wall of the sacral canal. The posterior ligament is attached only to the discs and adjoining edges of the vertebral bodies; opposite the middle of each vertebra it is separated from the bone by an interval through which pass thin-walled veins (Fig. 313). The free surface of the ligament is separated from the spinal dura mater by loose areolar tissue with veins running in it; in the lower part of the canal the ligament is rather more intimately connected to the dura by fibrous bands. The posterior ligament, like the anterior one, is composed of longitudinal fibres of varying length: the most superficial run over several vertebræ; the deepest pass only from one bone to the next.

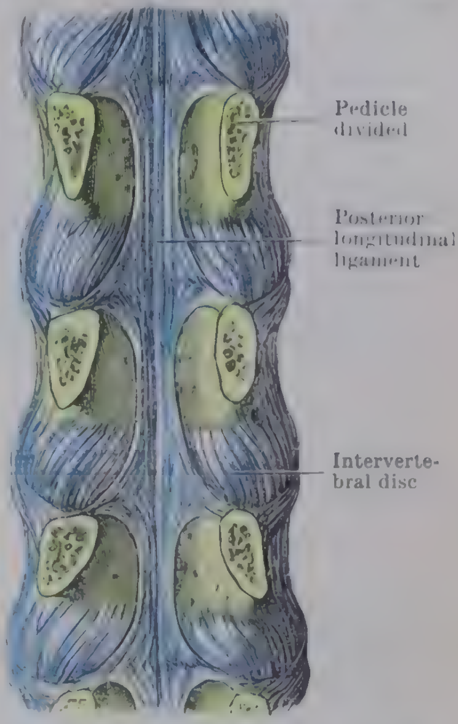

FIG. 314.—POSTERIOR LONGITUDINAL LIGAMENT OF VERTEBRAL COLUMN.

Joints between Vertebral Arches.—The vertebral arches are united by *synovial joints* between the articular processes, and by *accessory ligaments* which pass between the laminæ, between the transverse processes, and over and between the vertebral spines.

The **synovial joints** are of the plane variety; the shape and disposition of the joint-surfaces on the articular processes vary in the different regions of the column, as already described in the Section on Osteology. Each joint is surrounded by a thin **capsular ligament** lined with **synovial membrane**. The joint capsules are lax, particularly in the cervical region, so that slight gliding movements can take place between the bones.

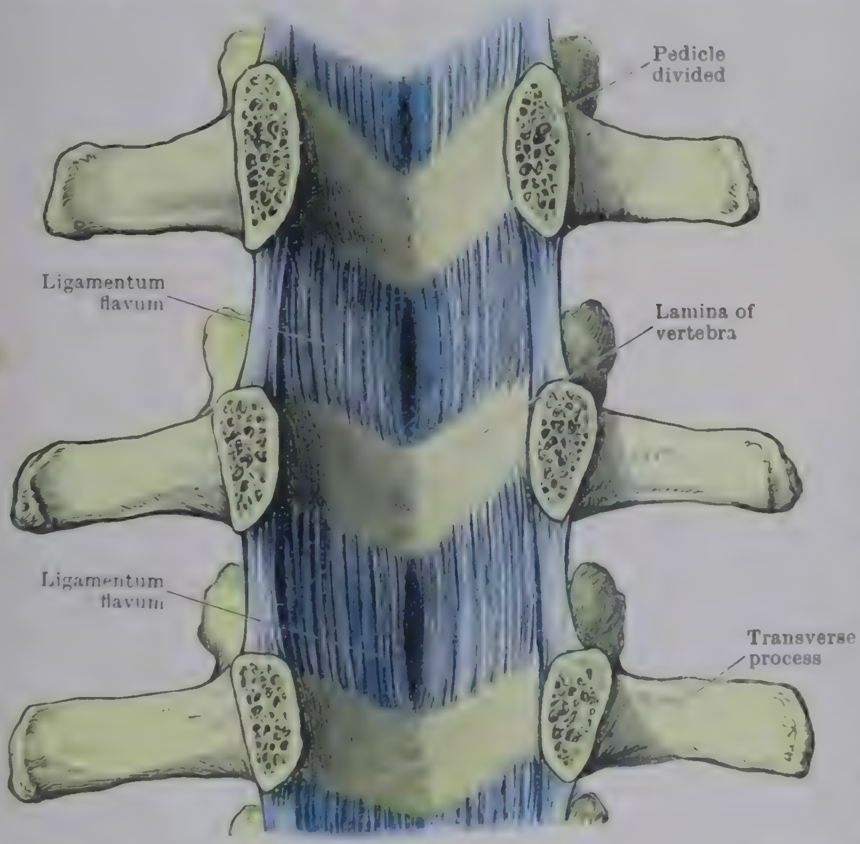

FIG. 315.—LIGAMENTA FLAVA SEEN FROM THE FRONT AFTER REMOVAL OF THE BODIES OF THE VERTEBRÆ BY SAW CUTS THROUGH THE PEDICLES.

The **accessory ligaments** are the supraspinous and interspinous, the intertransverse, and the ligamenta flava. The **interspinous ligaments** are relatively weak bands that run between the lower border of one vertebral spine and the upper border of the next below; they are longest and strongest in the loin (Fig. 313). The **supraspinous ligament** runs over the tips of the spines and is fused with the posterior edges of the interspinous ligaments; short fibres in the ligament join adjacent spines; longer ones connect spines several vertebræ apart.

In the neck, the supraspinous ligament merges into the triangular **ligamentum nuchæ**. This, in Man, is merely a fibrous partition between the muscles of the two sides of the back of the neck; it is attached above to the external occipital crest and deeply to the cervical spines, while its superficial border runs between

the external occipital protuberance and the spine of the last cervical vertebra. In quadrupeds the ligamentum nuchæ is a well-developed elastic ligament which relieves the muscles in supporting the head.

The intervals between the laminæ of adjacent vertebræ are filled by the **ligamenta flava**, so called because of their yellowish colour due to the presence of much elastic tissue. Each is attached above to the front of the lower border of a lamina, and below to the back of the upper border of the succeeding lamina (Fig. 315). There are two—a right and a left—in each vertebral interval; their medial borders are separated by a narrow, median chink through which pass veins that connect the venous plexus within the vertebral canal to the posterior vertebral plexus; laterally, they extend to the capsules of the intervertebral synovial joints, but do not blend with them. The ligamenta flava are the only markedly elastic ligaments in Man. By their elasticity they can permit separation of the laminæ in forward flexion of the vertebral column without falling, on extension of the column, into folds which might press upon the dura mater or be caught between the laminæ they connect; and their elastic tension assists the posterior vertebral muscles in maintaining the erect attitude.

The *intertransverse ligaments* are insignificant bands between the transverse processes. They are generally absent in the cervical region; they are marked only in the lumbar region. In the upper part of the column they tend to be replaced by the intertransverse muscles.

Movements of Vertebral Column

The adult vertebral column in the erect posture has four antero-posterior curves—cervical, thoracic, lumbar and sacro-coccygeal—and these have already been considered in the Section on Osteology on p. 135. As stated there, the *compensatory* or *secondary* curves (cervical and lumbar) are due mainly to the shape of the discs, whereas the thoracic curvature, which is a primary one, is caused mainly by the shape of the vertebræ. The sinuous form of the vertebral column, made up as it is of alternate bony vertebræ and resilient intervertebral discs, makes it a structure that is well adapted to its supporting and shock-absorbing functions. In old age the intervertebral discs shrink and the vertebral column tends to revert to its original primary curve; thus it is that some people in advanced years have a ' bowed back ' and appear to become smaller.

Movement between any two successive vertebræ is very slight; but the sum total of movement in the whole column is considerable (Pl. XXXI). The possibility of movement is due to the slight flexibility of the intervertebral discs coupled with the laxity of the capsules and the incomplete apposition of the articular surfaces of the intervertebral synovial joints. Where the discs are thick or numerous, movement is likely to be more free, though the arrangement of the fibres in the discs strictly limits movement between adjacent vertebræ in any direction; the semi-fluid nature of the nucleus pulposus tends to equalize pressure within each disc during movements between the vertebræ. The shape and set of the articular processes in the different regions affect the degree of movement permitted at the synovial joints.

The movements of the vertebral column are customarily described as forward **flexion**, backward **extension**, **lateral flexion**, and **rotation**. Lateral flexion and rotation are, however, always associated movements and neither can take place independently of the other. All the above types of movement can take place in all regions of the column, but the thickness of the intervertebral discs and the ' set ' and shape of the articular processes are the factors that largely determine the range of movements in the different regions. During flexion the anterior borders of the vertebræ are approximated whereas the distance between the posterior borders is increased: as full flexion is reached the anterior parts of the intervertebral discs are tightly compressed, but the posterior parts of the discs, the posterior longitudinal ligament and the ligaments of the vertebral arches all become taut, though the principal limiting factor to the movement is the tension of the posterior vertebral muscles. In extension, the vertebræ rock backwards on one another so that the distance between the anterior borders of the vertebræ is increased and the posterior borders are approximated (Pl. XXIX, p. 342). During this movement the anterior longitudinal ligament becomes increasingly taut whereas the other ligaments of the column are relaxed. The movement of extension of the column has a wider range than the movement of flexion, and is greatest in the cervical and lumbar regions. Much of

PLATE XXXII. THREE RADIOGRAPHS OF THE SHOULDER TO DEMONSTRATE THE MECHANISM OF ABDUCTION AND ELEVATION OF THE ARM. (See p. 487.)

Note that in addition to movement of the scapula on the chest wall, and of the humerus at the shoulder joint, lateral rotation of the humerus also takes place.

[Face p. 347

the apparent movement of flexion of the vertebral column during the bending forwards of the body is in reality due to flexion at the hip joints and also movement of the head at the atlanto-occipital joints.

In the neck, where the discs are relatively preponderant for the length of that part of the column, all movements are fairly extensive. The articular surfaces, set obliquely in a transverse plane, facilitate *flexion* and *extension* but cause *lateral flexion* and *rotation* to be accompanied each by some degree of the other movement. Thus, when the neck is bent to one side, each lower articular process on that side glides downwards and backwards on the upper process of the vertebra below, while on the other side each lower process mounts upwards and forwards upon the superior process below it; hence bending to one side is accompanied by a slight rotation to that side.

In the thorax, the small proportion of the fibro-cartilage relative to the length of the thoracic region, the presence of the ribs and sternum and the imbrication of the long, sloping spines all tend to limit movement. The vertical disposition of the articular processes hinders *antero-posterior* movement but interferes less with *lateral flexion*, which is accompanied by a crowding together of the ribs on the side of flexion and a spreading apart on the opposite side. *Rotation* is facilitated by the centre of curvature of the articular processes being near the centre of the vertebral body; but this is counterbalanced by the restraint imposed by the ribs and sternum. Rotation and lateral flexion are, however, always associated, and in complete extension of the vertebral column these movements are greatly diminished, if not altogether lost.

In the lumbar region the discs are thick; but the articular processes, vertically set with curvatures centred behind the vertebræ altogether, tend to restrict movements of all kinds—rotation in particular. Fairly free flexion and extension occur, especially at the lumbo-sacral joint where the intervertebral disc is thickest. When the vertebral column is flexed the lumbar curve is lost (Pl. XXXI) and lateral flexion, which is possible in the erect posture, is greatly diminished. Owing to the laxity of the intervertebral synovial joints some rotation may take place and this is associated with lateral flexion.

Atlanto-Occipital Joints

The skull is joined to the atlas by a pair of **atlanto-occipital synovial joints** between the occipital condyles and the superior articular facets of the atlas, and by the **anterior** and **posterior atlanto-occipital membranes**, which connect the arches of the atlas with the margins of the foramen magnum (Fig. 316).

Atlanto-Occipital Membranes.—The **anterior atlanto-occipital membrane** is attached superiorly to the anterior margin of the foramen magnum, and inferiorly to the anterior arch of the atlas; in the middle, the membrane is thickened by fibres prolonged upwards from the anterior longitudinal ligament: the right and left margins blend with the capsular ligaments of the synovial joints. The **posterior atlanto-occipital membrane** likewise reaches the capsular ligament at each side. Its upper border is attached to the posterior margin of the foramen magnum. The median part of its lower border is attached to the posterior arch of the atlas; but the lateral part, on each side, arches over the vertebral artery and the first cervical nerve as they cross the posterior arch of the atlas; this part of the lower edge of the membrane is thickened and is sometimes ossified.

Atlanto-Occipital Joint.—Each of the pair of synovial joints is enclosed by a **capsular ligament** which is attached at the margins of the articular surfaces and is lined with **synovial membrane**. The atlantal articular surface is concave; the occipital surface is convex. But the corresponding surfaces of the joints of the two sides are really segments of one ellipsoidal surface whose transverse diameter is the longer, and functionally the joints act together as a single ellipsoidal articulation. Movement therefore takes place around two principal axes—nodding or bending the head forwards and backwards around a transverse axis, and bending the head sideways around an antero-posterior axis. No rotation takes place between the skull and the atlas beyond a little slipping of the occipital condyles, the one forwards the other backwards, on the atlantal facets, giving the face a slight oblique tilt; the joint-surfaces are then in better apposition, and this is the natural pose of greatest ease and stability.

Atlanto-Axial Joints

The **atlas** and the **axis** have *bilateral synovial joints* between their opposed articular processes, and a *median synovial joint* formed by the articulation of the odontoid process with the anterior arch of the atlas and with the transverse ligament; in addition, various *accessory ligaments* connect the axis to the atlas, and the odontoid process to the occipital bone.

Lateral Atlanto-Axial Joint.—Each of the paired joints is of the plane variety, enclosed by a loose **capsular ligament** with a **synovial lining.** The articular surfaces have slight reciprocal curvatures, and are inclined obliquely laterally and downwards. Applied to the back of the capsule is an **accessory atlanto-axial ligament** which runs obliquely downwards and medially from the back of the lateral mass of the atlas to the back of the body of the axis (Fig. 317).

The anterior arch of the atlas is connected to the front of the body of the axis by a membranous expansion from each side of the pointed upper part of the anterior longitudinal ligament as it descends from the anterior tubercle of the

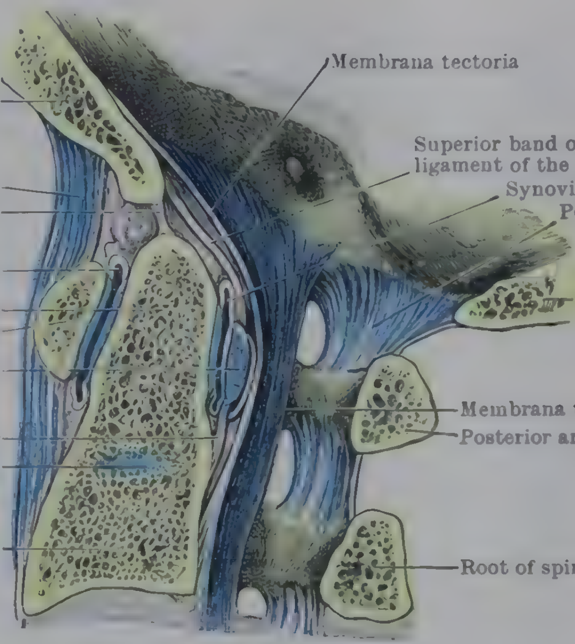

Fig. 316.—Median Section through Atlanto-Occipital and Atlanto-Axial Region.

atlas. The gap between the posterior arch of the atlas and the arch of the axis is bridged by a membrane, in series with the ligamenta flava, which is pierced at each side by the second cervical nerve. The position of this nerve behind the atlanto-axial joint bespeaks the different morphological value of this joint compared with other intervertebral synovial joints; it is held to be homologous with the small synovial cavity at the side of each cervical intervertebral disc.

Median Atlanto-Axial Joint.—The **articulation of the odontoid process with the atlas** is a pivot joint provided with two little synovial cavities (Fig. 316). The smaller of these cavities is between the facet on the front of the odontoid process and the facet on the back of the anterior arch of the atlas; the larger cavity is between the posterior facet on the odontoid process and the transverse ligament of the atlas; each cavity is enclosed by a thin capsular ligament lined with synovial membrane.

The transverse ligament of the atlas is a stout band that passes behind the odontoid process, between the tubercles on the medial sides of the lateral masses of the atlas (Fig. 317). From the middle of the transverse ligament a small band of longitudinal fibres passes upwards to the anterior edge of the foramen magnum, and another passes downwards to the back of the body of the axis (Fig. 316). These bands, together with the transverse ligament, constitute a cruciform structure known as the **cruciate ligament** of the atlas.

Occipito-Axial Ligaments

The axis is connected with the occipital bone indirectly by the longitudinal bands of the cruciate ligament, and, more directly, by the apical and alar ligaments of the odontoid process and by the membrana tectoria.

Ligaments of Odontoid Process.—Lying immediately in front of the upper band of the cruciate ligament, there is a slender cord which stretches from the apex of the odontoid process to the anterior edge of the foramen magnum: this is the **apical ligament** of the odontoid process, a structure developed from the rudiment of a supra-atlantal disc and the segment of notochord passing from the first cervical centrum to the cranial base. The **alar ligaments** of the odontoid process are short, stout bands that run, one from each side of the apex of the odontoid process, upwards and laterally to the medial side of each occipital condyle (Fig. 317).

Membrana Tectoria.—The odontoid process and the cruciate and alar ligaments are covered over posteriorly by the **membrana tectoria** (Figs. 316, 317), a broad

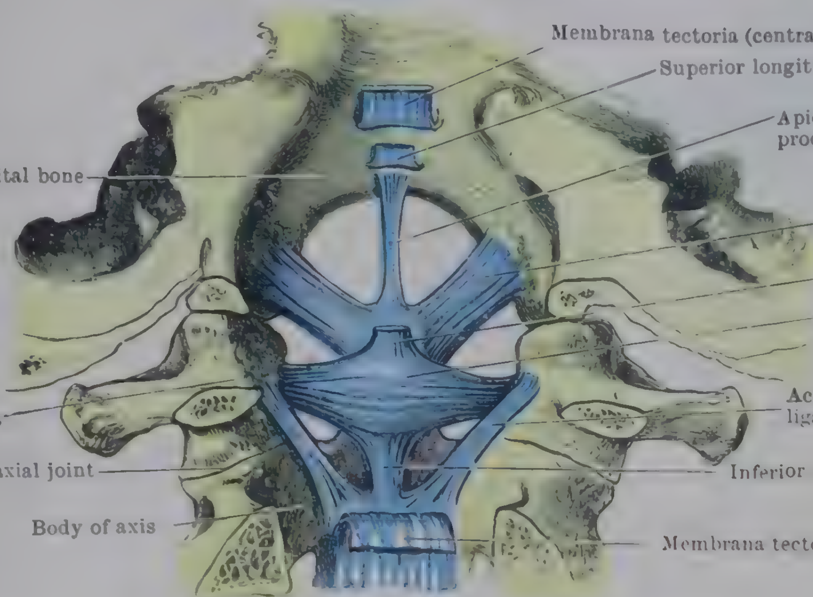

FIG. 317.—DISSECTION FROM BEHIND OF LIGAMENTS CONNECTING OCCIPITAL BONE, ATLAS, AND AXIS WITH ONE ANOTHER. (The capsular ligaments of the atlanto-occipital and atlanto-axial joints have been removed.)

sheet continuous below with the upper end of the posterior longitudinal ligament, and attached above to the occipital bone within the anterior edge of the foramen magnum between the anterior condylar canals. A small synovial bursa sometimes lies between the membrana and the median part of the transverse ligament of the atlas. The lateral margin of the membrana tectoria overlies and blends with the accessory atlanto-axial ligament. The upper end of the spinal dural tube is closely attached in front to the posterior surface of the membrana tectoria, and, behind, to the anterior surface of the posterior atlanto-occipital membrane.

Movements of the Head

The movements of the head at the **atlanto-occipital joints** have been referred to in the description of those joints.

The combined movements at the three **atlanto-axial joints** serve to effect rotation of the head around a vertical axis, the skull and the atlas moving as one. While the ring formed by the anterior arch and transverse ligament of the atlas pivots round the odontoid process, the lateral masses of the atlas glide, the one forwards and the other backwards, on the upper articular facets of the axis. Owing to the oblique disposition of these lateral joint-surfaces, rotation of the head to one side is accompanied by a slight vertical descent of the head, so that the median pivot joint around the odontoid process resembles in action a rising butt-hinge. Excessive rotation is checked by the alar ligaments and to a less extent by the accessory atlanto-axial ligaments. But the descent of the head, by approximating the attachments of the alar ligaments, serves to delay their check action, and this action can be obviated during a further degree of extreme lateral

rotation by tilting the head backwards and to the opposite side. When the face looks straight forward the lateral joint-surfaces are not fully in apposition; slight rotation to one side secures better apposition and a pose more easily maintained.

Mandibular Joint

The **mandibular joint** is formed by the articulation of the **head of the mandible** with the **articular fossa** and the **articular eminence** of the temporal bone. It is a synovial joint possessing a complete articular disc of fibro-cartilage which divides the joint-cavity into two separate compartments—an upper one between the disc and the articular surface on the temporal bone, and a lower one between the disc and the head of the mandible.

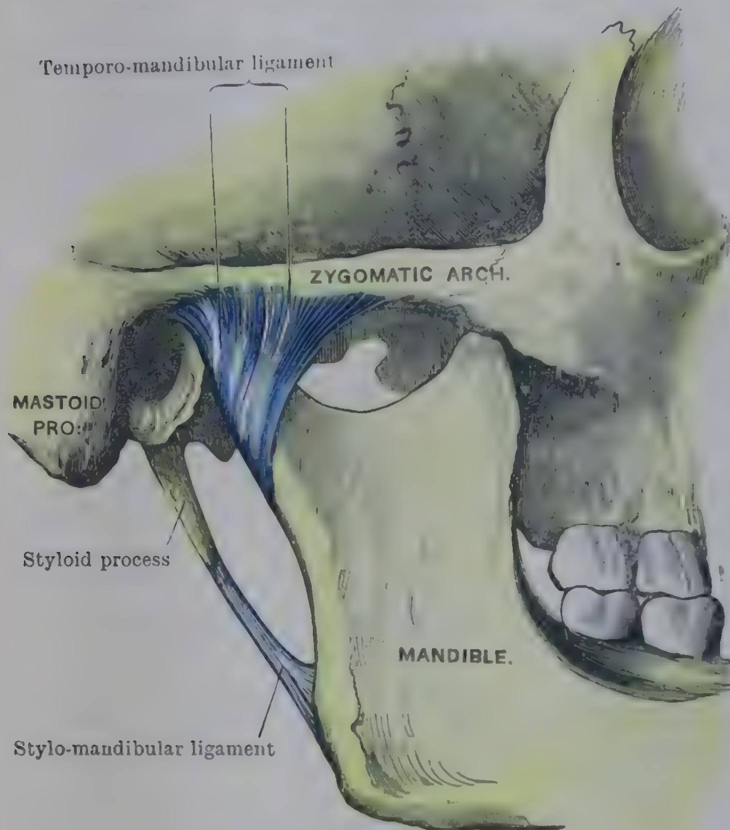

Fig. 318.—Mandibular Joint.

The **temporal articular surface** is concavo-convex from behind forwards, extending from the squamo-tympanic fissure over the articular fossa and eminence to the anterior border of the eminence (Fig. 319). The **head of the mandible** is a narrow ellipsoidal bar of bone directed medially and slightly backwards, markedly convex from before backwards but only slightly convex from side to side.

The **capsular ligament** is loosely arranged around the joint. It is attached superiorly around the limits of the temporal articular surface, and inferiorly to the neck of the mandible. Each compartment of the joint has its separate **synovial membrane**, which lines the capsular ligament but disappears over the surface of the disc. The capsular ligament is thickened laterally by a strengthening band, called the **temporo-mandibular ligament**, which is directed downwards and backwards from the lower border and tubercle of the zygoma to the lateral and posterior aspect of the neck of the mandible (Fig. 318). Anteriorly the capsular ligament receives part of the insertion of the lateral pterygoid muscle.

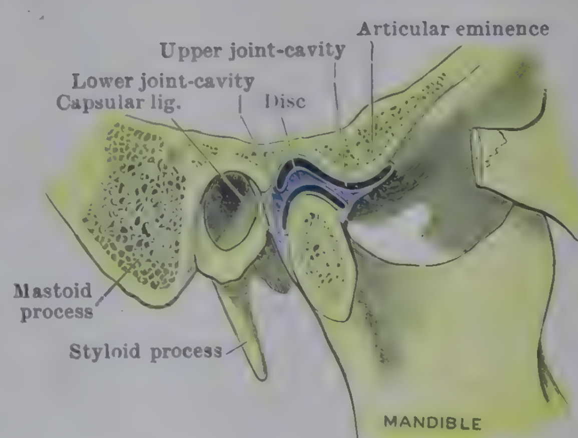

Fig. 319.—Antero-posterior Section through the Mandibular Joint.

The **articular disc** separates the highly incongruent joint-surfaces and is moulded upon them in different positions of the joint; it is therefore concave below and concavo-convex above (Fig. 319). It is attached all round to the capsular ligament, and, anteriorly, through the capsule, to the lateral pterygoid tendon. In the embryo the lateral pterygoid tendon passes backwards between the head of the mandible and the squamous temporal bone to be attached to the malleus, and it is the part between the bones that becomes compressed and forms the disc (Harpman and Woollard, 1938). The disc is thick anteriorly and in the middle; between these thickenings it is thin, and the posterior half of the disc thins out as it passes down behind the head of the mandible.

Accessory Ligaments.—Two other ligaments in the vicinity of the mandibular joint may be mentioned here. The **spheno-mandibular ligament** is a thin band that runs from the spine of the sphenoid bone and the adjacent medial end of the squamo-tympanic fissure downwards and forwards to the lingula and the adjoining part of the deep surface of the ramus of the mandible (Fig. 320). It lies a little medial to the capsule of the mandibular joint; intervening between the two, there are the maxillary artery and the first parts of its middle meningeal and inferior dental branches, the auriculo-temporal and inferior dental nerves, and a process of the parotid gland. This ligament is of interest because it is developed from the sheath of that part of the cartilage of the mandibular arch (Meckel's cartilage) that lies between the base of the skull and the mandibular foramen. The **stylo-mandibular ligament** is merely a thickened band of deep cervical fascia between the styloid process and the lower part of the posterior border of the ramus of the mandible (Figs. 318, 320).

Nerve-Supply.—The mandibular joint is supplied from the **mandibular** nerve by twigs from its **auriculo-temporal** and **masseteric** branches.

Movements at Mandibular Joints

Movement at each mandibular joint has two components. In the upper compartment the head of the mandible and the disc, acting as one by virtue of the attachment of the lateral pterygoid muscle to both, glide forwards and downwards round the postero-inferior surface of the articular eminence. In the lower compartment a hinge-like rotation of the head of the mandible under the concave surface of the disc takes place around a transverse axis. The upper part of the joint, therefore, acts like a plane joint, the lower part like a hinge joint; but the two components of movement are never completely dissociated, and for this reason there is no stationary axis of movement. In the movements of **opening** and **closing the mouth** the two components are equally involved; and, of course, the joints on both sides of the head act together. The forward and downward displacement of the mandibular foramen is compensated to some extent by backward movement of the angle of the jaw, so that no undue tension is put upon the inferior dental vessels and nerves.

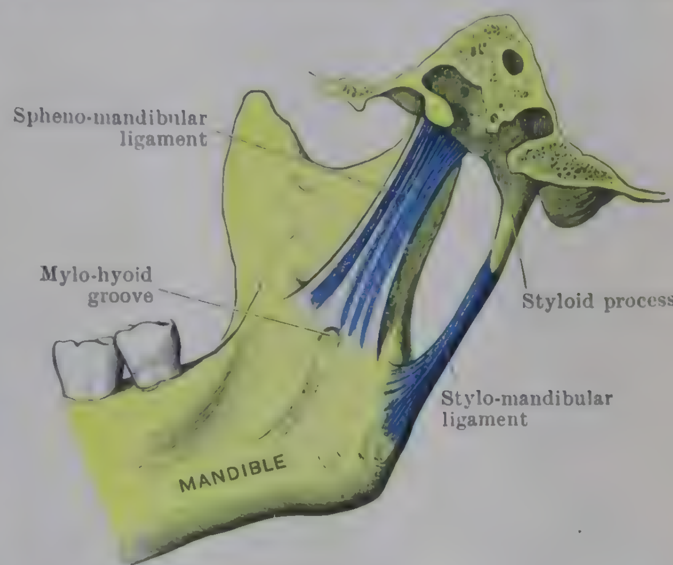

Fig. 320.—Accessory Ligaments of Mandibular Joint.

In the antero-posterior movements of **protraction** and **retraction** of the lower jaw, it is mainly the gliding action in the upper compartment which is involved, the joints of both sides acting together. The oblique **grinding** movements of chewing are brought about by alternate or opposite movements in the upper compartments of the two joints, combined with associated hinge movements in the lower compartments.

It is worth noting that the upper attachment of the main (anterior) band of the temporo-mandibular ligament is on the axis of the curved, downward-and-forward gliding movement in the upper compartment, and therefore, to some extent, the ligaments of the two sides resemble the collateral ligaments of a hinge joint. Their tension will not vary much throughout this upper-compartment movement, and hence they do not completely prevent the possibility of dislocation of the mandibular head on to the front of the articular eminence. As this danger, however, arises only in excessively wide opening of the mouth, the associated rotation in the inferior compartment in such a position, by putting a strain upon the ligament, brings about a certain amount of safeguarding tension.

JOINTS OF RIBS AND STERNUM

The ribs articulate posteriorly with the thoracic vertebræ; with the exception of the first rib and the last two or three ribs, which themselves deviate from the common form, each rib articulates after a common plan with the bodies of two adjacent vertebræ by its head and with the transverse process of the lower of these vertebræ by its tubercle. Anteriorly, the ribs end in costal cartilages, which, with the exception of the last two, make further connexions with the sternum or with one another.

Costo-Vertebral Joints

Joints of Heads of Ribs (Fig. 321).—The **head** of each typical rib has two articular facets—superior and inferior—separated by a horizontal crest. Between the bodies of each two typical thoracic vertebræ, there is situated, postero-laterally, a little cupped depression bottomed by the edge of the intervertebral disc and completed above and below by slightly concave facets on the sides of the adjacent vertebræ. Into this depression the head of the rib is fitted, its crest being bound to the intervertebral disc by a short, thick **intra-articular ligament**. The facets on the head articulate with the facets on the vertebral bodies, of which the lower is in numerical correspondence with the rib.

The whole articulation is surrounded by a **capsular ligament**, within which the intra-articular ligament forms a complete horizontal septum between upper and lower joint-cavities, both provided with synovial membranes. The anterior part of the capsular ligament is specially thickened to form the **radiate ligament** of the head of the rib, which passes medially from the front of the head to the adjacent parts of the disc and vertebral bodies, spreading fanwise upon them, under cover of the edge of the anterior longitudinal ligament. Three

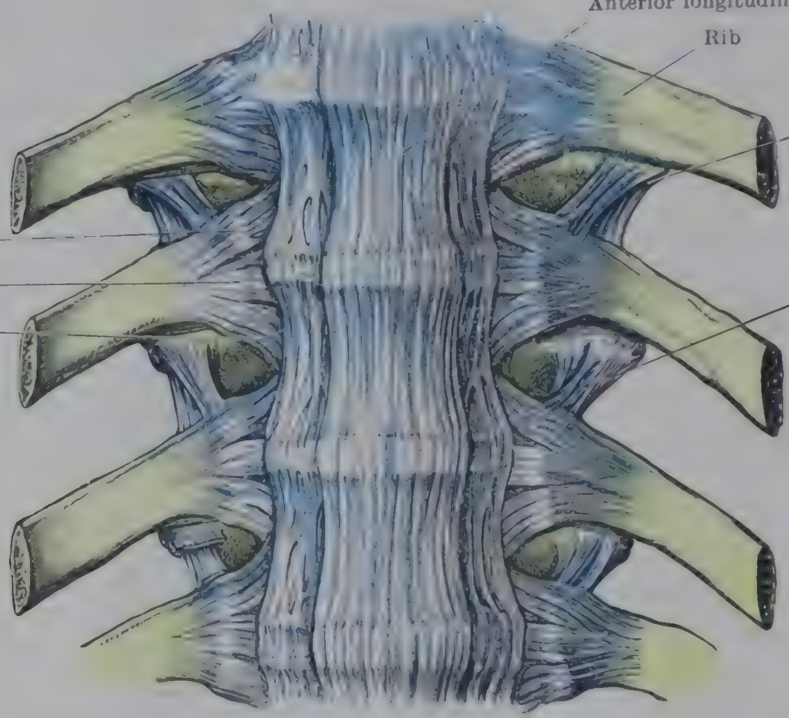

Fig. 321.—Anterior Longitudinal Ligament of Vertebral Column, and the Costo-Vertebral Joints as seen from the Front.

radiating bands are often to be seen, especially in the middle joints of the series, a central one blending with the intervertebral disc, and upper and lower bands attached to the vertebral bodies. The back of the capsule is connected to the adjacent denticulation of the posterior longitudinal ligament.

The intra-articular ligament and the connexion between the capsular ligament and the denticulation of the posterior longitudinal ligament are said to be related to the *conjugal ligament* which in certain mammals connects the heads of a pair of ribs across the back of the intervertebral disc. Conjugal ligaments are present in the human fœtus, but disappear later, except for the formation of the above-mentioned structures from their lateral ends.

Costo-Transverse Joints.—Each typical rib further articulates by its **tubercle** with the transverse process of the lower of the two vertebræ to which its head is joined; and it is attached to the transverse processes of both vertebræ by certain accessory ligaments. A small costo-transverse synovial joint surrounded by a thin **capsular ligament** is formed between the medial part of the costal tubercle and the circular facet on the anterior surface of the corresponding transverse process near the tip. Strengthening this joint, on its postero-lateral aspect, there is the **lateral costo-transverse ligament**—a stout band running between the rough,

lateral part of the costal tubercle and the tip of the transverse process. It is in contact with the capsular ligament of the costo-transverse joint but is not fused with it.

The **inferior costo-transverse ligament** also binds the rib to the same transverse process; it is composed of very short fibres that bridge the narrow interval between the back of the neck of the rib and the front of the transverse process.

Finally, the rib is attached to the transverse process of the vertebra above by the **superior costo-transverse ligament** (Fig. 321). This ligament consists of an anterior and a posterior band that spring from the upper border of the neck of the rib, and are separated laterally by the posterior fibres of the external intercostal muscle. The anterior band has medially a thickened free border, but laterally it blends with the posterior intercostal membrane; its fibres pass upwards and laterally to the lower border of the transverse process above. The posterior band ascends vertically, or with a medial inclination, to the medial part of the lower border of the transverse process above, and in some cases extends medially on to the inferior articular facet of the vertebra above.

The vertebral connexions of the **first rib** and of the **last two or three ribs** are atypical. The head of each of these ribs has a single facet that articulates with an impression on the side of only the corresponding vertebra. The intra-articular ligament is therefore absent in each case, and there is a **single synovial cavity**; the radiate ligament is incompletely developed. The superior costo-transverse ligament of the first rib is represented by feeble bands attached to the seventh cervical transverse process. The tubercles of the lowest ribs do not form synovial joints with the transverse processes; their costo-transverse ligaments are progressively less well defined: those of the last rib may be absent altogether.

Anterior Connexions of Ribs and Costal Cartilages

The anterior end of each rib is continuous with a bar of hyaline cartilage, called the *costal cartilage*, which is solidly united to the rib in a concavity at its end. The first seven costal cartilages articulate with facets on the side of the sternum; and certain of the cartilages articulate with one another.

Sterno-Costal Joints (Fig. 322).—Little synovial cavities usually develop in these joints between the sternum and the costal cartilages, except in the case of the first, which remains a continuous cartilaginous joint. The cavity of each of the others is divided into two by an **intra-articular ligament**, until the corresponding sternal segments fuse together; in most cases the second sterno-costal joint cavity remains double throughout life; the cavities in the remaining joints tend to become obliterated in old age. The **capsules** of these little joints are strengthened in front and behind by fibres that spread fanwise over the anterior and posterior surfaces of the sternum. These fibres are better marked in front, and there they interlace with those of the opposite side to form a felted membrane which is fused with tendinous fibres of the pectoralis major muscles.

Interchondral Joints.—The tips of the eighth and ninth costal cartilages form little **synovial joints**, each with the lower border of the cartilage above. In addition, synovial joints are formed between slight bosses developed on the adjacent margins of the fifth to the eighth or ninth cartilages. All these joints between cartilages are enclosed by short **articular capsules** strengthened in front and behind by oblique ligamentous bands. The terminal part of the tenth cartilage is united to the ninth by a syndesmosis.

The last two costal cartilages are short conical structures ending freely amongst the muscles of the flank.

Sternal Joints

The **manubrio-sternal joint** lies between the manubrium and the body of the sternum and is of a singular type. Prior to its ossification the sternum is a continuous bar of hyaline cartilage, but the manubrio-sternal joint is early demarcated by the transformation of the hyaline cartilage opposite the second costal cartilage into fibro-cartilage. When ossification in the sternum is complete a thin layer of the hyaline cartilage above and below the fibro-cartilage remains unossified so that the joint has an appearance similar to that of a secondary cartilaginous joint. Sometimes

the central part of the fibro-cartilage is absorbed and a cavity is formed within it, and less frequently the joint is obliterated by synostosis in old age. Special longitudinal fibres and the neighbouring sterno-costal ligaments strengthen this joint in front and behind. The cartilaginous **xiphi-sternal joint** between the body of the sternum and the ziphoid process is usually ossified in early adult life.

Movements of Ribs and Sternum

The active movements of the ribs and sternum are those associated with respiration. The capitular and costo-transverse joints of each rib together form a hinge with an axis through the two joints; owing to the backward tilt of the transverse process of the typical thoracic vertebra, this axis is directed laterally and backwards, and, at all except the first two costo-vertebral joints, also slightly downwards. At the second costo-vertebral joint the axis is in the horizontal plane, and at the first there is a slight inclination upwards. Thus hinged posteriorly, the anterior part of the rib is raised during inspiration and lowered during expiration. As the anterior end of the rib is below the level of the posterior end, raising the rib in inspiration causes the anterior end to travel forwards as well as upwards and, owing to the obliquity of the axis of the hinge, a little laterally as well. The sternum, attached to the anterior ends of the upper ribs, is also made to travel upwards and forwards, and the lateral deviation of the anterior ends of the ribs causes an opening out of the angles between the sternum and the costal cartilages. The obliquity of the axis of movement posteriorly is most marked in the case of the middle ribs, which possess long, inclined cartilages, and therefore the greater lateral movement of the anterior ends of these ribs can readily take place. But in the upper ribs, where the axis is less oblique, the lateral movement is slight or absent; shorter cartilages therefore suffice, set almost at right angles to the sternum. As the first rib is so much shorter than those which succeed it, the upwards and forward excursion of its anterior end is less in extent, and the movement of the upper border of the sternum is correspondingly reduced (see Haines, 1946). The greater travel—especially in the forward direction—imposed upon the rest of the sternum by the longer ribs causes a bending of the breastbone at the manubrio-sternal joint. The result of all this on the capacity of the thorax is to increase its antero-posterior diameter. But its transverse diameter also is increased, for the following reason. The sternal attachments of the ribs to some extent hamper the movements of their anterior ends and to that extent 'fix' the anterior ends, so that the raising of the ribs is in part translated into a twisting of the anterior parts of the costal arches, causing torsion of the cartilages and rotation at the sterno-costal joints. But to begin with, each costal arch is so disposed that the middle part is below the level of a line between its two ends—like a bucket-handle hanging down below the rim of the bucket. Hence this longitudinal twisting of the costal arch causes the middle part of the rib to rise upwards and outwards, so increasing the transverse width of the thorax.

Expiration is accompanied by reverse movements whereby the antero-posterior and transverse diameters of the thorax are diminished. Although it is convenient thus to describe the respiratory movements of the thorax as taking place in alternate opposite directions between the extreme inspiratory and expiratory positions, it should be explained that the 'resting' position of the thorax is midway between these extremes. This is the position of balance between the elastic tension of the costal arches tending upwards and the muscular and mechanical pull of the abdominal wall and contents tending downwards. The first half of the complete movement in either direction between full expiration and inspiration represents a recoil to this mean position; beyond this point, the second half of the movement is the result of positive muscular effort.

Apart from respiratory movements, the ribs move passively with changes in the thoracic part of the vertebral column. Flexion of the column causes a crowding together of the ribs; extension causes a spreading apart; bending of the column to one side brings about a crowding of the ribs on that side of the trunk, and spreading on the opposite side.

JOINTS OF UPPER LIMB

JOINTS OF SHOULDER GIRDLE

In order to promote freedom of movement of the arm, the shoulder girdle remains relatively independent of the skeleton of the trunk; only one joint, and a freely movable one—the *sterno-clavicular*—exists between the two. The scapula is

attached to the axial skeleton by muscles only. The bones of the girdle are themselves movably united to each other at the *acromio-clavicular joint.*

Sterno-Clavicular Joint

At the **sterno-clavicular joint** the medial end of the clavicle articulates with the sternum (an articular disc intervening), and with the first costal cartilage. The clavicular surface is more extensive than the sternal, but the medial articular surface is prolonged a little way over the upper surface of the cartilage of the first rib. The bony surfaces are reciprocally concavo-convex, being convex vertically and concave horizontally on the clavicular side. But the curvatures are slight and not fully congruent. and the clavicular and sternal surfaces are separated by the articular disc, so that the joint cannot function as a

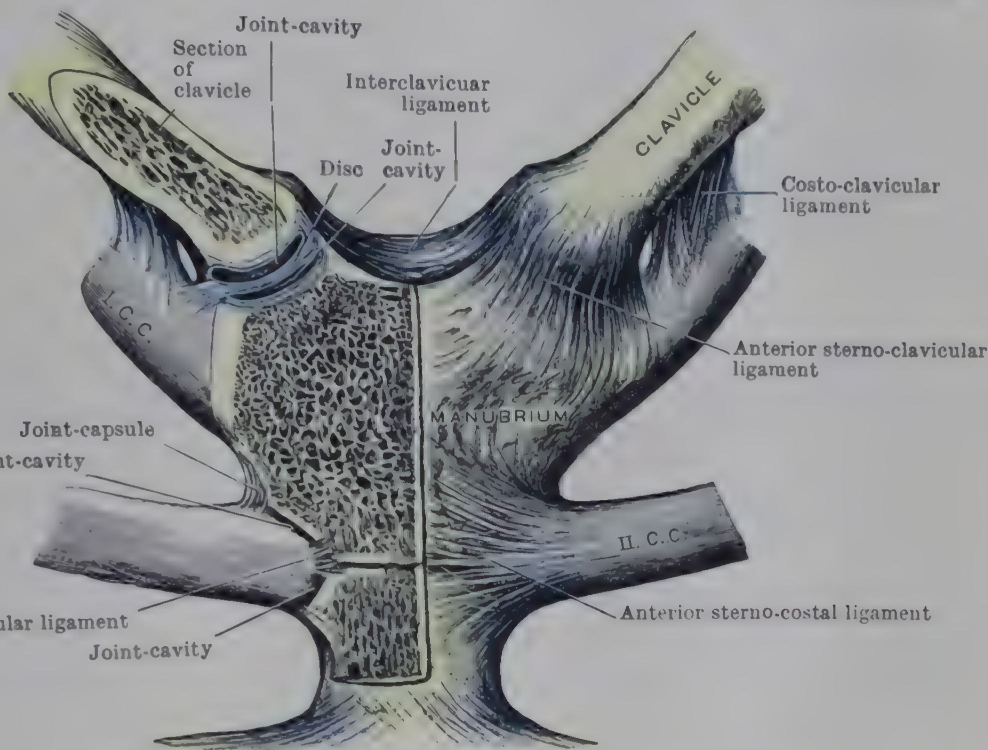

FIG. 322.—STERNO-CLAVICULAR AND STERNO-COSTAL JOINTS.

saddle joint. It is rather, in its movements, of the ball-and-socket type. The articular cartilage in this joint is partly fibrous.

A **capsular ligament** surrounds the whole joint and is attached around the clavicular and the sterno-chondral articular surfaces. The epiphysis at the sternal end of the clavicle is intra-capsular. The inferior part of the capsular ligament, passing between the costal cartilage and the clavicle, is weak, but the other parts of the ligament are strong. being reinforced in front, behind, and above, by thickened bands called the *anterior* and *posterior sterno-clavicular ligaments* and the *interclavicular ligament.*

The **anterior** and **posterior sterno-clavicular ligaments**, of which the anterior is the stronger, run downwards and medially from clavicle to sternum (Fig. 322). The origin of the sterno-hyoid muscle extends across the posterior ligament; this muscle and the sterno-thyroid separate the back of the left joint from the left innominate vein and the left common carotid artery, and the right joint from the innominate artery. The **interclavicular ligament** is formed by fibres from the strengthening band on the upper aspect of the capsular ligament that pass across the floor of the suprasternal notch, to which some of them are attached, to join similar fibres from the joint of the opposite side. The interclavicular ligament is thought to be a derivative of the embryonic *episternal band.*

Within the joint there is a complete fibro-cartilaginous **articular disc**, which blends with the capsular ligament in front and behind, but has its firmest attachment above to the clavicle and below to the first costal cartilage, just wide of the sternal articular surface. Hence the disc, in addition to cushioning the articular

surfaces from shocks transmitted along the clavicle from the shoulder, has an important ligamentous action in preventing such forces from driving the sternal end of the clavicle upwards and medially along the sloping chondro-sternal surface. Also, when the clavicle is depressed, as by a heavy weight carried in the hand, any tendency for the medial end of the bone to start up out of its sternal socket is resisted by the disc, supported by tension of the upper part of the capsular ligament and of the obliquely-disposed anterior and posterior bands.

There are two separate **synovial cavities** within the sterno-clavicular joint, save when, exceptionally, the thinner central part of the articular disc is perforated.

The **costo-clavicular ligament** is an accessory ligament placed on the lateral side of this joint. It ascends from the upper surface of the first costal cartilage near its lateral end to a rough tubercle on the under aspect of the medial part of the clavicle. The ligament is related anteriorly to the tendon of the subclavius muscle, and posteriorly to the innominate vein, on the right side, and, on the left side, to the subclavian or the innominate vein or to both. It limits elevation of the clavicle, and, by its strength in this connexion, compensates for the weakness of the adjacent inferior part of the sterno-clavicular joint-capsule; to a lesser extent it limits antero-posterior clavicular movement also.

Nerve-Supply.—The sterno-clavicular joint is supplied by twigs from the **medial supraclavicular nerve.**

Acromio-Clavicular Joint

The **acromio-clavicular joint** is a small synovial joint, of the plane type, between oval facets on the lateral end of the clavicle and on the medial border of the acromion (Fig. 324). The joint-surfaces, covered with fibrous articular cartilage, slope downwards and medially so that the clavicle tends to override the acromion.

A **capsular ligament**, of no great strength, surrounds the joint; it is stoutest above, and is there reinforced by fibres from the trapezius. A wedge-shaped, fibro-cartilaginous **articular disc**, attached to the upper part of the capsule, partially divides the joint-cavity in most cases. Only rarely does it form a complete partition; and sometimes it is absent altogether.

Nerve-Supply.—The acromio-clavicular joint is supplied by the **pectoral, suprascapular** and **circumflex** nerves.

Coraco-Clavicular Ligament.—The real strength of the union between clavicle and scapula depends on the powerful **coraco-clavicular ligament** (Fig. 324), which anchors the lateral end of the clavicle over the coracoid process. It is divided into two parts, called from their shape the conoid and trapezoid ligaments, which form anteriorly a re-entrant angle occupied by a synovial bursa.

The **conoid ligament** passes upwards and slightly backwards from an apical attachment at the angle between the two parts of the bent coracoid process to a wider insertion on the conoid tubercle on the under surface of the clavicle. The **trapezoid ligament** bears antero-laterally from the conoid ligament. Its lower attachment is to a short ridge on the posterior part of the upper surface of the coracoid process; its upper end is wider, and is attached to the trapezoid ridge on the under side of the acromial end of the clavicle. The attached borders of the trapezoid ligament are slightly askew, and its surfaces so oblique as to be more nearly horizontal than vertical.

The conoid ligament is so set as to restrain backward movement of the acromial end of the clavicle without similar movement of the scapula, the trapezoid ligament to restrain forward movement. Both ligaments, but more particularly the trapezoid, prevent the acromion from being carried medially below the lateral end of the clavicle when blows fall upon the lateral surface of the shoulder.

Movements of the Shoulder Girdle

Movements of the shoulder girdle serve to increase the range of movement at the shoulder joint by suitable alteration in the position of the socket for the head of the humerus, brought about by movement of the scapula upon the thoracic wall. Thus, forward movement of the scapula round the chest causes the glenoid cavity to be directed more

forwards; backward movement causes the cavity to look laterally; upward movement of the scapula, combined with rotation so that the inferior angle passes forwards and upwards, causes the fossa to be turned increasingly upwards; and sinking of the scapula with medial rotation of the inferior angle turns the cavity slightly downwards. But in all these changes of position the shoulder is kept boomed out from the trunk by the thrust of the clavicle upon the acromion, thus further to secure freedom of shoulder-movement. The lateral angle of the scapula must therefore travel in an arc of a circle whose radius is the clavicle: but the medial part of the scapular blade, in its ambit, is held close to the chest wall by the muscles, and must travel in a curve of shorter radius—the radius of the thoracic curvature. Hence, the set of the scapula relative to the clavicle must be capable of modification, and this is brought about by alteration, at the acromio-clavicular joint, of the angle between the clavicle and the scapular spine: that is the function of this gliding joint. One particular result of the different arc of travel of the acromion and lateral angle of the scapula from that of the medial part of the blade is to obviate, in forward movement of the shoulder, any marked change in direction of the glenoid cavity which would diminish the power of forward thrusting movement of the arm.

The clavicle is pivoted at its sternal end, but its acromial end moves, in association with the scapula, forwards, backwards, upwards, downwards, and, of course, in intermediate directions. A small amount of rotation around the long axis of the bone (not more than 45°) also can take place at the sterno-clavicular joint, but only in association with other movements of the acromial end and scapula. This rotation occurs particularly with elevation and depression, when scapular rotation also takes place.

Scapular Ligaments

The following ligaments attached wholly to the scapula are not connected with any joint.

The **suprascapular ligament** bridges the suprascapular notch, and so continues the line of the superior border of the scapula laterally to the root of the coracoid process. Sometimes it is partly or completely ossified. Fibres of the inferior belly of the omo-hyoid are attached to its medial portion. The suprascapular nerve enters the supraspinous fossa through the foramen completed by the ligament, while the suprascapular vessels pass over the ligament to reach the fossa.

The **spino-glenoid ligament** is a weak band that stretches between the lateral border of the scapular spine and the back of the neck of the bone, over the suprascapular nerve and vessels. It may be regarded as formed from a fusion of the fasciæ over the contiguous supraspinatus and infraspinatus muscles.

The **coraco-acromial ligament** is functionally related to the shoulder joint, with which it will be described.

SHOULDER JOINT

The **shoulder joint** is a synovial joint of ball-and-socket type in which freedom of movement is developed at the expense of stability. The spheroidal surface of the head of the humerus articulates with the shallow glenoid cavity of the scapula, each surface being covered with articular cartilage. The area of the scapular 'socket' is little more than a third of that of the humeral 'ball', so that the coaptation of these surfaces contributes very little to the security of the joint. Nor does the capsular ligament play a great part, for it is of necessity lax enough to permit the required freedom of movement. The real strength of the joint lies in the muscles which surround it. They are attached close up to the articular areas and are intimately related to the joint-capsule; hence they are admirably disposed for the purpose of keeping the articular surfaces in firm contact in all positions, although at the sacrifice of the greater power that would be obtained were they inserted farther from the centre of movement in the joint.

Labrum Glenoidale (Fig. 324).—The labrum glenoidale is a fibro-cartilaginous rim, triangular in cross-section, attached to the edge of the glenoid cavity, which is slightly deepened by it. At the notch above the middle of the anterior edge of the cavity the labrum is less solidly attached to the bone and a synovial fold intervenes between the two. The long tendon of the biceps arises within the joint from the supraglenoid tubercle, and is there fused to the labrum glenoidale.

Capsular Ligament.—The capsular ligament forms a cylindrical sleeve attached close to the articular area of each bone. On the scapular side it is attached external to the labrum glenoidale and partly to the labrum itself, especially above and behind. On the humeral side the ligament is attached above

to the anatomical neck immediately medial to the tuberosities; but below, it extends on to the medial surface of the shaft of the bone some way from the articular head. The upper epiphysial line of the humerus is therefore chiefly extracapsular, but comes within the joint on the medial side. When the arm is by the side the lower part of the capsule is lax and forms a redundant fold (Fig. 325) that becomes taut when the arm is abducted. The anterior part of the capsular ligament is immediately related to the tendon of the subscapularis muscle, the superior part to the supraspinatus tendon, and the posterior part to the tendons of the infraspinatus and teres minor muscles. All these tendons blend with the ligament towards their insertion, and as they are intimately concerned in the maintenance of the head of the humerus in its correct relationship to the glenoid cavity during move-

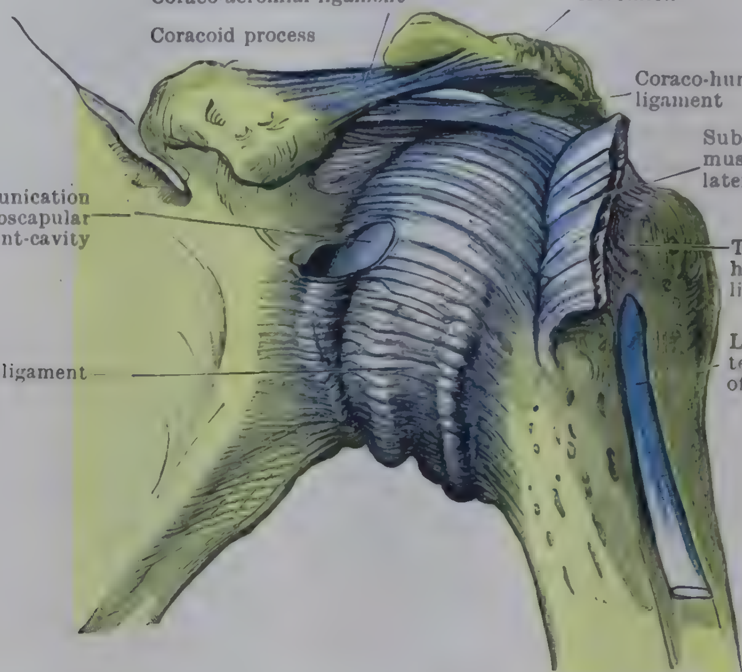

Fig. 323.—Capsule of Shoulder Joint from the Front.

ments at the shoulder joint they are often termed "articular" muscles. The inferior part of the capsular ligament, which is also the weakest, is relatively unsupported by muscles, but as the arm is raised from the side the long head of the triceps and the teres major are increasingly applied to this surface of the joint.

There are two **openings** in the capsular ligament (Fig. 323). One is an interruption in its attachment to the humerus at the upper end of the bicipital groove; the long tendon of the biceps escapes through the aperture so formed. The other opening is in the front of the capsular ligament under cover of the subscapularis tendon, and through it the subscapular bursa communicates with the synovial cavity of the joint.

The fibres of the capsular ligament run for the most part longitudinally from bone to bone. In addition to longitudinal fibres, a few fibres run transversely round the capsular ligament. The **transverse humeral ligament** is a special bundle of transverse fibres that arch over the opening through which the biceps tendon leaves the joint and bridge the upper end of the bicipital groove (Fig. 323).

Three slightly thickened bands of longitudinal fibres are to be seen on the internal surface of the anterior part of the capsule, although not visible on the outside of the joint. These are the *superior*, *middle*, and *inferior gleno-humeral ligaments* (Fig. 324). The **superior gleno-humeral ligament** is attached to the upper part of the labrum glenoidale immediately anterior to the long tendon of the biceps, and passes laterally, alongside the tendon, to reach the humerus near the upper surface of the lesser tuberosity. It has been considered homologous with the ligament of the head of the femur, but has also been regarded, possibly with more likelihood, as representing the base of the synovial fold by which, in the fœtus, the long tendon of the biceps is attached to the upper part of the capsule. The **middle gleno-humeral ligament** is attached to the scapula close to the superior band and reaches the humerus at the front of the lesser tuberosity. The opening in the capsular ligament under the subscapularis tendon is

between the superior and middle bands. The **inferior gleno-humeral ligament**, usually the best marked of the three, is attached to the scapula immediately below the notch in the anterior border of the glenoid cavity and to the humerus on the under surface of the neck.

Accessory Ligaments.—The **coraco-humeral ligament** is an accessory ligament on the upper aspect of the joint (Fig. 323). It springs from the lateral side of the root of the coracoid process and runs laterally upon the capsular ligament as a raised band which gradually flattens as it blends laterally with the upper and posterior part of the capsular ligament; it reaches the neck of the humerus opposite the greater tuberosity. This band greatly strengthens the upper part of the capsular ligament, which is under tension when the arm hangs by the side.

Arching over the upper aspect of the shoulder joint, but not connected to its

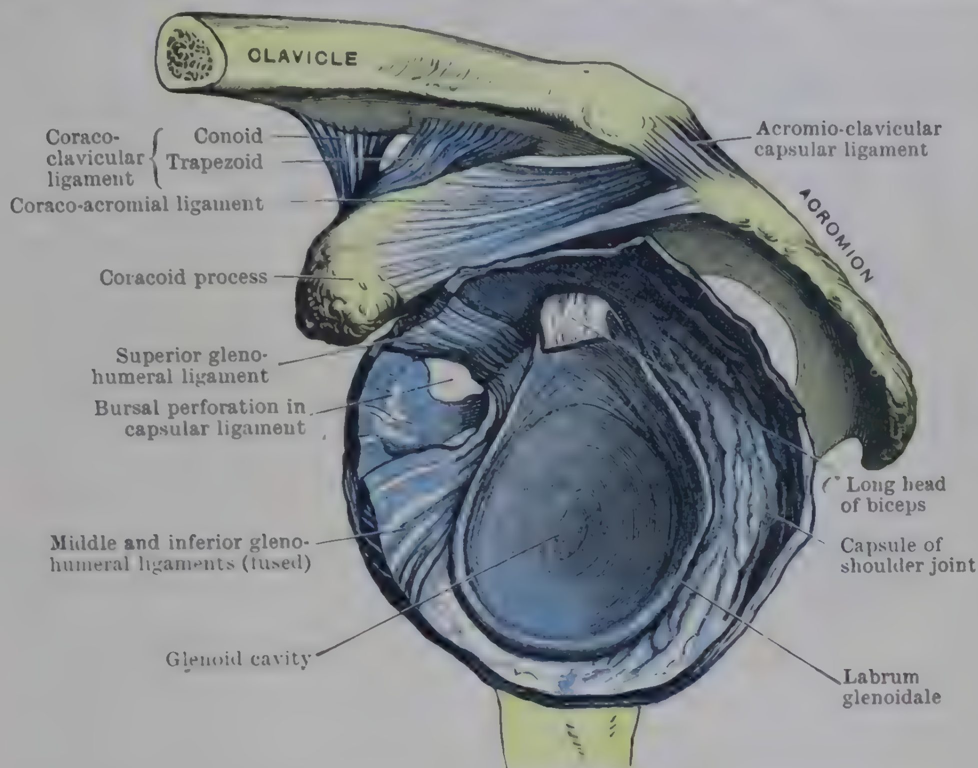

FIG. 324.—CAPSULE OF SHOULDER JOINT CUT ACROSS AND HUMERUS REMOVED.

capsule, is the **coraco-acromial ligament** (Figs. 323, 324). It is triangular, and horizontally placed. Its base is attached to the lateral border of the horizontal part of the coracoid process and its apex to the tip of the acromion in front of the acromio-clavicular joint. The anterior and posterior borders of the ligament are stronger than the middle portion. Sometimes a prolongation of the pectoralis minor tendon pierces the base of the ligament and blends, below it, with the coraco-humeral ligament. Superiorly, the coraco-acromial ligament is covered by the deltoid muscle; inferiorly, it is separated by the subacromial bursa from the supraspinatus tendon, which lies above the shoulder joint. The acromion and the coracoid process, with the coraco-acromial ligament stretching between them, form a protective arch against which the head of the humerus is pressed (the joint-capsule and overlying muscles intervening) when force is transmitted upwards along the humerus as when, standing at a table, the weight of the body is supported on the edge of the table by the down-stretched arms.

Synovial Membrane.—The synovial membrane of the shoulder joint lines the capsular ligament and thus extends downwards as a pouch when the arm is by the side. From the capsular ligament the membrane is reflected upwards on the humerus to the edge of the articular cartilage. The membrane protrudes through the opening in the front of the capsule to be continuous with the lining of the *subscapular bursa*. The size of this bursa varies; when large it may be wrapped round the upper border of the subscapularis tendon underneath the coracoid process, but this upper, *subcoracoid* extension may be represented by a separate bursa of that name, not communicating with the joint. Occasionally the synovial mem-

brane protrudes through an opening in the back of the capsular ligament to form a small bursa beneath the infraspinatus tendon.

In this neighbourhood there is always a large *subacromial bursa* which separates the coraco-acromial arch and the deltoid muscle from the upper and lateral aspect of the shoulder joint and the tendons lying upon it; this bursa does not communicate with the interior of the joint.

The relation of the *long tendon of the biceps* to the synovial membrane is important (Fig. 325). The intracapsular part of the tendon is covered with a sheath of synovial membrane which is continued along the tendon in the upper part of the bicipital groove. The synovial sheath is then reflected upwards as a lining to the osteo-fascial tunnel in which the tendon runs, and so passes into continuity with the synovial lining of the capsular ligament. As the tendon runs over the upper part of the articular head of the humerus, it has a steadying influence upon movements of the shoulder joint.

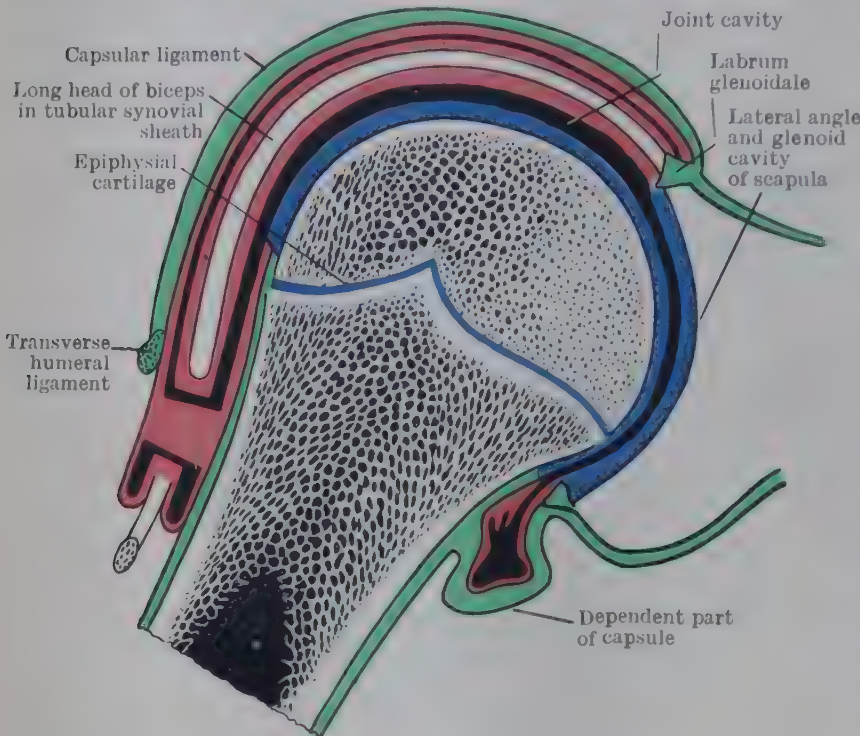

FIG. 325.—DIAGRAMMATIC CORONAL SECTION THROUGH SHOULDER JOINT.

The cavity of the joint is enlarged to show the relation of the synovial membrane to the long tendon of the biceps muscle. Articular cartilage, *blue*; synovial membrane, *pink*; capsular ligament and periosteum, *green*.

In the embryo the long tendon of the biceps at first lies outside the developing joint-capsule; this is the persisting relationship in some lower mammals. But later in human development the tendon sinks through the capsular ligament and is attached to its deep surface by a mesentery-like fold of synovial membrane; this condition persists in most higher mammals. Normally, in Man, the 'mesentery' breaks down before birth, leaving the tendon unattached to the capsule but surrounded by a sheath of synovial membrane.

Nerve-Supply.—The shoulder joint is supplied by branches from the **suprascapular, circumflex, and subscapular nerves.**

Movements at the Shoulder Joint

The form of the articular surfaces and the disposition of the capsular ligament allow a wider range of movement at the shoulder joint than at any other joint in the body. Being, as it is, a ball-and-socket joint, movement can take place around an infinite number of axes intersecting in the centre of the globular head of the humerus. The principal axes of descriptive convenience are: (1) a transverse axis around which the arm moves forwards in **flexion** and backwards in **extension**; (2) an antero-posterior axis around which occur the movements of **abduction** (away from the side of the trunk) and **adduction** (towards the side of the trunk); and (3) a vertical axis around which the arm **rotates medially** and **laterally**. **Circumduction** is a combination of antero-posterior and sideward movements around successive axes, when the arm swings round the side of a cone whose apex is the point of intersection of the various axes in the head of the humerus.

Since in the normal position, with the arm by the side, the glenoid cavity looks slightly forwards as well as laterally, and the humeral head is turned slightly backwards as well as medially, the strict 'transverse' and 'antero-posterior' axes of the joint are set obliquely to coronal and sagittal planes of the trunk. Thus, for example, the true transverse axis of the joint runs medio-laterally and slightly forwards, and, in flexion-extension movements around this axis, the arm swings forwards and medially, backwards and laterally. Similarly, in true abduction the arm is carried a little forwards as well

as laterally, in the "plane of the scapula", a plane at right angles to the glenoid fossa through its vertical diameter. Abduction in this plane does not involve torsion of the capsular ligament and therefore provides the most easeful position in the treatment of certain injuries at the shoulder (Johnston, 1937).

Rotation of the humerus takes place around an axis that passes through the centre of the head and the centre of the capitulum. The range of rotation varies with the position of the humerus. When the arm is by the side it can be rotated about 170° but when the arm is vertically upright the range of rotation is greatly reduced.

The amount of movement that occurs at the shoulder joint during movement of the upper limb is usually difficult to estimate because almost all free movements at the shoulder joint are accompanied by associated movements of the shoulder girdle. The total apparent movement of the humerus is therefore made up of its real movement upon the scapula plus movement of the scapula upon the chest-wall, with associated movements at the clavicular joints: the effective mobility of this ball-and-socket joint is thus increased by the mobility of the socket itself. The range of scapular movement is considerable and accounts for much of the apparent movement that takes place in the free limb; it is estimated, for example, that in moving the arm from the pendent position into a vertically upright one, almost half the movement is due to a displacement of the scapula (for movements of scapula see p. 356). Cathcart (1884) was the first to state that movement of the scapula occurs early in abduction—he estimated that after the arm has moved about 30°. The commencement of movement of the scapula is, however, usually coincident with the commencement of movement at the shoulder joint (Cleland, 1884, and Lockhart, 1930) and in raising the arm to an upright position the two movements are associated throughout. Gleno-humeral movement is, however, more concerned in the raising of the arm to the horizontal position, and scapular movement more concerned in bringing the arm into a vertically upright position from the horizontal. (See also p. 487 and Pl. XXXII, p. 347). It must be stressed, however, that in bringing the arm from the horizontal to the vertically upright position there is considerable gleno-humeral movement, and it is during this action that the humerus is brought approximately into line with the spine of the scapula, which is to be regarded as the fully abducted position of the shoulder joint proper (Lockhart, 1930).

The association of shoulder-girdle movement with shoulder-joint movement not only increases the range of movement of the free limb, but also increases its power of movement. It has already been stated that because the muscles that act upon the shoulder joint are attached close to the centre of movement in the joint, their force is thereby lessened. The muscles acting on the scapula (p. 482), however, have the advantage of much greater leverage, and therefore the scapular movements add greatly to the total force of movements of the arm. The adjuvant effect of scapular movements is strikingly illustrated in those in whom the scapulo-humeral joint is completely fixed as the result of disease or of surgical treatment to combat disease. Provided that care has been exercised to secure fixation in such a position as will allow full advantage to be taken of scapular movement, these patients may retain a considerable degree of mobility of the arm upon the trunk. Nevertheless it must be realized that, normally, movements at the shoulder joint and movements of the scapula are not dissociated but take place together.

It is to be observed that when the arm is raised to the vertically upright position the medial epicondyle of the humerus is always directed forwards and slightly medially, and this direction of the epicondyle is constant irrespective of the plane (sagittal, coronal or any intermediate) through which the limb has been raised. When the limb is raised in the coronal plane the humerus undergoes a lateral rotary movement of more than 90°, whereas if it is raised to the upright in the sagittal plane it undergoes a slight medial rotation if the initial dependent position of the limb is the anatomical one with the palm of the hand directed forwards. The causal factor of the lateral rotation is probably the muscular action of the scapulo-humeral muscles, though it has been suggested that a contributory cause is the contact of the greater tuberosity of the humerus with the sloping coraco-acromial arch when the humerus nears its limit of full abduction. (For discussion of this problem see Lockhart, 1933, Johnston, 1937, Martin, 1940, and MacConaill, 1946.)

ELBOW JOINT

The **elbow joint** is a large synovial joint, of the hinge type, in which the bones of the forearm articulate with the lower end of the humerus. The upper ends of the radius and ulna are tied together by the annular ligament of the radius,

but in such a way as to permit movement between these two bones at what is described separately as the superior radio-ulnar joint; the cavity of this joint is freely continuous with that of the elbow joint. The annular ligament plays a part in the structure of both, but it will be described with the superior radio-ulnar joint.

Articular Surfaces.—The **humeral articular surface** at the elbow comprises the grooved *trochlea* and the spheroidal *capitulum*, together with the sulcus between them. This composite surface is covered with a continuous layer of articular cartilage. The capitulum is limited to the anterior and distal aspects of the bone, while the trochlea extends from the lower edge of the coronoid fossa on the front of the humerus round to the lower edge of the olecranon fossa on the back (Figs. 223, 328). The **ulnar surface** of the elbow joint (Fig. 329) is the *trochlear notch*, covered with articular cartilage interrupted along a transverse line across the deepest part of the notch; this surface articulates with the trochlea of the humerus. The **radial surface** is the slightly cupped upper surface of the *head* of the radius, covered with articular cartilage continuous with that round the sides of the head in the radio-ulnar joint; the concave part of the upper surface of the head articulates with the capitulum, and the raised margin with the capitulo-trochlear groove. The radial and ulnar surfaces are not strictly congruent with the corresponding humeral surfaces, and the degree of accurate apposition varies slightly in different positions of the joint. The articular surfaces are most fully in contact when the forearm is in a position midway between full pronation and full supination and is flexed to a right angle.

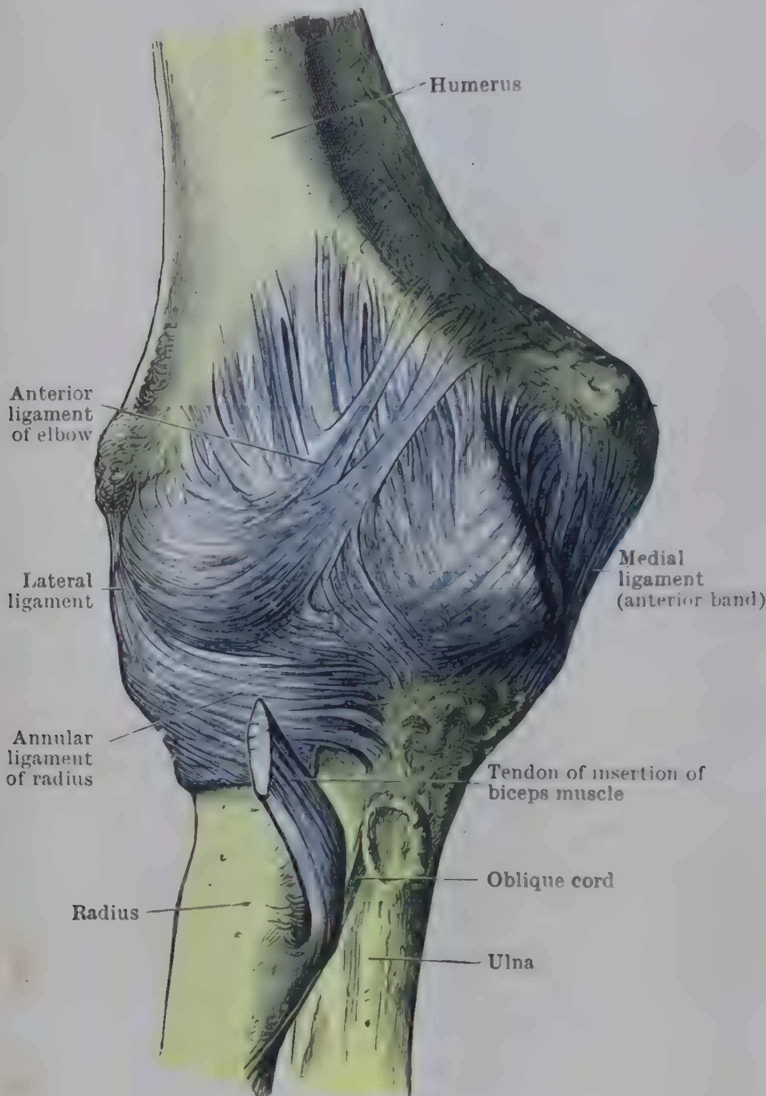

Fig. 326.—Front of Elbow Joint.

Capsular Ligament.—A capsular ligament completely invests the joint. Following the usual arrangement in a hinge joint, this ligament is relatively weak in front and behind, but is specially strengthened at the sides. The parts in front and behind are called the *anterior* and *posterior ligaments* of the elbow joint; the anterior is taut only in extension and the posterior only in flexion. The strong portions at the sides of the capsular ligament constitute the *lateral* and *medial ligaments*; these, being attached to the humerus in the axis of movement at the joint, remain tense in all positions.

The **anterior ligament** (Fig. 326) is composed of fibres that run for the most part longitudinally, but also transversely and obliquely; it is thicker in the middle than at the sides. Proximally, it is attached to the front of the humerus immediately above the radial and coronoid fossæ; distally, it is attached to the anterior border of the coronoid process of the ulna and to the anterior part of the

annular ligament of the radius; at the sides it blends with the medial and lateral ligaments. The brachialis muscle covers the greater part of the anterior ligament, and some deep fibres are inserted into the ligament, which is therefore drawn upwards when the muscle contracts to flex the joint.

The **posterior ligament** is very weak in its medial part, but is here closely attached to the overlying tendon of the triceps, which affords ample support to the joint-capsule and draws it upwards in extension. The fibres in that part of the ligament run mainly from the sides of the olecranon fossa to the margin of the olecranon; some fibres stretch across the fossa above the olecranon as a transverse band with a free upper edge which falls short of the upper margin of the fossa. Beneath these transverse fibres a few longitudinal strands pass to the upper part of the fossa and afford slight support to the synovial pouch within it. The lateral part of the posterior ligament is a stronger band that runs from the back of the lateral epicondyle to the ulna at the posterior border of the radial notch and also to the annular ligament. The posterior ligament blends at the sides with the medial and lateral ligaments.

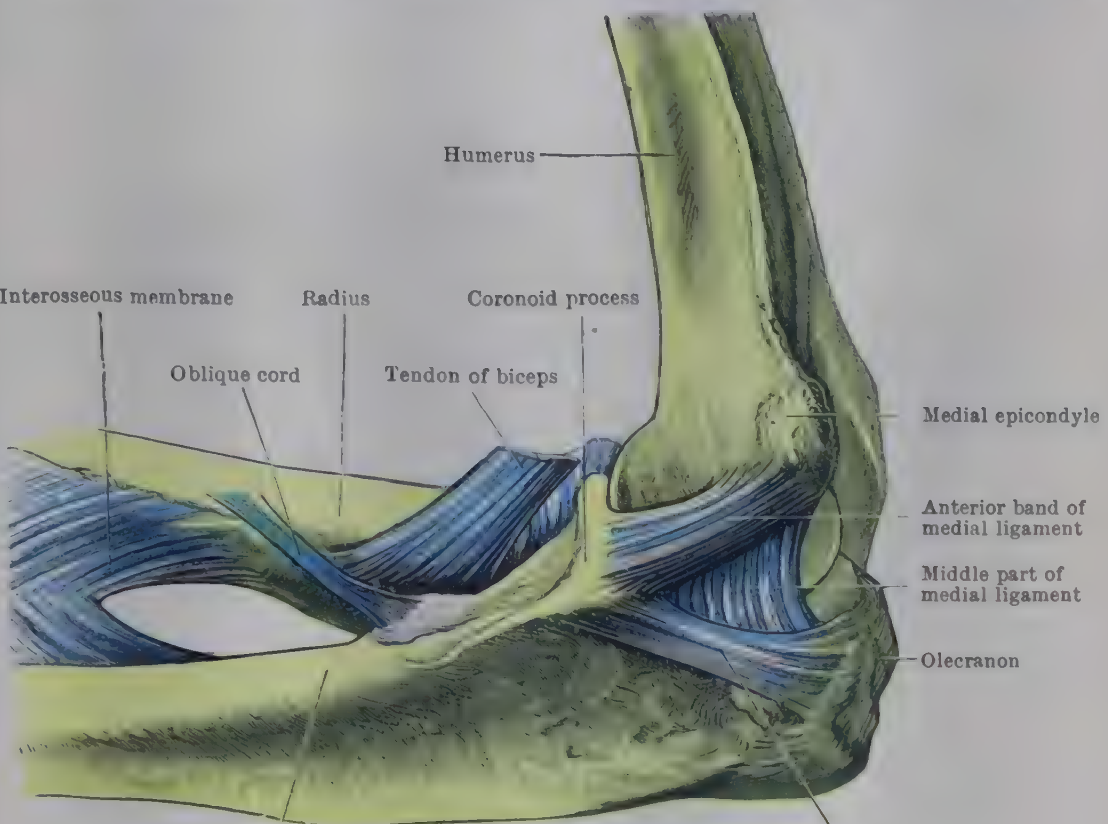

FIG. 327.—MEDIAL ASPECT OF DISSECTION OF ELBOW JOINT, WITH ANTERIOR AND POSTERIOR LIGAMENTS REMOVED.

The **lateral ligament** (Fig. 326) is a strong, triangular band whose apex is attached above to the antero-inferior aspect of the lateral epicondyle of the humerus in close relation to the overlying common origin of the extensor muscles. Distally, the middle part of the base of the ligament blends with the annular ligament of the radius, and the slightly thicker portions in front and behind sweep forwards and backwards to be attached to the margins of the radial notch on the ulna.

The **medial ligament** (Fig. 327) is composed of three fairly distinct bands, continuous with one another. An *anterior band* passes from the fore part of the medial epicondyle of the humerus to the medial edge of the coronoid process of the ulna; it is closely associated with the common origin of the superficial flexor muscles and gives rise to fibres of the flexor digitorum sublimis. A *posterior band* is attached above to the back of the medial epicondyle and below to the media edge of the olecranon. Between these bands there is a middle, thinner part of the ligament, triangular in shape, and presenting a grooved external surface which is

crossed by the ulnar nerve as it passes from upper arm to forearm; its upper end is attached to the under surface of the medial epicondyle, and its base is fixed distally to the upper border of a *transverse band* which stretches between the attachments of the anterior and posterior bands on the coronoid process and the olecranon. The lower edge of this transverse ligament is free, and through the narrow gap between this edge and the bone the synovial membrane protrudes slightly during movement of the joint.

Synovial Membrane.—The synovial membrane of the elbow joint lines the capsular ligament and is reflected on to the humerus to line the radial and coronoid fossæ in front and the olecranon fossa behind (Fig. 328). Distally, it is prolonged downwards on the deep surface of the annular ligament, and is then reflected on to the neck of the radius. This reflexion is supported by a few loose fibres which pass from the lower border of the annular ligament to the neck of the radius. The synovial membrane passing from the medial side of the radial neck to the

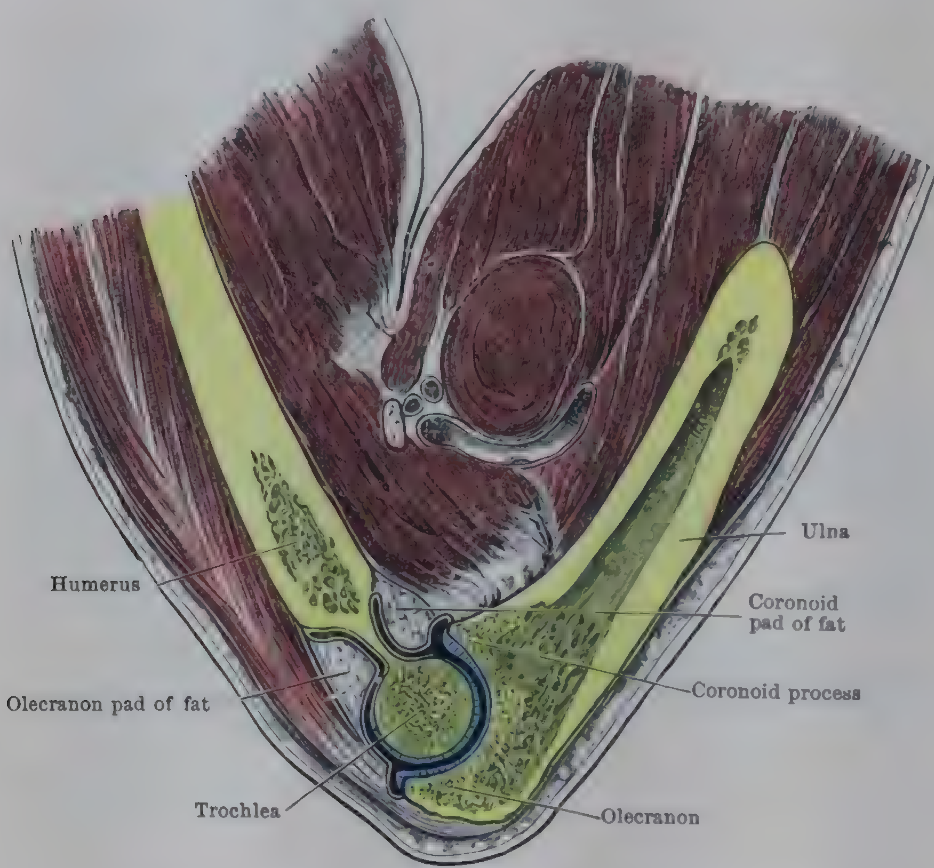

Fig. 328.—Vertical Section through Humero-Ulnar Part of Elbow Joint.

lower border of the radial notch on the ulna is supported by a lax band of fibres called the **quadrate ligament**, which stretches between these two points. Various synovial folds project a little way into the interior of the joint, filling small angular recesses between the edges of the articulating surfaces. Well-marked subsynovial fatty pads fill the radial and coronoid fossæ in extension of the joint and the olecranon fossa in flexion (Fig. 328). A synovial fold, which forms the greater part of a circle, also overlies the peripheral part of the head of the radius and is interposed between it and the corresponding part of the capitulum of the humerus. There are no openings in the capsular ligament of the elbow joint, but slight pouching of the synovial membrane may occur beneath the edge of the transverse band of the medial ligament, beneath the lower border of the annular ligament, and above the transverse fibres that bridge the upper part of the olecranon fossa.

Nerve-Supply.—The elbow joint derives its supply anteriorly from the **musculo-cutaneous, median** and **radial** nerves, and posteriorly from the **ulnar** nerve and the radial nerve through its **branch to the anconeus** muscle.

Movements at the Elbow Joint

This being a hinge joint, movement occurs only around a transverse axis—a movement of **flexion** when the forearm makes anteriorly a diminishing angle with the upper arm, and of **extension** when this angle is opened out again. The axis of movement passes through the humeral epicondyles and is not at right angles with either the humerus or the bones of the forearm. In full extension, with the forearm supinated, the upper arm and fore-arm form an angle—the 'carrying angle'—opening laterally, more pronounced in women than in men. The axis of movement bisects this angle; hence in full flexion the forearm comes up in line with the upper arm. If the humerus is rotated slightly medially, as it is with the arm hanging naturally by the side, the hand approaches the mouth when the forearm is flexed; this movement of bringing the hand to the mouth is also usually associated with some abduction of the upper arm at the shoulder joint. The 'carrying angle' is not apparent when the forearm is pronated (p. 367), and in that position the wrist, elbow and shoulder joints are all in line with one another when the elbow joint is extended—this is the position of the upper limb in which pushing and pulling movements are usually performed.

Flexion can proceed until checked by apposition of upper arm and forearm and by the tension of the posterior muscles and ligament. Extension cannot occur beyond the straight position of the limb; it is then limited by the tension of the anterior muscles and ligament. The lateral and medial ligaments are fairly tense in all positions, the anterior part of each being specially tight in extension and the posterior part in flexion.

Limitation of movement by locking of the bones seldom occurs. That it does take place in some persons is shown by the occasional presence of small cartilage-covered facets at the bottom of the coronoid fossa and at the sides of the olecranon fossa which obviously must have made contact during life with the coronoid and olecranon processes.

As already mentioned, the joint-surfaces are in closest contact in a position of right-angled flexion, with the forearm midway between pronation and supination. This is therefore the position of greatest stability and is the position naturally assumed when the hands are engaged in fine manipulations.

RADIO-ULNAR JOINTS

The bones of the forearm are united at their upper and lower ends by synovial joints which act together to provide movement of the radius on the ulna around a vertical axis; these joints are therefore of the pivot type. In addition, the shafts of the two bones are connected by fibrous interosseous bands in the manner of a syndesmosis.

Superior Radio-Ulnar Joint

At the **superior radio-ulnar joint** the discoidal head of the radius rotates within the ring formed by the radial notch on the ulna and the annular ligament of the radius. The notch on the ulna is lined with articular cartilage continuous with that on the lower half of the trochlear notch in the elbow joint; the surface of the radial notch is concave antero-posteriorly but is flat vertically and is inclined slightly laterally below (Fig. 329). The head of the radius is covered with a continuous layer of cartilage above and around the sides. The upper surface is slightly cupped and rotates under the capitulum of the humerus, while the sides of the head bear on the annular ligament and radial notch.

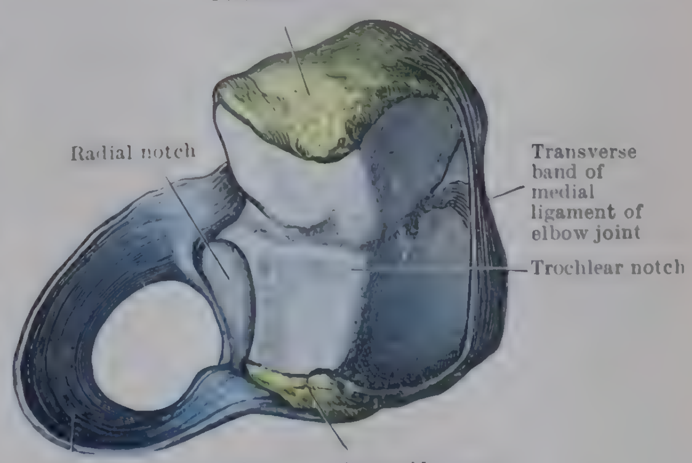

FIG. 329.—ANNULAR LIGAMENT OF RADIUS AND SUPERIOR ARTICULAR SURFACES OF ULNA.

Annular Ligament of Radius.—The annular ligament of the radius is a strong, well-defined curved band attached by its ends to the anterior and posterior margins of the radial notch on the ulna so as to form nearly four-fifths

of a ring which is completed by the notch itself. This ring is slightly narrower at its lower border than above, forming a segment of a hollow cone; and the radial head, enclosed by the ring, is reciprocally bevelled all round. This arrangement tends to prevent the radius from being pulled downwards through the ring. The annular ligament is supported above by its firm fusion with the lateral ligament and lateral parts of the anterior and posterior ligaments of the elbow joint (Fig. 326). Below, it is only feebly attached to the neck of the radius, distal to the epiphysial line, by fibres which are too loose to interfere with movement.

As already explained, the annular ligament is lined with **synovial membrane** which is carried down from the elbow joint and is reflected on to the upper part of the neck of the radius and carried across to the lower border of the notch on the ulna by the *quadrate ligament* (p. 364). The synovial cavities of the two joints are thus freely continuous with each other.

Inferior Radio-Ulnar Joint

The **inferior radio-ulnar joint** is formed between the head of the ulna and the ulnar notch on the radius. The bony surfaces are covered with articular cartilage; the lateral and distal ulnar surfaces are continuous with each other over a rounded border.

Articular Disc.—The chief uniting structure is the fibro-cartilaginous, triangular **articular disc**, which is attached by its base to the sharp edge on the radius between the ulnar and carpal surfaces and by its apex to the lateral side of the root of the ulnar styloid process (Fig. 330). This disc provides an additional joint-surface, for its upper surface articulates with the distal aspect of the head of the ulna. Thus, the joint-cavity is L-shaped in vertical section, with a vertical limb between the ulna and the radius and a horizontal limb between the ulna and the articular disc (Fig. 332). The distal surface of the disc forms part of the proximal articular surface of the wrist joint; but the cavities of the two joints do not communicate, except in some cases where the disc is perforated.

Capsular Ligament.—The capsular ligament is represented only by transverse bands of no great strength which stretch from radius to ulna across the front (Fig. 331) and back of the joint. The distal edges of these bands blend with the margins of the articular disc, but proximally they are separated from each other by a pouch of the synovial lining of the joint, called the *recessus sacciformis*, which extends upwards a little way between the radius and ulna.

Nerve-Supply.—The inferior radio-ulnar joint is supplied by twigs from the **anterior** and **posterior interosseous** nerves.

Connexion between Shafts of Radius and Ulna

The shafts of the radius and ulna are connected by the oblique cord and the interosseous membrane of the forearm.

Oblique Cord.—The oblique cord is a slender fibrous band which passes from the lateral border of the tuberosity of the ulna downwards and laterally to the radius just distal to its tuberosity (Figs. 326, 327); it is possibly a degenerated portion of the flexor pollicis longus.

Interosseous Membrane.—The interosseous membrane is a strong fibrous sheet which stretches between the interosseous borders of the radius and ulna. Proximally, it reaches to within an inch of the level of the radial tuberosity: through the gap between its upper edge and the oblique cord the posterior interosseous vessels pass to the back of the forearm. Distally, the interosseous membrane is continued into the fascia on the dorsal surface of the pronator quadratus muscle; this portion is pierced by the anterior interosseous vessels. The fibres of the interosseous membrane mostly run medially and downwards from radius to ulna; but on the back there are varying bands of an opposite obliquity which are probably connected with the long muscles of the thumb.

The interosseous membrane serves to increase the surfaces of origin of the deep muscles of the forearm, to brace together the radius and ulna, and, because of the

obliquity of the main fibres, to transmit to the ulna part of any force passing upwards from the hand along the radius. The tension of the membrane varies during radio-ulnar movement, being greatest in semi-pronation.

Movements at Radio-Ulnar Joints

Movement at the radio-ulnar joints takes place around an axis that passes through the centre of the head of the radius above and the apical attachment of the articular disc below. The movement is chiefly on the part of the radius; its upper end rotates under the humeral capitulum and within the ring formed by the annular ligament and the radial notch on the ulna, while its lower end, bearing the hand, travels round the lower end of the ulna, to which it is tethered by the articular disc. Starting from the supine position, in which the bones of the forearm are parallel and the palm is directed forwards (if the forearm is extended at the elbow), in the movement of **pronation** the lower end of the radius is carried forwards and medially round the lower end of the ulna until the palm is turned backwards and the shafts of the radius and ulna cross each other. Movement in the reverse direction is termed **supination.** These movements cannot be dissociated from slight accompanying rotation of the humerus at the shoulder joint—medially with pronation and laterally with supination—unless the elbow joint is flexed. But the ulna also changes position in pronation and supination. Its lower end precedes the lower end of the radius around the opposite half of the circle of excursion, moving backwards and laterally as the radius travels forwards and medially during pronation, and in the reverse direction during supination. This excursion of the lower end of the ulna is the magnified result of slight flexion-extension movements of its upper end at the elbow joint, which also cannot be dissociated from radio-ulnar movement proper, in conjunction with the humeral rotation already mentioned. The movement of supination is stronger than pronation; and screws and screwing instruments are made so as to be manipulated by supination of the right forearm.

When the upper limb is straight, the axis of humeral rotation is in the same line as the axis of radio-ulnar movement, and therefore pronation and supination can be supplemented by the full extent of rotation at the shoulder joint so that it is then possible to turn the hand through about three and one half right angles.

WRIST (RADIO-CARPAL) JOINT

The **wrist joint** proper is formed between the distal surface of the radius and the articular disc, and the proximal row of carpal bones (except the pisiform).

Articular Surfaces.—The radius and the disc together form a concave, ellipsoidal surface of shallower curvature in its long axis from side to side than in its short axis from before backwards (Fig. 330). A similar surface, but convex, is provided distally by the proximal articular areas of the scaphoid, lunate, and triquetral bones, closely united by interosseous ligaments which are flush with the articular cartilage on the proximal surface of the bones (Fig. 332). The joint is therefore ellipsoidal in type. The *articular cartilage on the radius* is divided by a low ridge into a triangular lateral area and a quadrangular medial area. In the normal, straight position of the hand, the scaphoid bone is opposite the lateral radial area, the lunate is opposite the medial area and the disc, and the triquetral is in contact with the medial portion of the joint-capsule (Fig. 332). When the hand is bent to the ulnar side, the triquetral is then moved over to lie opposite the disc (Pl. XXXIII, p. 370).

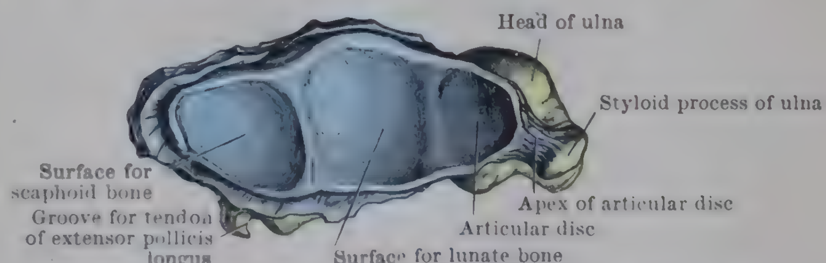

Fig. 330.—Proximal Articular Surface of Wrist Joint.

Capsular Ligament.—A capsular ligament surrounds the joint. It is attached close to the articular areas; its proximal attachment is distal to the inferior epiphysial lines of the radius and ulna.

The anterior part of the capsular ligament, called the **anterior radio-carpal ligament**, is formed chiefly of a broad band of fibres that spread downwards with a medial inclination, from the anterior edge of the distal end of the radius to the first carpal row—some longer fibres extending to the capitate bone in the second row (Fig. 331). From the anterior edge of the disc and the base of the ulnar styloid process some fibres pass downwards and laterally to the carpus, and others pass laterally to the radius, blending with the capsule of the inferior radio-ulnar joint.

On the back of the joint, the **posterior radio-carpal ligament** is composed of fibres that run mainly from the posterior edge of the lower end of the radius downwards and medially to the bones of the first carpal row, particularly the triquetral bone.

At the sides, the capsular ligament is specially strengthened to form the **lateral** and **medial ligaments** (Fig. 331). The lateral ligament runs from the radial styloid process to the scaphoid bone immediately lateral to its proximal articular surface; the radial artery crosses this ligament deep to the long abductor and short extensor tendons of the thumb. The medial ligament spreads downwards from the ulnar styloid process to the medial, non-articular border of the triquetral bone and to the pisiform bone.

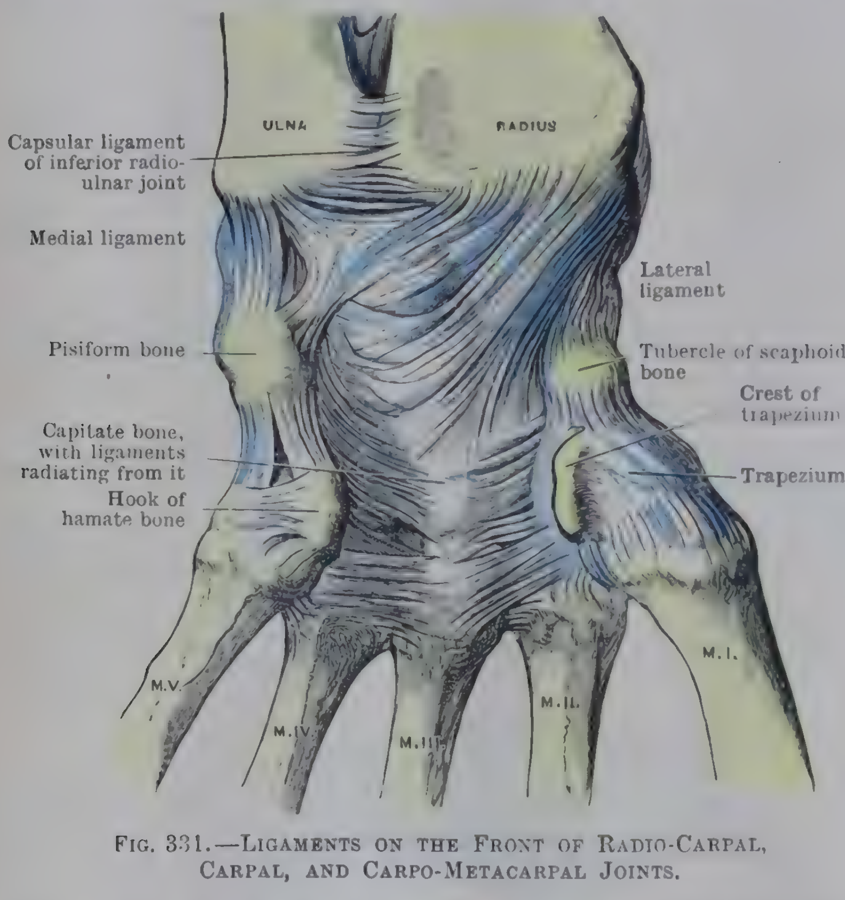

FIG. 331.—LIGAMENTS ON THE FRONT OF RADIO-CARPAL, CARPAL, AND CARPO-METACARPAL JOINTS.

Synovial Membrane.—A synovial membrane lines the capsular ligament. In exceptional cases the synovial cavity communicates with the inferior radio-ulnar joint through a perforated articular disc, or with the intercarpal joint when one of the interosseous ligaments of the proximal carpal row forms an incomplete barrier.

Nerve-Supply.—The radio-carpal joint (in common with the carpal and carpo-metacarpal joints—described later) receives its supply from all three main nerves of the upper limb:—from the median nerve, through the **anterior interosseous** branch; from the radial nerve, through the **posterior interosseous** branch; and from the ulnar nerve, through the **dorsal branch and deep (palmar) branch.**

Movements at the Radio-Carpal Joint

In free movements of the hand at the wrist much of the apparent movement at the radio-carpal joint is the result of movement between the proximal and distal rows of carpal bones (transverse intercarpal joint). Movements at the radio-carpal and transverse intercarpal joints are usually closely associated and for that reason movements at these joints are considered together (p. 370).

INTERCARPAL JOINTS

The carpal bones are articulated in two rows—proximal and distal—that form with each other an important joint called the **transverse intercarpal joint.** The joints between the individual bones of the carpus are mostly of the plane or gliding type, but the capitate undergoes a marked rotation during movements of the hand.

Joints of the Proximal Row.—Of the bones of the proximal row, the scaphoid, the lunate, and the triquetral are tied together by palmar, dorsal, and interosseous bands.

The **palmar** and **dorsal ligaments** pass between neighbouring parts on those aspects of the bones. The **interosseous ligaments** are short bands that pass between contiguous surfaces, uniting them in their whole antero-posterior depth near their proximal margins, and leaving joint-clefts between their distal parts, which are therefore coated with articular cartilage (Fig. 332).

Pisiform Joint.—The pisiform bone rests on the palmar surface of the triquetral bone, and forms with that bone a separate little synovial joint surrounded by a thin, but strong, **capsular ligament**. It is further anchored by strong bands—the **piso-metacarpal** and **piso-hamate ligaments**—to the base of the fifth metacarpal and the hook of the hamate bone; these ligaments resist the pull of the flexor carpi ulnaris muscle upon the pisiform bone, and, in effect, provide additional insertions for that muscle.

Joints of the Distal Row.—All four bones of the distal carpal row are connected by **palmar, dorsal,** and **interosseous ligaments**. The interosseous ligaments (Fig. 332) are, in general, not so extensive as those of the proximal row; they leave joint-clefts between the bones both proximally, running into the transverse intercarpal joint, and distally, running into the carpo-metacarpal joint. These two larger joints sometimes communicate with each other between bones of the distal row where an interosseous ligament is absent (most often that between the trapezium and trapezoid) or where it does not extend the whole way between the dorsal and palmar surfaces of the adjoining bones.

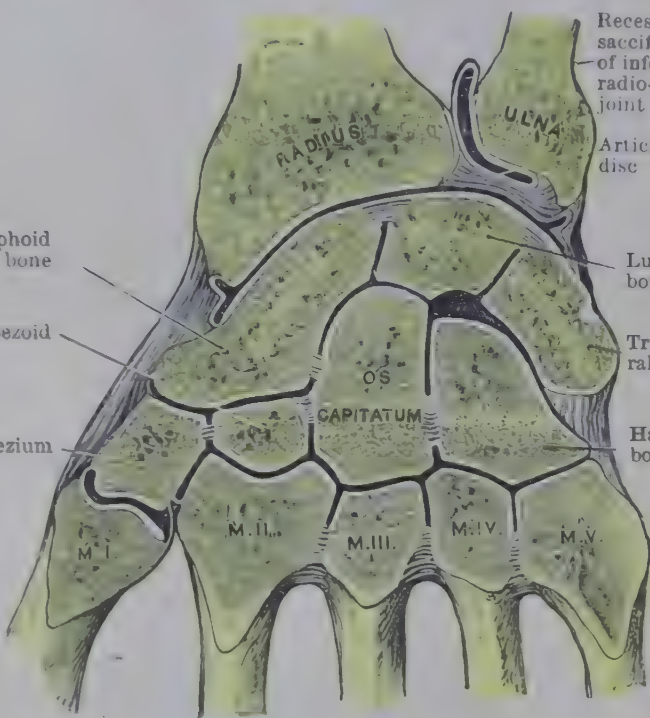

FIG. 332.—CORONAL SECTION through the radio-carpal, carpal, carpo-metacarpal, and intermetacarpal joints, to show joint-cavities and interosseous ligaments (diagrammatic).

Transverse Intercarpal Joint (Fig. 332).—This is the joint between the two carpal rows. The line of the joint is convex distally on the lateral side, where the trapezium and trapezoid are opposed to the rounded distal surface of the scaphoid. In the medial and larger part of the joint there is a deep concavity facing distally, bounded by the triquetral and lunate bones and the medial surface of the scaphoid bone, and occupied by the rounded head of the capitate bone and the proximal angle of the hamate bone.

The joint is surrounded by a **capsular ligament** made up, in front and behind, of irregular bands which run between the two rows of bones and constitute the **palmar** and **dorsal intercarpal ligaments**; the bands in the palmar ligament chiefly radiate from the head of the capitate bone (Fig. 331). At the sides of the transverse intercarpal joint the capsular ligament is strengthened as it passes between the scaphoid and trapezium and between the triquetral and hamate bones.

Intercarpal Synovial Cavity.—The intercarpal synovial cavity (Fig. 332) is large and complicated. The main part extends from side to side between the two rows of bones, and may be partially interrupted by an interosseous ligament connecting contiguous parts of the scaphoid and capitate bones. Offshoots of the cavity pass proximally between the three main bones of the proximal row until blocked by the interosseous ligaments; but, in rare cases, a deficiency in one of these may permit the intercarpal joint to communicate with the radio-carpal joint. Other offshoots pass distally between the four bones of the distal row, and not infrequently communicate with the carpo-metacarpal joint-cavity, especially on one or other side of the trapezoid.

Nerve-Supply.—The intercarpal joints are supplied by twigs from the **anterior** and **posterior interosseous** nerves and the **dorsal** and **deep branches of the ulnar** nerve.

Accessory Ligaments of Carpus.—The carpus, in each of its rows, forms a transverse arch with a palmar concavity. The concavity is bridged over by the **flexor retinaculum**, which is attached medially to the pisiform bone and the hook of the hamate bone, and laterally to the scaphoid tubercle and the crest of the trapezium. Through the tunnel behind the retinaculum, the median nerve and the flexor tendons enter the palm, while the ulnar vessels and nerve pass in front of it. The **extensor retinaculum** is merely a thickened portion of the deep fascia covering the back of the carpus and the lower end of the radius. By its intermediate attachments to the ridges on the radius, it provides a series of tunnels for the extensor tendons of the wrist and fingers (p. 512).

Movements at the Radio-Carpal and Carpal Joints.—The principal movements between the carpal bones are those that occur at the transverse intercarpal joint and, as movement at this joint is usually associated with movement at the radio-carpal joint, the movements at both joints are considered together; it is also to be noted that the muscle-groups acting on these joints are common to both.

Movements at these joints occur around transverse and antero-posterior axes. Around transverse axes the hand is bent towards the front of the forearm in **flexion** or towards the back of the forearm in **extension**. Around antero-posterior axes the hand is deflected towards the ulnar border of the forearm in **ulnar deviation (adduction)** or towards the radial border in **radial deviation (abduction)**. Oblique movements are also possible around intermediate axes, as well as a combined movement around successive axes bringing about **circumduction** of the hand on the forearm.

In *flexion* of the hand, movement occurs at both the radio-carpal and transverse intercarpal joints, but in full flexion, as can only occur when the fingers are extended, the greater part of the movement occurs at the transverse intercarpal joint. *Extension* of the hand is also a compound movement, but the range of movement is greater at the radio-carpal than at the transverse intercarpal joint. In both flexion and extension of the hand the distal row of carpal bones moves around a transverse axis that passes through the middle of the head of the capitate, and there is also, in both movements, a compensatory swing of the scaphoid on the lunate for the accommodation of the head of the capitate. In ulnar deviation (*adduction*) of the hand the greater part of the movement occurs at the radio-carpal joint, and during this movement the proximal row of carpal bones glides laterally so that the entire proximal surface of the lunate lies distal to the radius (Pls. XVI, p. 269, XXXIII). Radial deviation (*abduction*) of the hand is not such an extensive movement as ulnar deviation, and occurs entirely at the transverse intercarpal joint. In both ulnar and radial deviation the movement of the distal row of carpal bones upon the proximal row is round an antero-posterior axis that passes through the centre of the head of the capitate. (For a full consideration of these movements see Wright, 1935; MacConaill, 1941.)

It is important to note that slight extension is the position naturally assumed at the wrist when the hand is used for grasping purposes, and therefore, if the wrist joint is likely to become fixed through disease, fixation should be secured in a position of slight extension in order to conserve sufficient grasping power.

CARPO-METACARPAL AND INTERMETACARPAL JOINTS

Carpo-Metacarpal Joint of Thumb (Fig. 332).—This joint is self-contained between the base of the first metacarpal bone and the trapezium. The surfaces are reciprocally saddle-shaped, and the joint is completely enclosed by a strong but rather loose **capsular ligament** (Fig. 331), which is lined with synovial membrane. Deep to the capsular ligament lie three discrete ligaments that have been termed the **anterior** and the **posterior oblique** and the **radial carpo-metacarpal ligaments** (Haines, 1944). The radial ligament is attached to the adjacent surfaces of the trapezium and the first metacarpal on their radial sides. The anterior and posterior oblique ligaments are respectively attached to the corresponding surfaces of the trapezium and converge as they pass distally to be attached to the ulnar side of the base of the first metacarpal.

Movements.—This is a saddle joint and movement can therefore occur around two principal axes at right angles to each other; oblique movements are also possible around intermediate axes as well as a combined movement around successive axes that allows the movement of circumduction of the thumb. In addition, a limited amount of rotation can take place, and though this movement does not have a wide range it is extremely important as it allows the **opposition** of the thumb to the other fingers.

For the understanding of the movements of the thumb it is to be noticed that the dorsal surface of the first metacarpal is directed laterally and the palmar surface medially. In **flexion** the thumb is moved to the ulnar side in the plane of the palm and in **extension** it is carried to the radial side in the same plane. In **adduction** the thumb is carried directly backwards and in **abduction** it is carried forwards. In the movement of full flexion the thumb is carried directly in front of the palm of the hand and it is during the latter part of this movement that the metacarpal bone undergoes a *medial* rotation of about 30° so that the palmar surface of the thumb becomes opposed to the corresponding surfaces of the fingers. Conversely, when the thumb is

[Facing p. 371

moved into full extension the first metacarpal undergoes a slight lateral rotation as the movement nears its completion. The movement of medial rotation has been shown to be caused by the posterior oblique carpo-metacarpal ligament that becomes increasingly taut during flexion of the metacarpal, and similarly lateral rotation is dependent on the anterior oblique carpo-metacarpal ligament becoming taut during extension (Haines, 1944). During the movement of opposition a certain amount of medial rotation of the first phalanx occurs at the metacarpo-phalangeal joint and this supplements the rotation of the metacarpal (Bunnell, 1938).

Common Carpo-Metacarpal Joint (Fig. 332).—The bases of the medial four metacarpal bones form, with the distal row of carpal bones, a common carpo-metacarpal joint. The line of the joint is highly irregular. Laterally, the base of the second metacarpal is recessed between the trapezium and trapezoid and between the trapezoid and the capitate bone, with all of which it articulates; next, the third metacarpal articulates with the capitate bone at a small transverse segment of the joint-line; the fourth metacarpal causes the line to become angular again as it articulates to a small extent with the capitate and to a greater extent with the hamate bone; finally, the fifth metacarpal articulates only with the medial, bevelled facet on the hamate bone.

The joint is surrounded by a **capsular ligament** in which various **palmar** and **dorsal carpo-metacarpal** slips can be distinguished passing from the distal carpal bones to the metacarpal bases. An **interosseous ligament** is usually present, stretching from contiguous parts of the capitate and hamate bones to the third or the fourth metacarpal base or to both; this ligament may divide the joint into separate medial and lateral compartments.

The **synovial cavity** of the common carpo-metacarpal joint extends upwards between the four distal carpal bones, and there usually communicates with the transverse intercarpal joint. Distally, the cavity is continuous with the little joints between the bases of the medial four metacarpal bones. (Fig. 332.)

Intermetacarpal Joints (Figs. 331, 332).—These joints are formed between small articular facets on the contiguous sides of the bases of the medial four metacarpal bones. The three little joints are closed in front, behind, and below by **palmar, dorsal,** and **interosseous ligaments** that pass transversely between adjacent bones. Proximally, their cavities open into the common carpo-metacarpal joint.

Nerve-Supply.—The carpo-metacarpal and intermetacarpal joints are supplied by twigs from the **anterior** and **posterior interosseous** nerves and the **dorsal** and **deep branches of the ulnar** nerve.

Movements.—Very little movement is possible between the carpus and the medial four metacarpal bones. It is more appreciable in the case of the fifth metacarpal, whose articulation with the hamate bone is of a flattened saddle type; around an oblique axis, this metacarpal bone can be flexed a little way across the palm in a fashion similar to the more extensive opposition movement of the metacarpal bone of the thumb.

METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS

Metacarpo-Phalangeal Joints.—Each metacarpo-phalangeal joint (Fig. 333) is formed between the slightly cupped base of the proximal phalanx and the rounded metacarpal head, which is covered with articular cartilage distally and on the front but not on the back.

Capsular Ligament.—The capsular ligament is strengthened on each side by a **collateral ligament** which radiates fanwise from the tubercle and adjacent

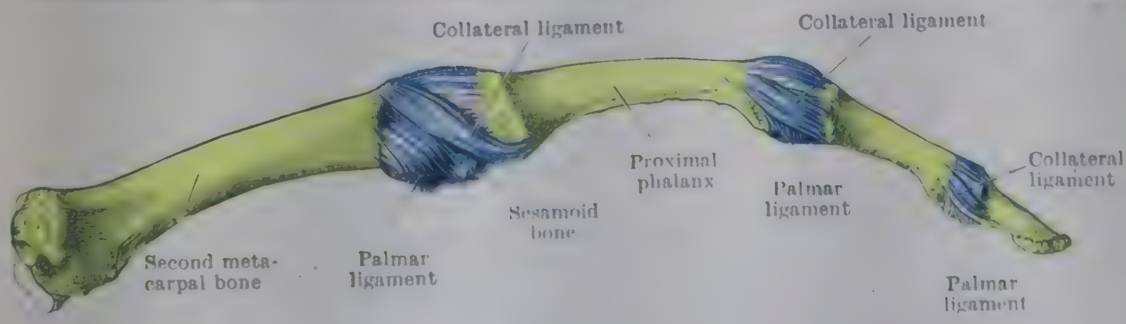

Fig. 333.—Metacarpo-Phalangeal and Interphalangeal Joints.

depression on the side of the metacarpal head to the side of the base of the proximal phalanx and to the front of the joint-capsule.

On the front there is a dense, fibrous pad, called the **palmar ligament**, which

blends with the collateral ligaments at the sides and is firmly fixed distally to the base of the phalanx but is only weakly attached proximally to the neck of the metacarpal bone. This pad is grooved in front by the long flexor tendons. In the thumb there are two sesamoid bones embedded in it; there is usually one such sesamoid in the radial side of the pad on the index finger and occasionally in the ulnar side in the little finger.

The capsular ligament is deficient **dorsally**, where it is replaced by the expansion of the long extensor tendon, which blends at the sides with the collateral ligaments.

Deep Transverse Ligaments of the Palm.—The palmar ligaments of the medial four joints are connected by strong transverse bands, called the **deep transverse ligaments of the palm**, which indirectly bind together the heads of the medial four metacarpal bones. The interossei tendons descend behind these bands; the lumbrical tendons pass in front of them.

Nerve-Supply.—The metacarpo-phalangeal joints of the thumb, the forefinger, and the middle finger are supplied by the **median** and **radial** nerves; those of the ring and little fingers by the **ulnar** nerve. (See also the paragraph on nerve-supply below.)

Movements.—The metacarpo-phalangeal joints are of condyloid type, having all the movements of a ball-and-socket joint except rotation. The proximal phalanges can be **flexed** to at least a right angle with the metacarpal bones but can be **extended** little beyond the line of the metacarpals. In the extended position the fingers can be **adducted** or **abducted** towards or away from the centre line of the middle finger. When the fingers are flexed, sideward movements become impossible because of increased tension of the collateral ligaments, which are fixed to the metacarpals nearer the distal than the palmar surface of their heads, and are also more stretched in flexion owing to the greater width of the palmar aspect of the metacarpal articular surface. The metacarpo-phalangeal joint of the thumb has much less extensive movement than the others—hardly any at all from side to side—though medial rotation occurs at it during the movement of opposition of the thumb to the fingers (p. 370).

Interphalangeal Joints (Fig. 333).—The interphalangeal joints are constructed, as regards ligaments, in exactly the same fashion as the metacarpo-phalangeal joints. But owing to the bi-condyloid shape of the articular surfaces these are pure hinge-joints, capable only of **flexion** and **extension**. Although the fingers are of unequal length, the phalanges are so proportioned that in flexion the finger-tips come into line and meet the palm simultaneously.

Nerve-Supply.—The interphalangeal joint of the *thumb* is supplied by the **median** nerve, with twigs occasionally from the **radial** also; the joints of the *forefinger* and *middle finger* by the **median** nerve; those of the *ring finger* by the **ulnar** nerve and probably **median** also; and those of the *little finger* by the **ulnar** nerve.

The **nerve-supply of the metacarpo-phalangeal and interphalangeal joints** has been specially studied by Stopford (1921), whose principal findings are here summarized. Individual variation in the articular nerve-supply is closely related to variations in the cutaneous distribution of the nerves concerned. The joints of the **thumb** are supplied by the **radial** and **median** nerves—chiefly the radial in the *metacarpo-phalangeal joint*, which, however, in a few cases may be supplied by either nerve alone; and chiefly the median nerve in the *interphalangeal joint*, of which it is often the sole supply. In the **index** and **middle fingers** the *metacarpo-phalangeal joints* are supplied by both **median** and **radial** nerves—chiefly the median—but in some cases either nerve may supply the joint; the *interphalangeal joints* are supplied by the **median** only. The joints of the **ring finger** are supplied by the **ulnar** nerve, probably supplemented by the **median** in most cases. The joints of the **little finger** are supplied by the **ulnar** nerve alone.

JOINTS OF THE PELVIS

The skeleton of the pelvic girdle is joined to the skeleton of the trunk in such a way as to provide great strength in the region of weight transference from trunk to girdle at the sacrifice of almost all mobility. The girdle, formed of a single unjointed piece—the hip-bone—is firmly but not quite immovably joined to the sacrum behind and to its fellow of the opposite side in front. These two joints, sacro-iliac and interpubic, with the sacro-coccygeal union and the lumbo-sacral articulation between the pelvis and the last lumbar vertebra, make up the pelvic joints.

LUMBO-SACRAL AND SACRO-COCCYGEAL JOINTS

Lumbo-Sacral Joint.—At the lumbo-sacral joint the fifth lumbar vertebra is united to the first piece of the sacrum, just as any two typical vertebræ are united, by an intervertebral disc, the anterior and posterior longitudinal ligaments, synovial joints between articular processes, ligamenta flava, and interspinous and supraspinous ligaments. In addition there are two special ligaments that spring from the fifth lumbar transverse process on each side—the ilio-lumbar and the lateral lumbo-sacral ligaments.

The **ilio-lumbar ligament** (Fig. 334) is a strong ligament that spreads laterally from the fifth lumbar transverse process to the posterior part of the inner lip of the iliac crest; it is really the thickened lower border of the anterior layer of lumbar fascia lying in front of the quadratus lumborum muscle.

The **lateral lumbo-sacral ligament**—usually partly blended with the preceding ligament—consists of variable bundles that pass downwards and laterally from the lower border of the fifth lumbar transverse process to the ala of the sacrum, where they intermingle with the anterior sacro-iliac ligament; its attachments indicate its homology with the superior costo-transverse ligaments of the thoracic region.

Sacro-Coccygeal Joint.—At the sacro-coccygeal joint there is an intervertebral disc between the last sacral and first coccygeal segments, reinforced all round by longitudinal strands called the **sacro-coccygeal ligaments** (Fig. 334).

SACRO-ILIAC JOINT

The **sacro-iliac joint** is formed between the auricular facets on the sacrum and on the iliac bone. Reciprocal sinuosities on these two surfaces, or even in some cases more pronounced irregularities in the form of tubercles with depressions opposite to them, cause a certain amount of interlocking between the facets. The shape and the irregularity of the auricular surfaces not only vary considerably in different individuals, but also may show marked differences on the two sides in the same individual. The auricular surface of the sacrum is covered with hyaline cartilage, but the cartilage on the corresponding facet of the ilium is usually of a fibrous type (Schunke, 1938). The joint is a synovial one, with a complete capsular ligament lined with synovial membrane, but movement is greatly restricted by the irregularity of the articular surfaces and the thickness and disposition of the posterior sacro-iliac ligaments. In later life, particularly in males, it is usual to find fibrous or fibro-cartilaginous adhesions between the articular surfaces, with partial or complete obliteration of the cavity of the joint (Brooke, 1924).

The **anterior sacro-iliac ligament** is a broad band, of no great thickness, which closes the joint in front both above and below the pelvic brim. It stretches from the ala and pelvic surface of the sacrum to the adjoining surface of the iliac bone.

The **posterior sacro-iliac ligaments** present a very much stronger and thicker formation. It consists of three strata. The deepest—the **interosseous sacro-iliac ligament**—short, thick, and very strong, fills the narrow cleft between the rough areas on the bones immediately above and behind the articular surfaces (Fig. 335). Occasionally one or two small accessory joint-cavities are found in the substance of this ligament between facets near the posterior superior spine and bosses on the sacrum in the position of transverse tubercles (Jazuta, 1929).

Superficial to the interosseous fibres, longer bands run obliquely medially and downwards between more divergent parts of the bones; these constitute the **short posterior sacro-iliac ligament** (Figs. 334, 335). Still longer fibres, descending almost vertically from the posterior superior iliac spine to the third and fourth sacral segments, behind and lateral to the short ligament, compose the **long posterior sacro-iliac ligament**. The lateral part of the long ligament is indistinguishable from the upper part of the sacro-tuberous ligament.

Nerve-Supply.—The sacro-iliac joint is supplied (1) by twigs directly from the **sacral plexus** and the **posterior primary rami of the first two sacral nerves**, and (2) by branches from the **superior gluteal and obturator nerves**.

Accessory Ligaments.—The gap left in the bony pelvis between the sacrum and the ischial part of the hip-bone is bridged by a system of widespread fibres that form accessory ligaments of the sacro-iliac joint called the sacro-tuberous and sacro-spinous ligaments (Figs. 334, 335).

The **sacro-tuberous ligament** has an extensive attachment to the posterior superior and posterior inferior iliac spines, the back and side of the lower part of the sacrum and the side of the upper part of the coccyx. Thence the fibres converge towards the ischial tuberosity, but, twisting upon themselves, they diverge again to be attached to the medial margin of the ischial tuberosity and the lower margin of the ramus of the ischium. The fibres to the ramus form a sickle-shaped extension of the ligament called the **falciform process**.

The superficial fibres attached to the tuberosity are intimately associated with

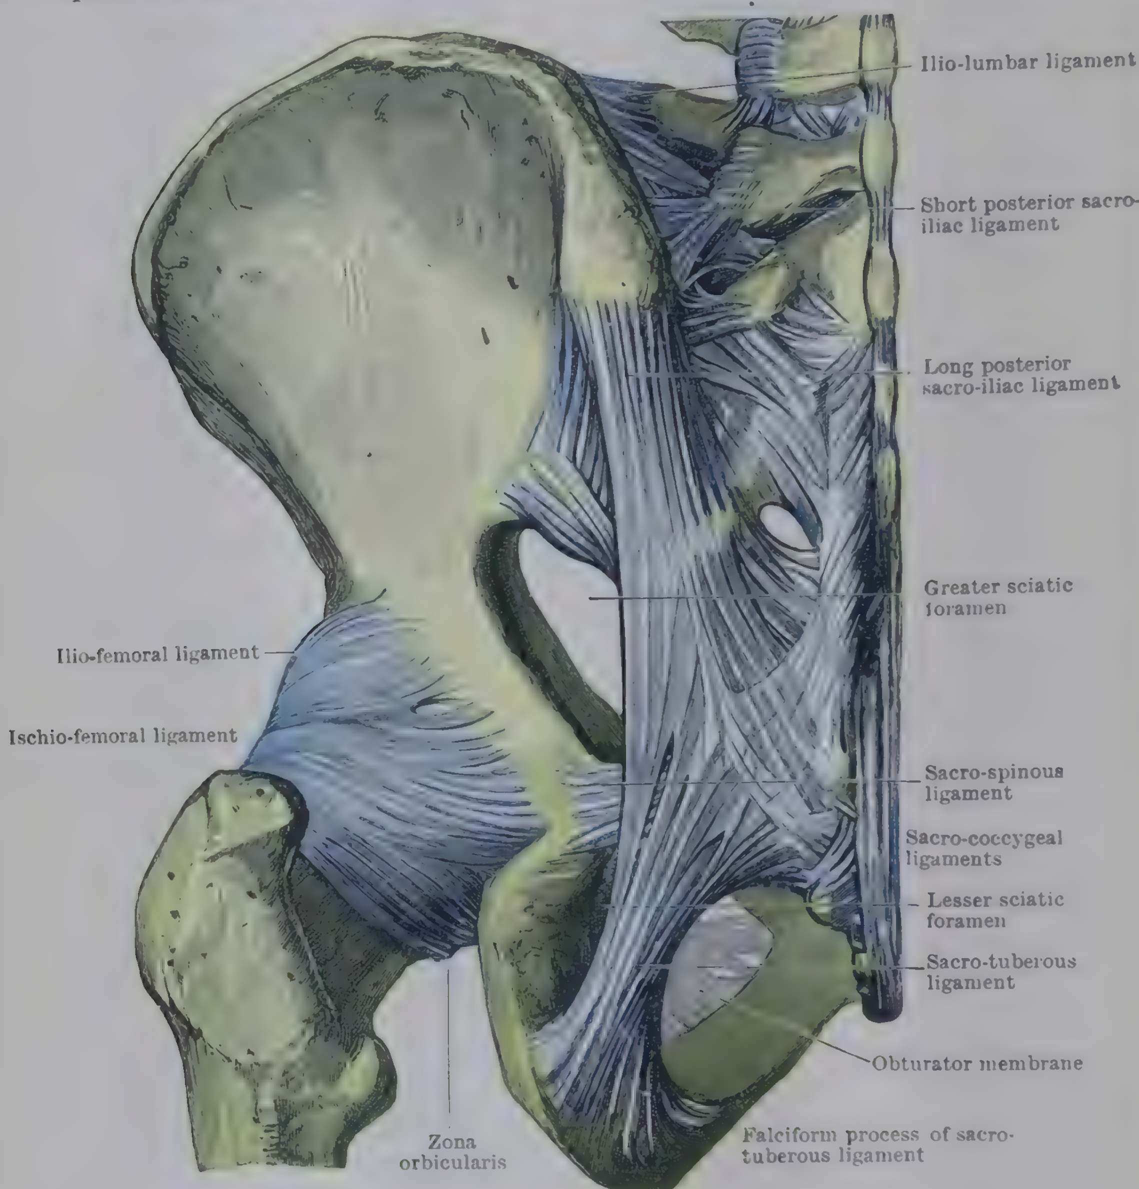

Fig. 334.—Posterior View of Pelvic Ligaments and Hip Joint.

the long head of the biceps femoris muscle; the whole ligament, indeed, is usually regarded as a stranded proximal portion of this muscle.

The **sacro-spinous ligament** lies on the pelvic surface of the sacro-tuberous ligament. It is triangular in outline. Its base is attached to the edge of the lower sacral and upper coccygeal segments, in front of the sacro-tuberous ligament; its apex is attached to the ischial spine. This ligament is closely blended with the coccygeus muscle, and may be regarded as the result of a fibrous degeneration of the dorsal part of the muscle.

Sciatic Foramina.—The sacro-tuberous ligament, by its lateral border stretching between the posterior inferior iliac spine and the ischial tuberosity, converts the greater and lesser

sciatic notches of the hip-bone into foramina separated by the apical part of the sacro-spinous ligament (Figs. 334, 335). The piriformis muscle runs out through the **greater sciatic foramen** with the superior gluteal vessels and nerve above the muscle, and below it the sciatic nerve, the posterior cutaneous nerve of the thigh, the inferior gluteal vessels and nerve, the internal pudendal vessels and the pudendal nerve, and the nerves to the quadratus femoris and obturator internus muscles. The tendon of the obturator internus emerges from the **lesser sciatic foramen**; the nerve to that muscle and the internal pudendal vessels and pudendal nerve enter the perineum above the tendon.

PUBIC SYMPHYSIS

The **pubic symphysis** is a median joint between the bodies of the pubic bones (Fig. 335). Each pubic articular surface is covered with a layer of hyaline cartilage united to the cartilage of the opposite side by a thick fibro-cartilaginous **interpubic disc.** In the upper and back part of this disc a slit-like cavity appears during early life, and it may extend later, in women especially, through the greater part of the fibro-cartilage. There is no true synovial membrane. The joint is therefore of secondary cartilaginous type, modified by the appearance of an imperfect joint-cavity.

Ligaments of Pubic Symphysis.—The perichondrio-periosteal investment of the joint is strengthened all round by the **pubic ligaments.**

The **anterior ligament** is an interlaced decussation across the front of the joint of fibres largely derived from tendons of adjacent muscles, especially the rectus abdominis and external oblique muscles. The **posterior ligament** is represented by a few transverse fibres across the back of the joint. The **superior ligament** crosses the joint between the pubic crests and tubercles. The **inferior ligament** arches across the joint below, between the inferior pubic rami, and so rounds off the subpubic angle; it is separated from the perineal membrane by an interval through which the deep dorsal vein of the penis (or clitoris) enters the pelvis.

Obturator Membrane (Fig. 336).—The obturator membrane, unconnected with any pelvic joint, is an interlacement of ligamentous bundles that close the obturator foramen save in its antero-superior part. It is attached to the margin of the foramen all round except in the neighbourhood of the **obturator canal.** This aperture is bounded above by a rounded part of the margin of the foramen and completed below by the short, free edge of the membrane; it transmits the obturator vessels and nerve. The obturator muscles arise from the surfaces of the membrane.

Pelvic Mechanics

The bony pelvis protects the pelvic viscera and gives attachment to muscles of the trunk and lower limb, but its primary skeletal function is to provide for stable transference of body-weight from the vertebral column to the thigh-bones. From the last lumbar vertebra the weight is transmitted through the upper part of the sacrum and the adjoining part of each iliac bone to the head of the femur; these parts constitute a pelvic arch of thickened bone, the concave border of which corresponds to the posterior half of the pelvic brim. The ventral pelvic bar formed by the superior rami and bodies of the pubic bones acts as a horizontal tie-beam connecting the bases of the pillars of the arch. Owing to the sinuous nature of the sacro-iliac joint-surfaces and the inclination of the long axis of the joint downwards, backwards and medially, the direction of the joint-line varies in sections cut in different planes and also at different levels in the same plane. For example, a section, in the plane of weight transference, through the middle of the joint shows the sacrum to be wedged between the hip-bones with the base above (Fig. 335) but a section near the lower end of the joint and in the same plane shows the sacrum as a wedge with the base below.

The weight of the body tends to displace the sacrum downwards into the pelvis, with separation of the hip-bones. This downward displacement and separation is resisted by the strong ligaments behind the sacro-iliac joints and the reciprocal sinuosities on the auricular surfaces. Any tendency to flattening of the arch, with opening out of the sacro-iliac joints below and in front, is resisted by the tie-beam action of the ventral pelvic bar. The body-weight, superimposed on the upper end of the obliquely-placed sacrum, tends to drive that end downwards and to tilt the lower end upwards and backwards; this is prevented by the strong sacro-tuberous ligaments holding down the lower part of the

sacrum. The ilio-lumbar ligaments help to prevent the last lumbar vertebra from slipping forwards on the oblique upper surface of the body of the first sacral segment. A slight amount of separation or gliding movement is possible at the sacro-iliac joints and the pubic symphysis; the cartilaginous plates in those joints have a cushioning action against jarring shocks. In these ways the pelvic joints provide that element of controlled resilience necessary to perfect function.

The **female pelvis** is modified in association with the requirements of child-bearing. Differences are seen in the joints as in the bones. At the sacro-iliac joint there is less interlocking by reciprocal irregularity of the bones, and more movement is permitted than in the male pelvis; the limitation of movement by fibrous ankylosis in later life is not nearly so marked in women as in men. The larger cavity in the interpubic disc, characteristic of the female joint, allows greater separation of the bones. The coccyx,

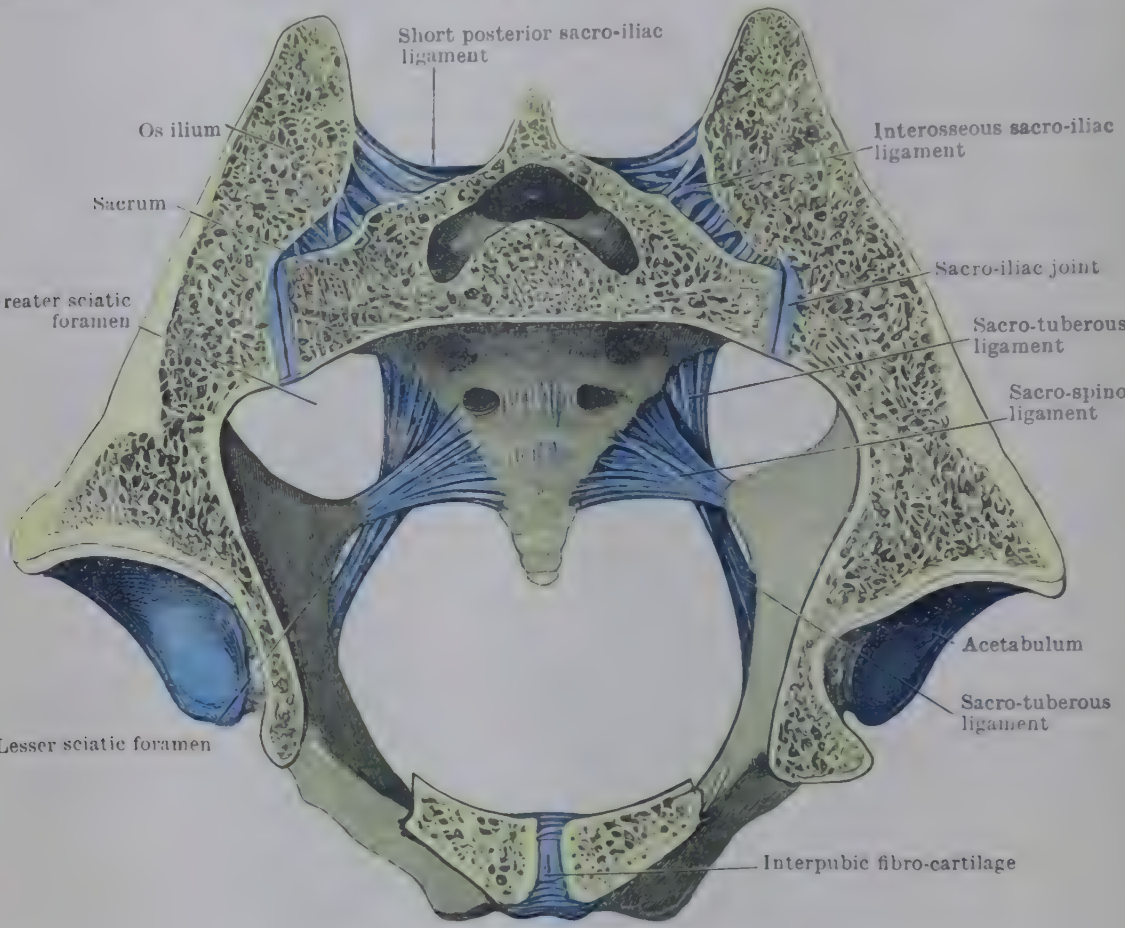

FIG. 335.—CORONAL SECTION OF PELVIS.

which in men is usually fused to the sacrum by synostosis in later life, is more mobile and preserves its mobility longer in women.

During pregnancy a softening and relaxation of the pelvic ligaments occur which allow an increase in the separation of the pelvic bones and an increase in the movements at the pelvic joints. These joint changes were formerly regarded as of importance during child-birth, but radiographic observations indicate that they do not materially affect the diameters of the pelvis (Young, 1940).

JOINTS OF LOWER LIMB

HIP JOINT

At the **hip joint** the globular head of the femur articulates with the cup-like acetabulum of the hip-bone, and provides the most striking example in the body of a ball-and-socket joint.

The mechanical requirements at this joint are severe. It must be capable not merely of supporting the entire weight of the body—as in standing on one leg—but of stable transference of that weight even during movement of the trunk upon the femur such as occurs with rapid alternation at the two hip joints

during walking and running. The joint must therefore possess great strength and stability even at the expense of limitation of range of movement. To this end, the deep socket securely holding the contained ball, the strong, tense capsular ligament, the insertion of the controlling muscles at some distance from the centre of movement, are all in marked contrast to the conditions at the shoulder joint.

Articular Surfaces.—The **femoral articular surface** forms nearly two-thirds of a spheroid. The covering cartilage is interrupted at the pit on the head of the femur, and it ends at the commencement of the neck of the femur along a sinuous line which sometimes makes a scalloped excursion upon the front of the neck. The **acetabular articular surface** is limited to a broad horseshoe-shaped belt which is covered with cartilage and is interrupted below and in front opposite the acetabular notch. The depressed central part of the acetabulum within the horseshoe lodges a pad of fat covered with synovial membrane.

Transverse Ligament and Labrum Acetabulare.—The acetabular notch is bridged by the **transverse ligament** of the acetabulum. The superficial edge of the ligament is flush with the acetabular rim; its deep edge does not reach the bottom of the notch but bounds an aperture which admits articular vessels and nerves. The acetabulum is deepened all round by a fibro-cartilaginous lip, called the **labrum acetabulare,** which is firmly attached to the bony rim and the transverse ligament. The thin, free edge of the labrum forms a slightly smaller circle than its attached base, and so is able to grasp the femoral head (Figs. 336, 337).

Capsular Ligament (Figs. 334, 336).—The capsular ligament encloses the joint and the greater part of the femoral neck as with a cylindrical sleeve. It is very strong and uniformly tense in full extension—in contrast to the thin and lax capsule of the shoulder joint. The tendons of surrounding muscles are much less intimately connected with it, but it does receive expansions from the rectus femoris, the gluteus minimus, and the piriformis muscles.

Proximally, the capsular ligament surrounds the acetabulum and is attached above and behind directly to the hip-bone just wide of the labrum, while below and in front it is fixed to the bone and the outer surface of the labrum and the transverse ligament of the acetabulum. Distally, the ligament is attached in front to the trochanteric line at the junction of the femoral neck and shaft; above and below it is attached to the neck close to its junction with the trochanters; but, behind, it extends over only the medial two-thirds of the neck. Thus, the whole of the neck of the femur is intracapsular in front, but the lateral third is extracapsular behind. The epiphysial line of the head is intracapsular; the trochanteric epiphysial lines are extracapsular.

The fibres of the capsular ligament run for the most part longitudinally from pelvis to femur. Some deeper fibres pass circularly round the joint, constituting the **zona orbicularis**; this is marked only on the back of the capsule, where it appears on the surface, winding round behind the femoral neck (Fig. 334).

Some of the deepest longitudinal fibres, on reaching the neck of the femur, turn upwards upon the neck towards the articular margin; these reflected fibres form bundles, best marked on the upper and lower surfaces of the neck, called *retinacula* or cervical ligaments (Fig. 337).

The main longitudinal fibres of the capsular ligament are massed to form certain thickened bands developed to resist particular stresses to which the capsule is subjected. These bands are specially named after the regions of the acetabulum (iliac, pubic, and ischial) from which they arise—the ilio-femoral, pubo-femoral, and ischio-femoral ligaments.

The **ilio-femoral ligament**, of great strength and considerable thickness, is a triangular band attached proximally by its apex to the lower part of the anterior inferior iliac spine and adjoining part of the acetabular rim, and distally by its base to the trochanteric line. It occupies all the front of the capsule except at the medial side above. Usually the sides of this triangular ligament are stronger than the middle part, so that the stronger bands, diverging below from a common stem above, resemble an inverted Y (⅄). The upper or lateral of the two diverging

bands is attached distally to a special tubercle on the front of the greater trochanter at the upper end of the trochanteric line (Fig. 336).

In full extension of the hip joint the ilio-femoral ligament becomes taut. It therefore resists the strain put upon the anterior part of the capsular ligament in the standing position, when the incidence of body-weight tends to roll the pelvis backwards on the femoral heads.

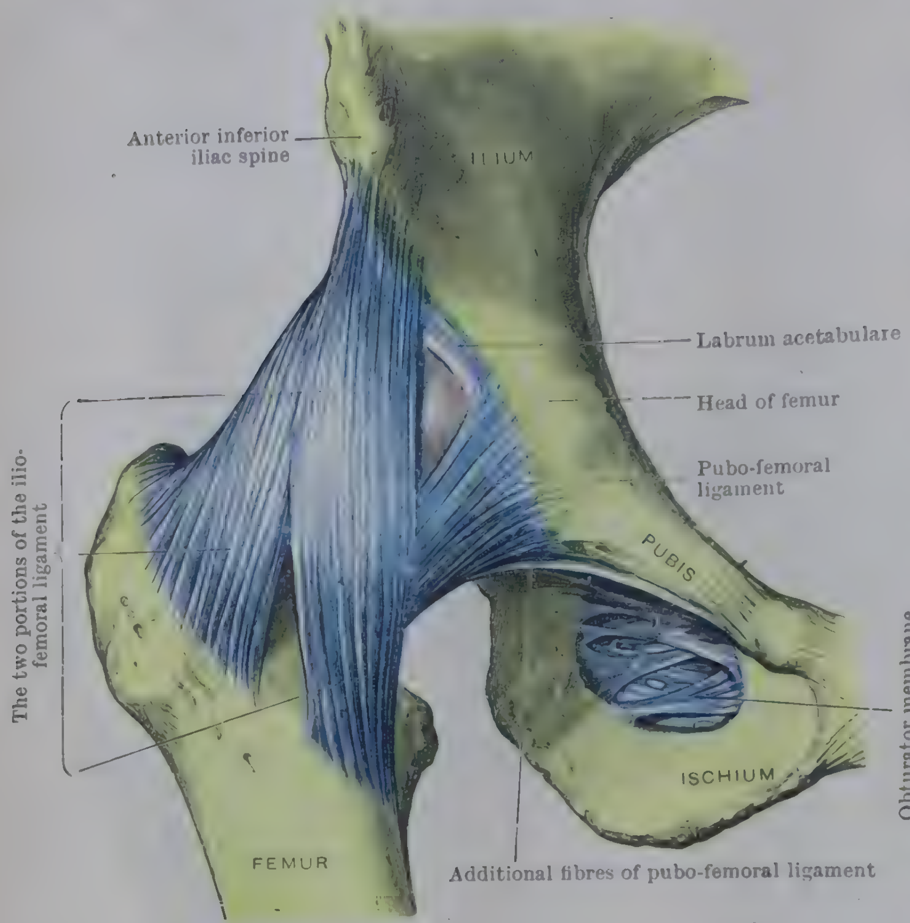

Fig. 336.—Dissection of Hip Joint from the Front.

The **pubo-femoral ligament** arises from the pubic part of the acetabular rim, with additional fibres from the superior pubic ramus overhanging the obturator groove (Fig. 336), and it loses itself distally in the general capsular ligament. Some fibres, however, reach the under part of the femoral neck. This ligament, like the ilio-femoral, becomes taut in extension of the joint and it also helps the adductor muscles in checking excessive abduction of the thigh.

The **ischio-femoral ligament**, less well defined than the others, springs from the ischial wall of the acetabulum on the hinder and lower aspect of the joint (Fig. 334). The upper fibres pass out horizontally across the back of the joint, the lower ones ascend spirally; and both sets of fibres, converging on the upper and lateral part of the femoral neck, are attached to the neck, medial to the root of the greater trochanter, close behind the upper band of the ilio-femoral ligament. The general spiral course of the ischio-femoral ligament upwards and laterally across the back of the joint causes the ligament to be most tense in the position of extension.

Ligament of Head of Femur.—In the hip joint there is also an intra-articular ligament of flattened triangular shape, known as the **ligament of the head of the femur** (Fig. 337). Its base is attached within the joint to the deep border of the transverse ligament and to the margins of the acetabular notch, especially the lower or ischial margin. It then narrows to its apical attachment in the upper part of the pit on the head of the femur. Between these attachments the ligament runs free within the joint-cavity, surrounded by a synovial sheath. It passes round the head of the femur between it and the non-articular part of the acetabular floor (Fig. 337).

The ligament of the head of the femur varies in size, and in rare cases it is absent. Its function is uncertain. It is stretched when the flexed thigh is adducted or rotated laterally, but in many cases it is too weak to have any definite ligamentous action. No appreciable disability results from its rupture or absence. Morphologically, it has been reckoned a relic of the avian *ambiens* muscle or a detached portion of the pectineus. A more feasible ontogenetic explanation of its appearance in Man is that it represents a part of the capsule as first developed which is subsequently included within the joint by the wing-like extension of the femoral head round each side of its femoral attachment and by the increasing size of the ischial contribution to the acetabulum. These developmental changes are associated with provision for increased

rotation in the human joint, which is much specialised in comparison with the simple hinge-like type of joint in lower vertebrates.

A small artery is always found within its substance; this vessel takes little, if any, part in the blood-supply of the femoral head in children, though in adults it may supplement the supply derived from the vessels within the retinacula (*vide infra* and Tucker, 1949).

Synovial Membrane.—The synovial membrane of the hip joint lines the capsular ligament and covers the labrum acetabulare. At the acetabular notch it passes over the inner face of the transverse ligament to cover the fatty tissue in the non-articular part of the acetabulum, and extends as a funnel-shaped sheath upon the ligament of the head of the femur to the edge of the pit on the femoral head. Distally, at the femoral attachment of the capsular ligament, the synovial membrane is reflected upwards on the neck of the femur as far as the edge of the articular cartilage on the head. The retinacula raise this reflected part into prominent folds (Fig. 337), within which blood-vessels run upwards to the head of the bone. At the back of the joint a fold of synovial membrane may protrude beneath the lateral border of the capsular ligament, which is here composed mainly of fibres passing circularly round the femoral neck; the few longitudinal fibres that reach the back of the neck afford some slight support to this synovial protrusion.

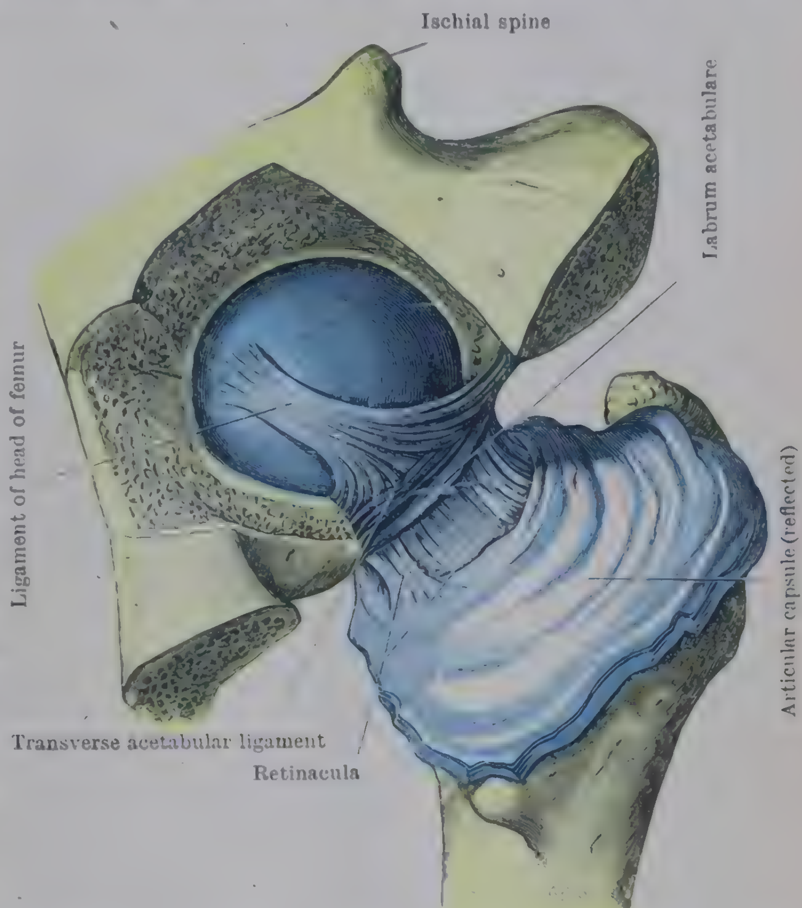

FIG. 337.—DISSECTION OF RIGHT HIP JOINT FROM PELVIC SIDE. The bottom of the acetabulum has been removed, and the capsule of the joint thrown laterally towards the trochanters.

In this joint, where the tense ligaments are, in places, closely applied to the femoral head, the synovial lining is not recognizable as a definite membrane in areas under constant pressure, as on the deep surface of the front of the capsule. The excursion of articular cartilage on to the front of the neck of the femur, already referred to, is probably a reaction to the pressure of the overlying ilio-femoral ligament.

There may be one extra-articular extension of the synovial membrane: the psoas tendon passes over a thin portion of the capsule between the upper ends of the ilio-femoral and pubo-femoral ligaments, with a small bursa intervening; sometimes there is an opening in the capsular ligament under the tendon, and the bursa is then continuous with the synovial membrane of the joint.

Nerve-Supply.—The hip joint is supplied (1) from the lumbar plexus by twigs from the **femoral** and **obturator nerves**, and (2) from the sacral plexus by twigs from the **superior gluteal nerve** and the **nerve to the quadratus femoris muscle** (see Gardner, 1948 *b*).

Movements at the Hip Joint

The movements are those typical of a ball-and-socket joint. They can be analysed as: (1) **flexion** and **extension** around a transverse axis; (2) **abduction** and **adduction** around an antero-posterior axis; (3) **medial** and **lateral rotation** around a vertical axis;

with movements compounded of these around intermediate axes. In the movement of **circumduction**, the limb swings round the side of a cone the apex of which is in the hip joint. All axes intersect at the centre of the head of the femur.

Flexion is limited by the tension of the hamstring muscles when the knee joint is extended; but these muscles are relaxed when the knee is bent, and the thigh can then be brought against the anterior abdominal wall. All parts of the capsular ligament are relaxed in flexion, and dislocation is therefore most liable to occur then. Extension takes place very little beyond the vertical position with the limb in line with the trunk. The limitation of extension is in part due to the tension of the ligaments and in part to the form of the articular surfaces. The head of the femur is not truly spherical but has an ellipsoidal form that is only fully congruent with the acetabulum in the position of complete extension. In bringing the limb into full extension from the position of flexion the capsular ligament becomes increasingly tense and draws the head of the femur more and more tightly against the acetabulum. When the femur has passed about 15° behind the vertical, the articular surfaces of femur and acetabulum are fully congruent, the capsular ligament is taut and no further extension of the joint can take place—the joint is then said to be 'locked' (Walmsley, T., 1928). During this 'screwing home' of the head of the femur, part of the pad of fat in the acetabular fossa is displaced from the fossa and passes outwards between the transverse ligament and the acetabular notch, but when the limb is again flexed the fat is drawn into the acetabulum to help to occupy the potential space that is created by the lateral movement of the head of the femur. A perpendicular line through the centre of gravity of the trunk falls behind a line joining the centres of the femoral heads; hence, in the erect position the pelvis, bearing the trunk, tends to roll backwards on the femora, but is prevented from so doing by the 'locking' that occurs at the hip joints. The 'locked' position is the one in which the body weight is normally borne by the limbs, and it is maintained with the minimum of muscular effort. Abduction is limited by tension of the adductor muscles and the pubo-femoral ligament; adduction, by tension of the abductors and the lateral part of the ilio-femoral ligament. Rotation is termed medial or lateral according to the direction in which the toes are turned; it is rather more free when combined with flexion than in the extended position of the hip. Medial rotation is limited by tension of the lateral rotator muscles and the ischio-femoral ligament; lateral rotation, by the medial rotators and the ilio-femoral ligament. A small amount of rotation at the hip joint occurs automatically in association with the termination of extension and the commencement of flexion at the knee joint (see p. 387).

The difference between average mobility and the extreme mobility possessed by trained contortionists is nowhere more marked than at the hip joint. The greater limitation of movement in the ordinary person is probably largely due to muscle shortening. The final limitation imposed by the impact of the femoral neck on the rim of the acetabulum does not arise in the ordinary use of the joint.

KNEE JOINT

The **knee joint** is the largest joint in the body, and is structurally the most complicated. It is, in the main, a hinge-joint; but, even as such, it is modified in some ways, and, in addition, it is capable of rotation. The human knee joint must possess great stability, especially in extension, and it must at the same time permit full freedom of movement. In the mechanism of joints in general, stability and mobility are to some extent incompatible qualities, and most joints secure one of these at the expense of the other. At the knee joint both are secured to a remarkable degree by such an alliance of muscle and ligament in controlling the joint as prevails nowhere else. Here, to a large extent, the muscles *are* the ligaments.

Articular Surfaces.—Functionally, as well as phylogenetically, the knee joint is compounded of three articulations—an intermediate one between the patella and the patellar surface of the femur, and lateral and medial articulations between the femoral and tibial condyles.

The **articular surface of the femur** comprises: the *condylar areas*, which are opposed to the tibia and are separated behind by the intercondylar notch; and the *patellar surface*, which unites the condyles in front and is opposed to the patella. Each condylar surface is delimited from the patellar surface by a shallow groove on the articular cartilage. On the lateral condyle this groove is almost transverse and is emphasized at each end. On the medial condyle the groove begins farther for-

ward medially, and, passing obliquely backwards across the condyle, disappears before reaching the lateral edge, where a narrow crescentic facet is marked off which engages with the patella in acute flexion. The axis of the medial condylar surface turns laterally in its anterior part; the whole surface is made up of a posterior part which lies parallel to the lateral condylar surface and is equal to it in extent, and an additional wedge-shaped part in front, where the axis turns laterally, which has no corresponding part on the lateral condyle. Each condylar surface is convex from side to side and from before backwards, the antero-posterior curve being much flatter in front than behind. The patellar surface is grooved vertically between two prominent borders—the lateral the more salient (Fig. 338).

The **articular surface of the patella** is broadly oval, and it is divided into a

FIG. 338.—DISSECTION OF RIGHT KNEE JOINT FROM THE FRONT: PATELLA THROWN DOWN.

larger lateral area and a smaller medial area by a rounded vertical ridge apparent even on the macerated bone. The cartilaginous covering reveals a further subdivision of the surface: on each side of the vertical ridge two faint transverse ridges separate three facets paired with the facets on the other side, and another faint vertical ridge delimits a medial perpendicular facet adjoining the medial border of the articular surface. In acute flexion the medial facet rests on the crescentic facet on the medial femoral condyle; the other facets engage in succession from above downwards with the patellar surface of the femur as the joint moves towards full extension. Owing to the angulation of the femur on the tibia the patella tends to be displaced laterally during forced extension of the knee joint, as in rising from a chair. This is prevented by the prominent lateral patellar surface of the femur and by the action of the lower part of the vastus medialis muscle which is inserted into the medial border of the patella.

The **articular surfaces of the tibia** are the cartilage-covered areas on the upper surface of each tibial condyle. These areas are separated by a non-articular intercondylar area formed by the intercondylar eminence in the middle, and rough, triangular depressions in front and behind. The medial articular area is oval and concave. The lateral area, smaller and more circular, is concave from side to side and concavo-convex from before backwards; posteriorly it is prolonged downwards

over the back of the condyle in relation to the popliteus tendon (Fig. 340). A peripheral flattened strip on each condyle underlies a semilunar fibro-cartilage. The tibial articular surfaces are far from congruent with the femoral condyles, which rest upon them; but the effect of this incongruence is lessened by the interposition of the semilunar cartilages.

Articular Capsule.—The capsule of the joint is a complicated structure. There is no complete, independent capsular ligament uniting the bones. Instead, the joint is surrounded by a thick ligamentous formation constructed chiefly of muscle tendons or expansions from them; only here and there is it composed of true capsular fibres running between the articulating bones. Inside the capsule, the synovial lining of the joint is in places separated from the ligamentous stratum by wide intervals occupied by fatty pads or special intra-articular structures.

At the **front of the joint** this ligamentous formation is built up mainly of the fused tendons of insertion of the rectus femoris and vasti muscles. These descend on the patella from above and from each side to a marginal insertion around the upper half of the bone. Superficial tendinous fibres are continued downwards over the front of the bone into the **ligamentum patellæ**. This thick band securely anchors the patella to the tibia, and is in reality the distal part of the quadriceps insertion; it is attached to the apex and the posterior surface of the patella below the articular area, and to the tubercle of the tibia. Other thinner bands pass down from the sides of the patella, diverging slightly, to the front of each tibial condyle; these constitute the **medial** and **lateral patellar retinacula**. Tendinous fibres of the vasti muscles pass obliquely downwards across the patella into the retinaculum of the other side. Other deeper fibres from each side of the patella pass across to the anterior part of each femoral epicondyle.

Superficial to all these bands there are strong expansions of the fascia lata. The ilio-tibial tract descends across the antero-lateral aspect of the joint to be inserted into the lateral tibial condyle. A strong band diverges anteriorly from this tract to be attached to the upper part of the lateral edge of the patella, forming a *superior patellar retinaculum*. Less definite fascial expansions sweep down over the patella, and on each side of it, towards the upper part of the tibia; some fibres form U-shaped loops in front of the ligamentum patellæ.

The whole of this anterior covering of the knee joint, with the patella inset on its deep aspect, is kept tense by the tone of the extensor muscles, and is tightly braced up when these muscles contract in extension. In the ordinary type of hinge-joint the extensor portion of the capsule must be loose in the extended position to permit the possibility of flexion. But at the knee this part of the capsule is, as it were, continued into muscle above, instead of being attached directly to the proximal bone, and can be kept taut in all positions.

The **back of the joint** is covered over by a ligamentous feltwork of intersecting bands which form a **posterior ligament**. True *capsular fibres* descend over the upper part of the joint from a femoral attachment along the base of the popliteal surface and invest the back of each condyle with a thin covering overlain by the corresponding head of the gastrocnemius, which in part arises from it. Distally, other capsular fibres ascend from the posterior border of the proximal end of the tibia, leaving an opening laterally for the escaping popliteus tendon. The stronger central portion of the posterior ligament is formed by a well-marked expansion from the semimembranosus tendon which turns obliquely upwards and laterally to blend with the general capsular fibres over the lateral condyle of the femur. This expansion is called the **oblique posterior ligament**. The lower lateral part of the back of the joint is strengthened by the **arcuate ligament of the knee**, which springs from the back of the head of the fibula, arches upwards and medially over the popliteus tendon as it emerges from the joint, and spreads out on the back of the capsule. Sometimes the most lateral fibres of the arcuate ligament are specially developed as a separate band that runs from the head of the fibula to the back of the lateral femoral condyle (Fig. 339).

At the **sides of the joint** there are true capsular fibres which descend from the sides of the femoral condyles to the sides of the tibial condyles. They blend posteriorly with the ligamentous feltwork, and anteriorly with the various

tendinous expansions already described. Here are found the special *medial* and *lateral ligaments* characteristic of hinge-joints, but the ligaments of the two sides differ greatly in form and relations.

The **medial ligament** is a broad, flat band in the true capsular plane. Its upper end has an extensive attachment on the medial epicondyle of the femur; some fibres may be traced upwards into the adductor magnus tendon, and the ligament has been regarded as formed, in part at least, from an original tibial

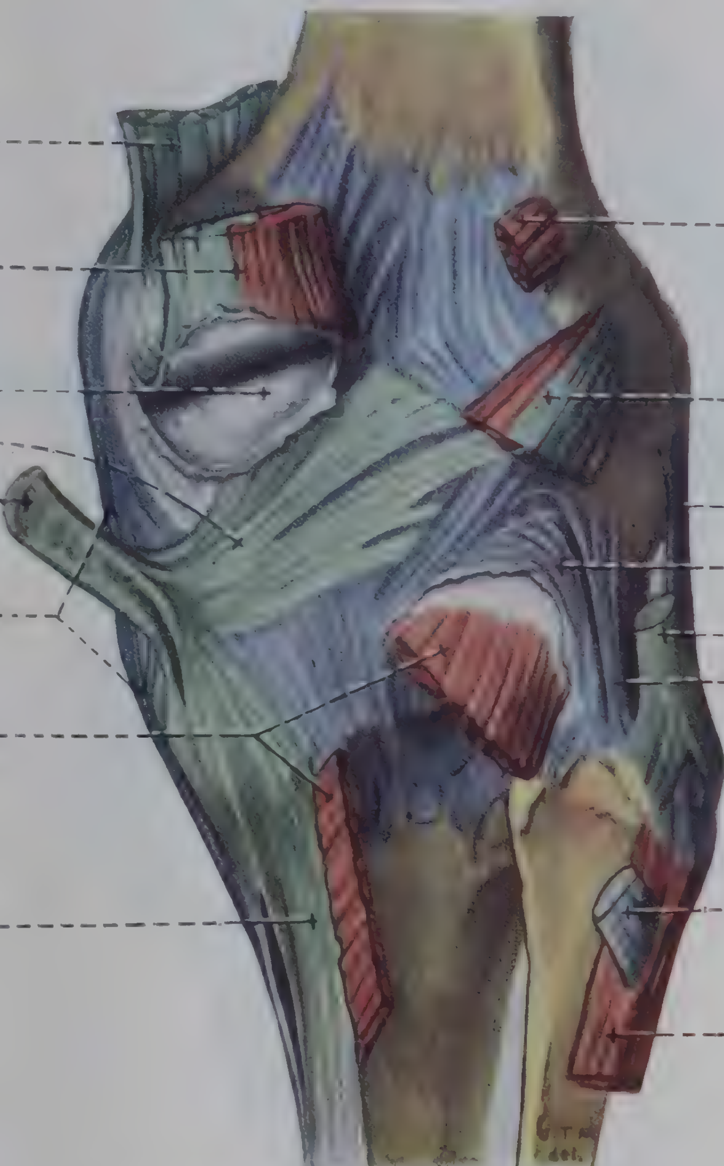

FIG. 339.—RIGHT KNEE JOINT FROM BEHIND.

In the specimen the lateral part of the *arcuate ligament* was present as a separate band; and the continuity between the lateral ligament of the knee and the peroneus longus muscle was specially well marked.

insertion of this muscle. The ligament passes downwards and slightly forwards and is attached at its lower end to the medial surface of the tibia: the superficial fibres descend to below the level of the tibial tubercle; deeper fibres have a shorter course from femur to tibia, the deepest of all having an intermediate attachment to the medial semilunar cartilage. Posterior to the upper part of the main band, shorter fibres reach the edge of the tibial condyle immediately above the principal insertion of the semimembranosus tendon. A downward expansion from this tendon reaches the shaft of the tibia, partly under cover of the posterior border of the main band (the medial inferior genicular vessels and nerve running forwards between them) and partly blending with this border of the ligament.

The **lateral ligament** (Figs. 338, 339), round and cord-like, stands altogether clear of the capsular ligament, and is wrapped round by an expansion of the

fascia lata. It is attached above to the lateral epicondyle of the femur; below, it reaches the head of the fibula in front of its highest point, splitting the tendon of the biceps as it does so. As in the specimen drawn in Fig. 339, the ligament is sometimes partly continued into the upper end of the peroneus longus muscle, and may be regarded as a stranded femoral tendon of this muscle.

On the lateral side of the joint the true capsular fibres are short and weak; they bridge the interval between the femoral and tibial condyles, and some of them

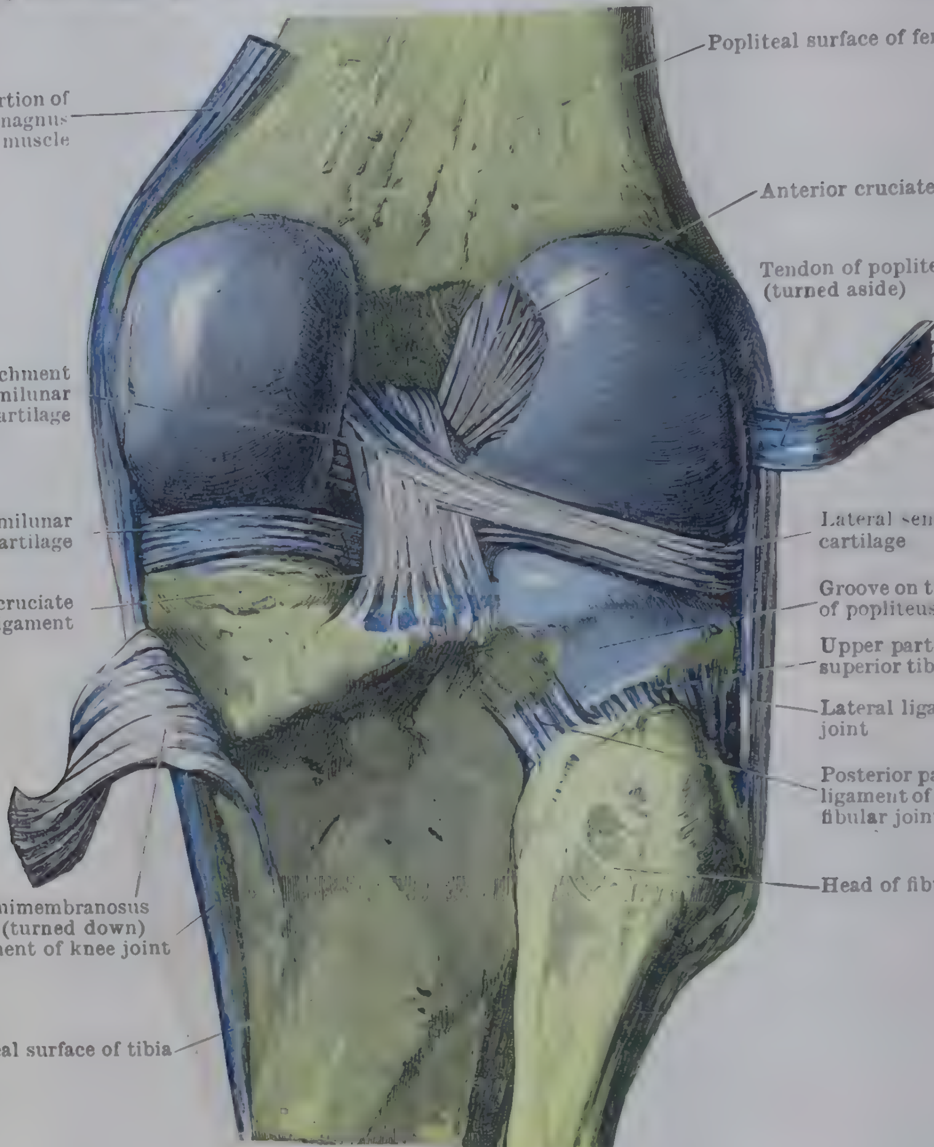

FIG. 340.—RIGHT KNEE JOINT OPENED FROM BEHIND BY REMOVAL OF THE POSTERIOR LIGAMENT.

are separated from the lateral semilunar cartilage by the popliteus tendon. There is a distinct interval between these capsular fibres and the lateral ligament: through the interval the lateral inferior genicular vessels and nerve run forwards.

The medial and lateral ligaments prevent disruption of the joint at the sides. They are most tightly stretched in extension, and then their direction—the fibular ligament downwards and backwards, the tibial downwards and forwards—is such as to prevent rotation of the tibia laterally or of the femur medially.

Intra-Articular Ligaments (Figs. 338, 340, 341).—In addition to the capsular ligamentous formation, there are two intra-articular ligaments that stretch between the tibia and femur. These are the **cruciate ligaments**—strong, rounded bands named from the way in which they cross each other between their attachments, and distinguished as **anterior** and **posterior** from their relative positions on the tibia, from which they ascend to the sides of the intercondylar notch of the femur. The **anterior cruciate ligament** extends obliquely upwards and backwards from the rough, non-articular area in front of the intercondylar eminence of the tibia to the back part of the medial side of the lateral femoral condyle. The **posterior cruciate ligament** passes upwards and forwards on the medial side of the other; it extends

from the sloping, non-articular surface behind the eminence to the lateral side of the medial condyle. The attachments of the cruciate ligaments are such that the anterior cruciate prevents posterior displacement of the femur on the tibia and the posterior ligament prevents anterior displacement. In flexion the ligaments are less taut than in extension and they then allow a small amount of passive antero-posterior movement of the tibia on the femur if the thigh is fixed and the leg is forcibly moved. Furthermore, the ligaments become taut when the flexed leg is rotated medially and they become less taut when the leg is rotated laterally and the ligaments tend to become uncrossed.

Semilunar Cartilages (Figs. 338, 340, 341).—Two **semilunar cartilages** also are found within the joint, interposed between the femoral and tibial condyles, and help to compensate for their incongruence. The name is rather misleading because they are formed almost entirely of fibrous tissues with relatively few cartilage cells interspersed. Each is a flattened pad of crescentic form (hence the name "meniscus" formerly used) and is wedge-shaped in cross-section, with the edge of the wedge at the concave border.

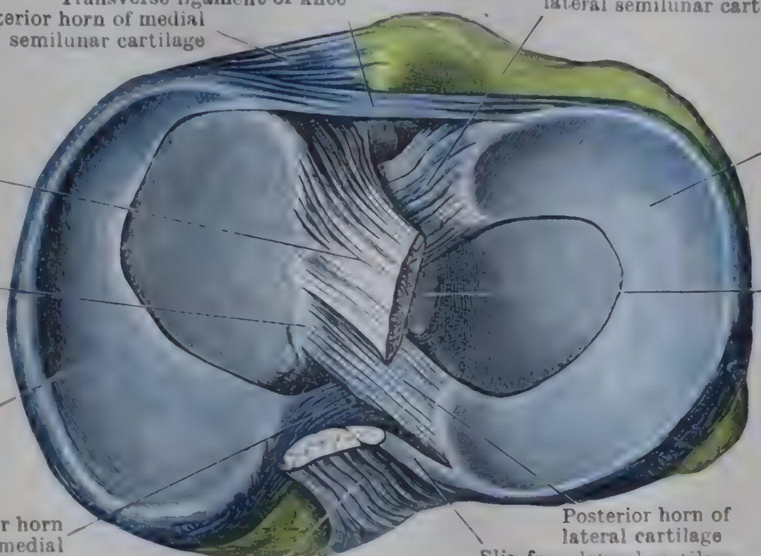

FIG. 341.—UPPER END OF TIBIA WITH SEMILUNAR CARTILAGES AND ATTACHED PORTIONS OF CRUCIATE LIGAMENTS.

The thick, convex border of each cartilage is bound down to the peripheral margin of the tibial condyle by short ligamentous fibres, and is also fused to the deep surface of the capsular ligament. This means that the **medial cartilage** is much more firmly anchored, for through its capsular attachment it is fixed to the medial ligament of the knee, whereas the **lateral cartilage** is attached only to the weak fibres which represent the capsular ligament on the lateral side of the joint and not at all to the lateral ligament of the joint. At one point—where it is crossed by the popliteus tendon—the peripheral edge of the lateral cartilage is quite free from capsular attachment.

The extremities of each cartilage are prolonged into fibrous horns which are firmly attached to the intercondylar area on the top of the tibia (Fig. 341). The *anterior horn* of the **medial semilunar cartilage** is fixed to the fore-part of this area in front of the anterior cruciate ligament; its *posterior horn* is fixed towards the back, between the posterior cruciate ligament and the posterior horn of the lateral cartilage. The *two horns* of the **lateral semilunar cartilage** are attached close together, in front of and behind the intercondylar eminence, so that this cartilage comes much nearer to completing a circle than the other one does.

The anterior parts of the two cartilages are joined by a variable fibrous band called the **transverse ligament** of the knee (Figs. 338, 341). The posterior horn of the lateral cartilage gives off a ligamentous slip which joins the posterior cruciate ligament (Figs. 340, 341); this slip may split into two, one part joining the back of the cruciate ligament and the other joining the front.

The connexion between the lateral cartilage and the posterior cruciate ligament recalls the typical lower mammalian condition where the lateral semilunar cartilage is attached posteriorly not to the tibia but to the medial femoral condyle behind the posterior cruciate ligament.

Synovial Membrane.—The synovial cavity of the knee joint is very extensive. The central part lies between the patella in front and the femur (patellar surface) and cruciate ligaments behind, and passes laterally and medially between the femoral and tibial condyles, where the cavity is partially divided into upper and lower compartments by the semilunar cartilages. In the anterior wall of this central part the synovial membrane passes from the edges of the articular surface of the patella in all directions on the deep aspect of the anterior wall of the joint. Below the patella, the membrane is carried towards the tibia over a mass of fatty, fibrous tissue, called the **infrapatellar pad of fat**, which fills up the angle between the deep surface of the patellar ligament and the front of the tibia above the tubercle. From the synovial surface of this pad a vertical, crescentic fold of

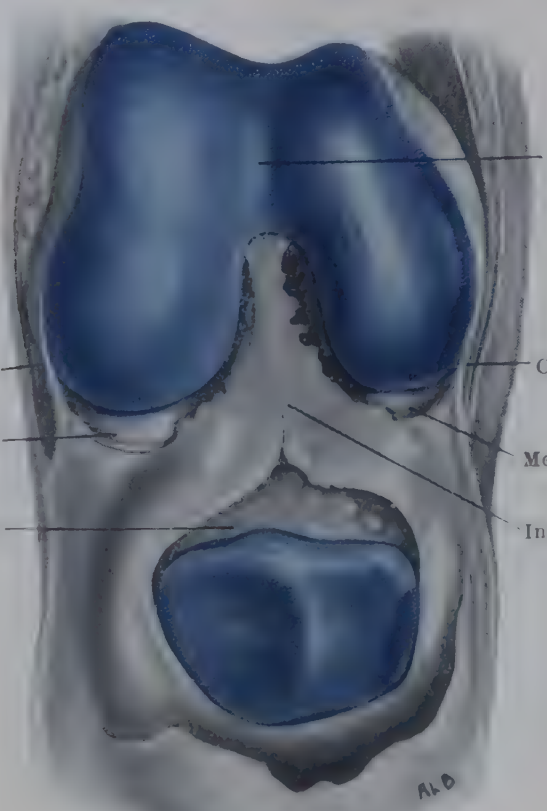

FIG. 342.—RIGHT KNEE JOINT OPENED FROM THE FRONT TO SHOW THE INFRAPATELLAR AND ALAR SYNOVIAL FOLDS.

The joint is flexed to a right angle and the patella turned down (cf. Fig. 338). Articular cartilage, *blue*.

synovial membrane, called the **infrapatellar fold**, runs towards the cruciate ligaments. Similar folds, called the **alar folds**, run horizontally across the fatty pad, one from each side of the vertical fold (Fig. 342). These synovial folds are vestiges of the original partitions that separated the three components of the cavity of the knee joint

Three recesses open off the central part of the cavity. One is median, and is called the **suprapatellar synovial pouch**. It lies above the level of the patella between the quadriceps muscle and the lower part of the shaft of the femur; it develops as a bursa separate from the joint, with which it eventually communicates. The articularis genu muscle, composed of fleshy slips that arise from the femur above the pouch, is inserted into its wall and draws it upwards in extension of the joint. The other recesses lie one behind the posterior part of each femoral condyle; in this situation the capsular ligament is overlain by the gastrocnemius muscle, and there is usually a bursa between the muscle and the ligament, especially on the medial side (Fig. 339), where the bursa sometimes communicates with the joint-cavity through an opening in the capsule. These posterior recesses are separated from each other by a thick, median septum which

projects into the joint-cavity from behind and is formed by the cruciate ligaments carrying forward a broad, vertical fold of synovial membrane which clothes them in front and at the sides.

The **synovial relations of the popliteus tendon** are important. As the tendon passes backwards from its origin deep to the lateral part of the capsular ligament, the synovial membrane is wrapped round its medial side, separating it from the edge of the lateral semilunar cartilage. When the tendon leaves the joint through the opening in the posterior part of the capsule, a *synovial pouch* is carried down on its deep surface across the back of the superior tibio-fibular joint. In some cases the cavity of this joint communicates with the bursa-like pouch which accompanies the tendon, and therefore also with the cavity of the knee joint.

Additional Bursæ.—In addition to the bursæ mentioned, numerous others are found in the vicinity of the knee joint. The more constant of these others are: the *subcutaneous prepatellar bursa*, under the skin over the lower part of the patella; the *subfascial prepatellar bursa*, between the fascial and tendinous expansions in front of the patella; the *subtendinous prepatellar bursa*, between the superficial and deep layers of the tendinous fibres that cross the patella; the *deep infrapatellar bursa*, between the upper part of the tibia and the lower part of the ligamentum patellæ, separated from the knee joint by the infrapatellar pad of fat; a bursa between the medial ligament of the knee and the overlying tendons of the sartorius, gracilis and semitendinosus; bursæ between the semimembranosus tendon and the medial ligament of the knee and between that tendon and the medial head of the gastrocnemius; and a bursa between the biceps tendon and the lateral ligament of the knee.

Nerve-Supply.—The knee joint is supplied by several branches from the **femoral** nerve and from both divisions—**medial** and **lateral popliteal**—of the sciatic nerve, and by a filament from the **obturator** nerve (see Gardner, 1948 *a*).

Movements at the Knee Joint

These are primarily **flexion** and **extension** around a transverse axis as in an ordinary hinge-joint, but with these differences: that the axis changes its position during movement owing to the different curvature of different parts of the femoral condyles, and that the end of extension or beginning of flexion is accompanied by a special **rotatory movement**. (For details of the mechanism of the knee joint, consult Goodsir, 1858.)

In voluntary flexion the leg may be moved through 130° or more from the position of full extension, but this may be increased by forced movement or by the adoption of the squatting position. In full flexion the posterior surfaces of the femoral condyles articulate with the posterior part of the articular surface of the tibia and the corresponding parts of the semilunar cartilages, but, as the joint passes from flexion to extension, if the tibia is fixed as in rising from a chair with the feet planted on the floor, the femoral condyles roll and glide forwards upon the tibia. The curvatures of the femoral condyles become progressively less as they are traced forwards and they therefore have an increasingly greater contact with the tibia as the femur passes into full extension, and for the same reason the curvatures of the semilunar cartilages tend to be opened. Just before full extension is reached, the tibial surface of the lateral femoral condyle is almost exhausted, although the anterior, oblique part of the surface on the medial condyle has still to be brought into play. While the lateral condyle completes its forward roll, the medial condyle rolls forward equally but at the same time glides backwards—until the oblique part in front is exhausted—in a horizontal arc centred in the lateral condyle, which is therefore twisted vertically and a medial rotation of the femur results. This terminal rotatory movement tightens the medial and lateral ligaments of the knee and the joint is then, as it were, 'screwed home'. In the fully extended position the other ligaments of the knee joint, most notably the posterior oblique, are also taut, and as the articular surfaces of the femur and tibia are then in maximal contact, the joint is said to be 'locked'. Before flexion can take place the rotatory movement must be undone, and this is accomplished by the action of the popliteus muscle. At the end of extension, before the terminal rotation takes place the anterior cruciate ligament is at its tightest; the rotation lessens its tension sufficiently to prevent it checking the initial opposite (*i.e.*, lateral) rotation of the femur at the beginning of flexion. These rotations of the femur on the tibia occur when the tibia is fixed during the movement at the knee. But if, as in the extension movement of kicking, the tibia as well as the femur is free to rotate, the rotation may be partly of the tibia on the femur—laterally at the end of extension, medially at the beginning of flexion.

When the body is erect, the axis of gravity of the body falls in front of a line between

the knee joints; gravity therefore tends to produce a 'locking' at the knee joint. When standing in the natural upright position, however, the knee joint is not usually 'locked' but is maintained in a position a little short of full extension. In such a position the quadriceps muscle is relaxed and the patella can be moved freely from side to side on the femur. The hamstring and gastrocnemius muscles, on the other hand, are in such a degree of contraction as just to maintain the joint in this position against the action of gravity. In reaching forwards, however, the knee joint often becomes fully extended and 'locked', and in this position also the quadriceps is relaxed.

The relation of the patella to the femur during flexion-extension movement has already been mentioned (p. 381).

In addition to the hinge movements of flexion and extension, some **rotation** of the leg around a vertical axis can take place except when the joint is fully extended. In full extension, apart from the special, small rotatory movements already described, all rotation is prevented by the tension of the medial and lateral and cruciate ligaments. Rotation is most free when the knee is flexed to about a right angle; for neither cruciate ligament is then very tight and the tension of the medial and lateral ligaments, slightly reduced by the special rotatory movement at the beginning of flexion, is further lessened during flexion by descent of their femoral attachments.

The **semilunar cartilages**, as already explained, compensate for the incongruity of the opposed femoral and tibial surfaces and, by slight movement, accommodate themselves to the differently shaped parts of the femoral condyles that rest upon them in different positions of the joint. They shift slightly forwards in extension and open out their curve under the 'flatter' anterior parts of the condyles then opposed to them. In flexion they shift backwards and curl in upon the more rounded posterior parts of the femoral condyles. The attachment of the medial cartilage to the medial ligament causes this cartilage to be drawn medially when the ligament tightens in extension. In a sudden, unguarded movement, the cartilage may at that moment be pinned between femur and tibia before its normal opening out has occurred. The pull of the medial ligament may then split the cartilage in its long axis, producing one form of the commonest derangement of the knee joint—torn medial semilunar cartilage.

According to MacConaill (1932) the semilunar cartilages play an important part in relation to efficient lubrication in the joint. No easy movement can take place between the congruent surfaces of a bearing unless they are separated by a layer of viscous fluid, which must maintain a wedge-shaped space between them; as the surfaces roll over one another they squeeze out in advance of their approximation a diminishing wedge of lubricating fluid. The necessity for this 'wedge' of lubricant is greater where, as in the knee joint, there is a considerable thrust transmitted from one joint-surface to the other, and here the interposed fibro-cartilages separate the intervening synovial fluid into two 'wedges', thereby increasing the efficiency of the mechanism. The slight mobility of the fibro-cartilages permits them to assume the proper angulation to the joint-surfaces necessary for the maintenance of the wedge-shaped synovial films.

TIBIO-FIBULAR JOINTS

The fibula is closely bound to the tibia by a joint at each end; and the shafts of the two bones are connected by an interosseous membrane.

Superior Tibio-Fibular Joint (Figs. 338, 341).—This is a small synovial joint, of plane type, between a flat, circular or oval facet on the head of the fibula and a similar facet on the tibia placed postero-laterally on the under aspect of the overhanging lateral condyle. The **capsular ligament** surrounding the joint is strengthened in front and behind by fibres directed upwards and medially from the fibula to the adjoining part of the tibia.

The tendon of the popliteus muscle is intimately related to the postero-superior aspect of the joint; and the pouch of synovial membrane prolonged under the tendon from the knee joint sometimes communicates with the synovial cavity of the tibio-fibular joint through an opening in the upper part of the capsule.

Nerve-Supply.—The superior tibio-fibular joint is supplied by twigs from the **lateral popliteal nerve** and from the branch of the **medial popliteal nerve** to the popliteus muscle.

Inferior Tibio-Fibular Joint (Figs. 343, 346).—This is a fibrous joint. The rough, triangular, opposed surfaces of the bones are united by a strong **inter-**

osseous ligament. In addition, the joint is strengthened in front and behind by longer bands called the **anterior** and **posterior inferior tibio-fibular ligaments.** These bands stretch from the lower border of the tibia, in front and behind, to the back and front of the distal end of the fibula, each inclined laterally and downwards. Under cover of the posterior ligament there is a longer band, called the **transverse tibio-fibular ligament**, which is attached to the whole length of the posterior edge of the inferior surface of the tibia and to the upper end of the malleolar fossa on the fibula. This band closes the posterior angle

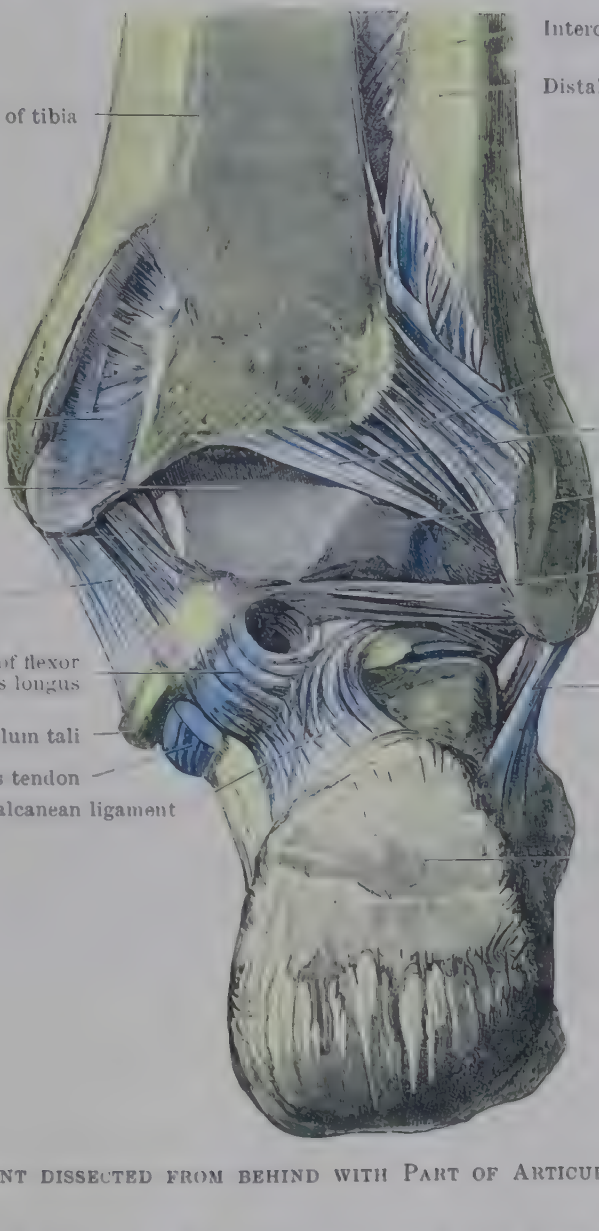

FIG. 343.—ANKLE JOINT DISSECTED FROM BEHIND WITH PART OF ARTICULAR CAPSULE REMOVED.

between the tibia and fibula and articulates with the bevelled posterior half of the lateral border of the trochlea tali (Fig. 343).

A recess of the cavity of the ankle joint usually extends upwards between the tibia and fibula for about a quarter of an inch. It is blocked above by the base of the interosseous ligament and is occupied by a fold of synovial membrane of the ankle joint. Sometimes the articular cartilage on the lower ends of the tibia and fibula extends upwards for a little way on the walls of this recess.

Nerve-Supply.—The inferior tibio-fibular joint is supplied by twigs from the **anterior** and **posterior tibial nerves.**

Interosseous Membrane.—The interosseous membrane of the leg is tightly stretched between the interosseous borders of the two bones: its fibres in great part run downwards and laterally from tibia to fibula. The membrane reaches up to the under aspect of the superior joint and downwards to blend with the upper edge of the interosseous ligament of the inferior joint. There is an

oval aperture near the upper end of the membrane through which pass the anterior tibial vessels (Fig. 338), and a smaller one at the lower end for the perforating branch of the peroneal artery (Fig. 343).

Movement at the tibio-fibular joints is slight and entirely passive. It is occasioned by changes in the ankle joint, with which it will be described (p. 392).

ANKLE JOINT

The **ankle joint** is a synovial joint of typical hinge pattern. The lower ends of the tibia and fibula provide a socket in which the upper part of the talus rocks around a transverse axis. The only special feature of the hinge is an arrangement whereby the sides of the socket come to exercise a positive 'grip' upon the moving member of the joint as an aid to increased stability.

Articular Surfaces.—The **proximal articular surface** provides the socket (Fig. 344). It is formed by the cartilage-covered areas on the lower ends of the leg bones. The roof of the socket, wider in front than behind, is the *distal surface of the tibia,* concave from before backwards and slightly convex from side to side. The medial wall is the *lateral surface of the medial malleolus,* the cartilage here being continuous with that on the roof at a rounded angle. The lateral wall is the triangular facet on the fore part of the *medial side of the lateral malleolus.* The angle between this wall and the roof corresponds to the narrow cleft between the tibia and fibula distal to the interosseous ligament between these bones; but, posteriorly, this angle is filled up by the *transverse tibio-fibular ligament.*

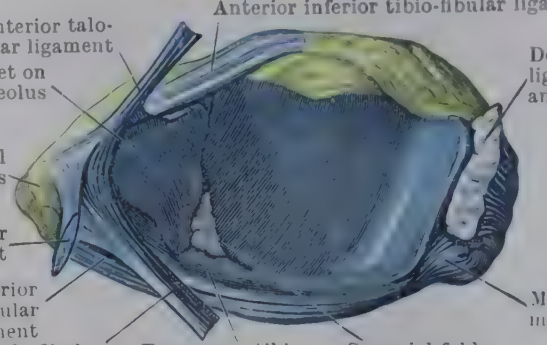

Fig. 344.—Articular Surfaces of Tibia and Fibula which are opposed to the Talus in the Ankle Joint.

The **distal articular surface** is formed entirely by the upper part of the body of the talus—the *trochlea tali*—which is shaped like the upper part of a short cylinder placed transversely. The cylinder is square-cut medially, but obliquely cut laterally, in such a way that the cylindrical surface is broader in front than behind. This surface articulates with the distal surface of the tibia—the roof of the socket—which also is broader in front. A shallow, wide antero-posterior groove on the upper trochlear surface corresponds to the convexity on the tibial surface. The cartilage on top of the trochlea is continued on to its sides—the 'ends' of the cylinder. The medial articular surface or 'end' is vertically set, and is shaped like a comma laid on its side, tail backwards: it is opposed to the medial malleolar wall of the proximal articular surface. The lateral articular area or 'end' of the trochlea is triangular, corresponding to the opposed facet on the lateral malleolus; it is obliquely set, inclining laterally below and medially behind. The angle between the upper and lateral surfaces of the trochlea is bevelled off posteriorly where it articulates with the transverse tibio-fibular ligament (Fig. 343).

Capsular Ligament.—The capsular ligament surrounds the joint. As is usual in a hinge-joint, it is weak in front and behind but is strengthened at the sides by special medial and lateral ligaments.

The **anterior** and **posterior ligaments of the ankle** are membranous and weak. They are attached proximally to the anterior and posterior borders of the lower end of the tibia, and distally to the upper surface of the talus in front of and behind the articular area.

Medial and Lateral Ligaments.—These ligaments have in common an upper attachment to the corresponding malleolus, a middle band descending to the

calcaneum, and anterior and posterior bands to the talus; the medial ligament has other parts in addition. The medial ligament is fused with the medial part of the capsule; the anterior and posterior bands of the lateral ligament are fused with the lateral part of the capsule, but the middle band is not.

In the **lateral ligament** (Figs. 343, 346) the three bands are quite distinct from one another. The middle one—the **calcaneo-fibular ligament**—runs from in front of the tip of the lateral malleolus downwards and slightly backwards to the middle of the lateral surface of the calcaneum, a little above and behind the peroneal tubercle. The **anterior talo-fibular ligament** runs from the anterior border of the lateral malleolus forwards and medially to the neck of the talus. The **posterior talo-fibular ligament** is attached to the fibula at the bottom of the malleolar fossa and passes medially and slightly backwards to the upper surface of the posterior tubercle of the talus.

The **medial ligament** (Figs. 343, 345) is made up of several bands which, however, are differentiated only by their distal attachments. They are fused in a

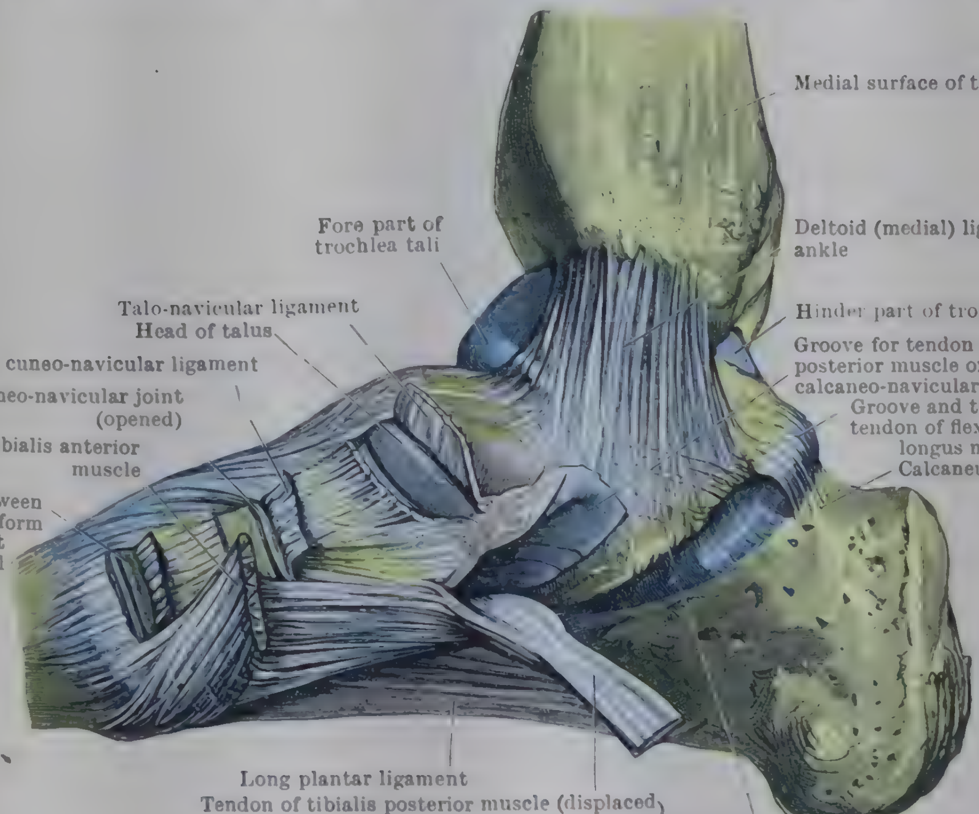

FIG. 345.—ANKLE JOINT AND TARSAL JOINTS FROM THE TIBIAL SIDE.

strong ligamentous formation which, on account of its triangular shape, is usually called the **deltoid ligament**. The apical part of this structure is attached to the pit on the lower border of the medial malleolus. Its thick base has a continuous attachment—to the rounded upper and medial part of the navicular bone (*tibio-navicular fibres*), to the medial part of the neck of the talus (*anterior talo-tibial fibres*), to the plantar calcaneo-navicular ligament and the medial border of the sustentaculum tali (*calcaneo-tibial fibres*), and to the medial side of the talus, under the "tail" of the comma-shaped facet (*posterior talo-tibial fibres*). The talo-tibial fibres are on a deeper plane than the others; the tibio-navicular and calcaneo-tibial portions are continuous over the superficial aspect of the anterior talo-tibial fibres.

Synovial Membrane.—The synovial membrane of the joint lines the capsular ligament and covers well-marked fatty pads that lie in relation to the anterior and posterior ligaments. A synovial fold (Fig. 344) occupies the cleft between the tibia and fibula below the base of the interosseous tibio-fibular ligament; the sides of this cleft may be covered in part by an extension of the articular cartilage on the tibia and fibula.

Nerve-Supply.—The ankle joint is supplied by twigs from the **anterior** and **posterior tibial** nerves.

Movements at the Ankle Joint

Movement takes place around a transverse axis on a level with the tip of the lateral malleolus and slightly below the level of the medial malleolus. In the normal, standing position the foot makes a right angle with the leg. Considerable confusion has resulted in the past from the use of the terms 'flexion' and 'extension' in describing the movements that occur at the ankle joint, and for that reason the terms **'dorsi-flexion'** and **'plantar-flexion'** are to be preferred. In *dorsi-flexion* the foot is drawn upwards, the trochlea tali turning backwards in its socket; movement in the opposite direction is *plantar-flexion*. The range of plantar-flexion is greater than that of dorsi-flexion but there is considerable individual variation in the extent of the movements.

In **dorsi-flexion**, the broader, anterior part of the trochlea tali is forced back into the

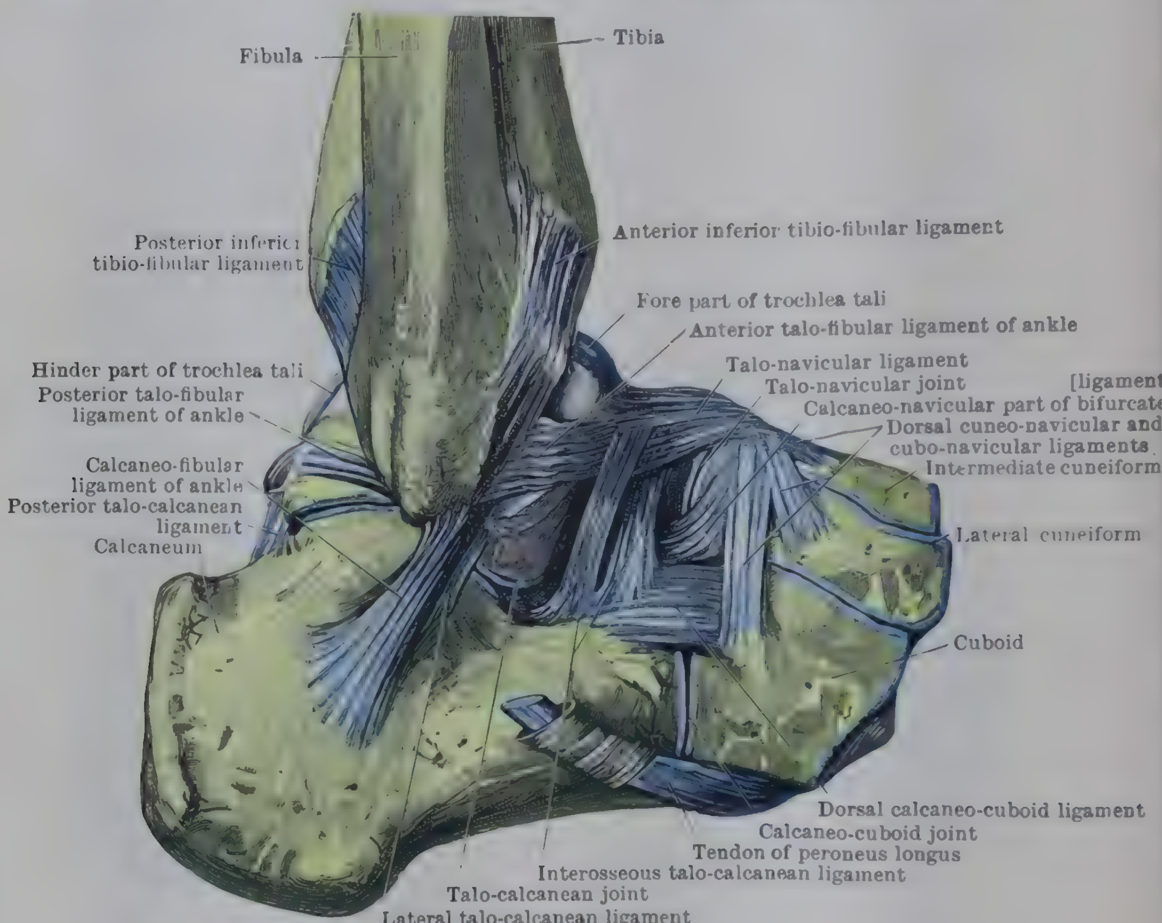

FIG. 346.—LIGAMENTS ON LATERAL SIDE OF ANKLE JOINT AND ON DORSUM OF TARSUS.

narrower, posterior part of the tibio-fibular socket; this causes slight separation of the tibia and fibula, with increased tension of the interosseous and transverse tibio-fibular ligaments. The talus is then most securely held between the malleoli. In **plantar-flexion,** as the narrower part of the trochlea turns forward into the broader part of the socket, the malleoli spring together again, so retaining up to a point their grasp upon the sides of the talus; but in full plantar-flexion a little side-play can be demonstrated in the joint. The wedge-shaped form of the joint-surfaces helps to prevent backward displacement of the foot on the leg when coming to a sudden stop in running or jumping. The maintenance of this positive grasp upon the talus is the function of the *inferior tibio-fibular joint*, the strong ligaments of which provide the spring mechanism involved. The *superior tibio-fibular joint* permits slight gliding movement in association with the displacement of the lower ends of the bones of the leg.

When the body is erect, muscular effort, mainly soleus and gastrocnemius, is needed to prevent falling forwards, owing to the incidence of body-weight in front of the ankle joints. But this effect of gravity is minimized in so far as the feet are usually turned a little laterally, and the axes of the two ankle joints are inclined to each other so as to make an angle pointing forwards.

The ankle joint is strongly supported by the tendons of the muscles of the leg which

descend in close relation to it. In front, the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius pass over the anterior ligament in that order medio-laterally; posteriorly and medially are the tibialis posterior and flexor digitorum longus tendons; posteriorly is the tendon of the flexor hallucis longus; and posteriorly and laterally are the tendons of the peroneus longus and peroneus brevis.

JOINTS OF THE FOOT

The joints between the tarsal bones, between metatarsal bases, and between tarsus and metatarsus are intricate in their arrangement and several of them are complicated in their movements. The significance of the structure of these joints and of the movements that occur at them can only be understood in the light of the architecture of the foot as a whole. The account of the foot in this text is, of necessity, curtailed, and for further study the reader is advised to consult the works of Wood Jones (1944 *a*) and Morton (1937).

Arches of the Foot

The human foot is a structure that is highly specialized for the support of the body in the erect posture and for the propulsion of it during movement. To subserve these functions efficiently it must be able to adapt itself to the ground in many different positions and must be capable of absorbing mechanical shocks. This is achieved by the presence of a series of resilient arches, convex above, which become slightly flattened by the incidence of the body-weight in standing or during progression, and resume their original curvature when the pressure on them is relieved. The arches are formed by the tarsal and metatarsal bones, and are disposed both longitudinally (Pl. XXVII, p. 320) and transversely (Fig. 294, p. 319).

The **longitudinal arch** is higher on the medial side than on the lateral, and on account of the arrangement of the tarsal and metatarsal bones in two columns (p. 322) it is customarily described in two parts called the **lateral** and **medial arches**. The posterior part of the calcaneum forms a common posterior pillar for both arches (Pl. XXXVI, p. 383). The **lateral arch** proceeds from this through the anterior part of the calcaneum, which forms a joint with the cuboid bone; the arch is continued through the cuboid into the lateral two metatarsal bones, which articulate with the cuboid. This arch is a very low one and receives the weight of the body through the talus at the talo-calcanean joint. The **medial arch** is higher and more important. The posterior pillar is continued into the sustentaculum tali, and the summit of the arch is then formed by the head of the talus placed above and between the sustentaculum tali and the navicular bone. The anterior pillar is formed by the navicular bone, the three cuneiform bones, and the medial three metatarsal bones.

The **transverse arch** is placed across the anterior part of the tarsus and the posterior part of the metatarsus, and is best marked along the line of the tarso-metatarsal joints. The arch is gradually lost as the metatarsals are traced forwards towards their heads which are all in functional contact with the ground.

For the preservation of these arches the integrity of the tarsal, tarso-metatarsal, and intermetatarsal joints is important, for at them the bones are held in their proper relationship as segments of the arches. For this purpose certain ligaments of the joints are much more important than others. The important ligaments are specially strengthened to resist undue yielding of the joints and consequent collapse of the arches; they are therefore found on the plantar aspect of the joints (that is, on the concave side of the arches) or, especially in the joints of the transverse arch, in interosseous positions. But it must be emphasized once more that unsupported ligaments will, in time, stretch under continuous strain, and the arches of the foot are in every case supported by muscles as well.

The body-weight is transmitted from the bones of the leg to the longitudinal arches through the talus. The talus forms two joints with the rest of the tarsus (Fig. 347), each being more particularly concerned in the transference of weight to one of these arches. The more posterior joint—the *talo-calcanean*—is specially associated

with the lateral arch and at the more anterior joint—the *talo-calcaneo-navicular*—the weight is transmitted to the medial arch. At both joints the talus rests on the calcaneum, and between the joints there is the canalis tarsi (see below) to the walls of which parts of the capsular ligaments of the two joints are attached.

INTERTARSAL JOINTS

Talo-Calcanean Joint (Figs. 346, 347).—This joint is formed between the facet on the under surface of the body of the talus and the posterior facet on the upper surface of the calcaneum; each facet is approximately cylindrical in curvature—that on the talus concave, the other convex.

The **capsular ligament** surrounding the joint is made up of short fibres attached close to the articular surfaces all round. Slightly stronger portions, specially named

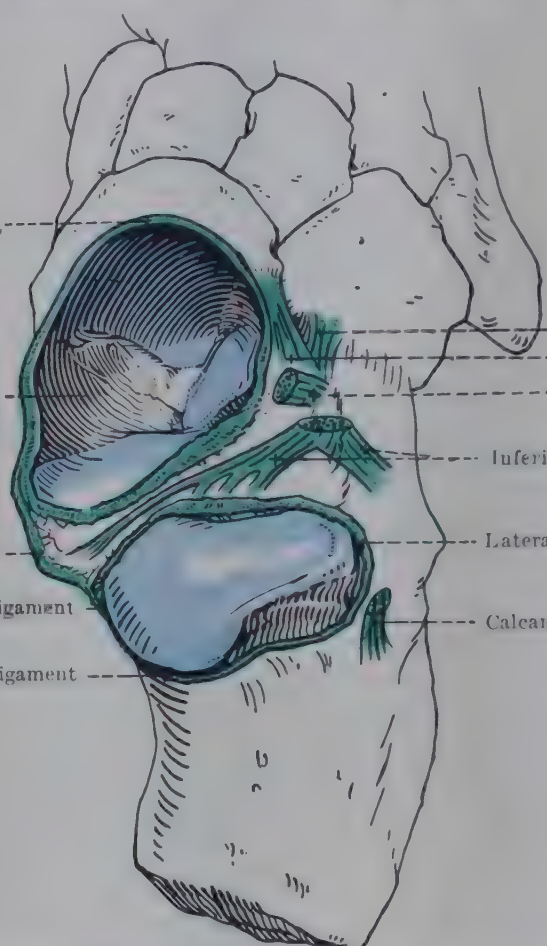

FIG. 347.—LIGAMENTS AND INFERIOR ARTICULAR SURFACES OF TALO-CALCANEAN AND TALO-CALCANEO-NAVICULAR JOINTS (seen from above after removal of the Talus).

the *posterior*, *medial*, and *lateral talo-calcanean ligaments*, are situated in corresponding parts of the capsule.

The anterior part of the capsular ligament is thin and is attached to the roof and floor of the canalis tarsi. The *canalis tarsi* is a narrow tunnel which is bounded by the grooves on the talus and the calcaneum and runs obliquely forwards and laterally in front of the articular facets of this joint; at its antero-lateral end the canal expands to form the *sinus tarsi*. In addition to the anterior ligament of the talo-calcanean joint the canalis tarsi gives attachment to the posterior part of the capsule of the talo-calcaneo-navicular joint (p. 396), and these two ligaments together constitute the *interosseous talo-calcanean ligament* which forms a weak connexion between the two bones. Between the two parts of the interosseous ligament lies the deep extension of the lateral limb of the inferior extensor retinaculum which is attached to the floor of the canalis tarsi (Barclay Smith, 1896) (Figs. 347, 349). Lying in the sinus tarsi is a strong discrete band that is attached above to the neck of the talus and below to the calcaneum; this ligament has been termed by Wood Jones (1944 *b*) the *ligamentum cervicis*, and it is of importance because it forms the only strong

ligamentous bond between the two bones and because movement of the bones occurs around it in inversion and eversion (Fig. 347).

The calcanean parts of the medial and lateral ligaments of the ankle joint act as accessory ligaments of the talo-calcanean joint.

The articular capsule is lined with **synovial membrane**; the synovial cavity does not communicate with any other joint (Fig. 349).

Talo-Calcaneo-Navicular Joint (Fig. 347).—At this joint a large facet on the head and the lower surface of the neck of the talus articulates with a deep and extensive socket that is formed partly by bone and partly by ligaments. The anterior part of

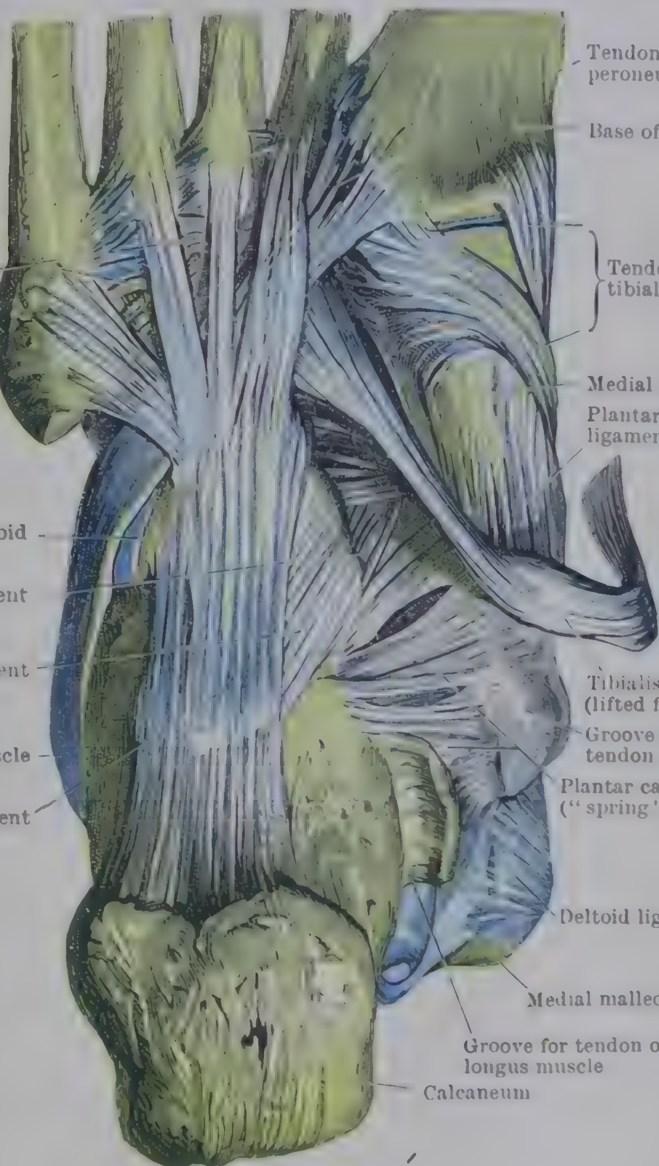

FIG. 348.—PLANTAR ASPECT OF TARSAL AND TARSO-METATARSAL JOINTS.

the **socket** is formed by the concave articular surface of the navicular bone, and the posterior part by the upper surface of the sustentaculum tali and a facet that is usually present on the upper surface of the calcaneum antero-lateral to the sustentaculum. Between the navicular and the calcaneal articular surfaces there is an appreciable interval that is greatest in its medial part. The medial part of this interval is occupied by the *plantar calcaneo-navicular ligament* and the much smaller lateral part by the *calcaneo-navicular* fibres of the *bifurcated ligament*.

The **plantar calcaneo-navicular ligament** articulates with the medial and inferior surfaces of the head of the talus and is a fibro-cartilaginous band of great strength (Figs. 345, 347, 348). It is attached behind to the anterior end and medial border of the sustentaculum tali; in front it spreads out on to the plantar, the medial, and the adjacent part of the upper surface of the navicular bone; its medial part is joined and supported by fibres of the deltoid ligament of the ankle joint. The tendon of the tibialis posterior muscle turns down into the sole under the ligament and acts as a

sling for it and for the head of the talus (Figs. 345, 348). The tension of the plantar calcaneo-navicular ligament, supported by the tibialis posterior muscle, resists the tendency of the weight of the body to drive the head of the talus downwards between the bones which it braces together, and the resilience it imparts to the medial arch is recognized in its common appellation—the *spring ligament*.

The **calcaneo-navicular part of the bifurcated ligament** completes the socket on the lateral side. It is composed of short fibres that pass from the upper surface of the anterior end of the calcaneum to the adjacent lateral surface of the navicular bone (Figs. 346, 347). Sometimes the part of the articular head of the talus in contact with this band is faceted by it.

The rounded **head of the talus** has a continuous covering of articular cartilage that is continued on to the under surface of the neck and the body. This articular surface conforms in shape to the socket and is marked off by faint ridges into a facet for the navicular bone in front, one for the sustentaculum tali below, and between these, a third for the plantar calcaneo-navicular ligament.

Capsule.—On account of the extensive form of the bony and ligamentous socket a true capsular ligament is present only on the posterior and the dorsal aspects of the joint.

The posterior part of the capsular ligament is relatively weak. It is to be regarded as the anterior component of the interosseous ligament (p. 394).

The capsular ligament is completed round the dorsal aspect of the joint, between the two calcaneo-navicular bands, by a thin sheet, called the **talo-navicular ligament** (Figs. 345, 347), which extends from the neck of the talus to the dorsal surface of the navicular bone. It blends medially with the anterior fibres of the deltoid ligament that go to the navicular bone.

The **synovial cavity** of this joint makes no communications with neighbouring articulations (Fig. 349).

Calcaneo-Cuboid Joint (Figs. 346, 347).—The calcaneo-cuboid joint is the highest point in the lateral longitudinal arch, which, as already mentioned, is formed by the calcaneum, the cuboid bone, and the lateral two metatarsal bones. The body-weight falls on this arch behind its summit, at the talo-calcanean joint, and the strain is most felt at the joint immediately in front of the calcaneum—the calcaneo-cuboid joint. This joint, like the talo-calcaneo-navicular joint at the summit of the medial arch, must therefore be specially reinforced on its under aspect, and here are placed the strong bands called the long and short plantar ligaments. In addition, the tendon of the peroneus longus, passing under the cuboid bone in front of the articulation, acts as a sling after the manner of the tibialis posterior tendon under the medial arch.

The **articular facets** on the opposed surfaces of the calcaneum and cuboid bone are quadrilateral and reciprocally concavo-convex.

Capsule.—An articular capsule completely surrounds the joint, and certain special ligaments are to be described in connection with it.

Applied to the dorso-medial aspect of the joint is the **calcaneo-cuboid part of the bifurcated ligament**, which springs from the upper and fore part of the calcaneum in common with the calcaneo-navicular part of the ligament, and is attached to the adjacent dorso-medial angle of the cuboid bone (Fig. 347).

On the plantar aspect of the joint are two special ligaments, superficial and deep, separated by areolar tissue (Fig. 348). The deep one is the **short plantar ligament**. It is a broad band of short fibres immediately applied to the joint; it runs from the anterior part of the inferior surface of the calcaneum to the cuboid bone behind the ridge that bounds the peroneal groove. The superficial and much longer band is the **long plantar ligament**. It arises from the whole length of the rounded, keel-like ridge on the plantar surface of the calcaneum and stretches to the ridge on the cuboid bone, to which its deep fibres are attached. The more superficial fibres pass on over the peroneus longus tendon to the bases of at least the lateral three metatarsal bones. This ligament therefore stretches under nearly the whole length of the lateral arch and strengthens the plantar aspect of all the joints in the arch. As this arch has little height, a long band of this nature stretching, like a tie-beam, from

pillar to pillar is more effective in preserving the arch than short ties between adjacent segments of the arch.

Synovial membrane covers the inside of the capsular ligament. The joint cavity is self-contained, making no communication with any other (Fig. 349).

Transverse Tarsal Joint. — The talo-calcaneo-navicular joint and the calcaneo-cuboid joint, although they do not communicate with each other, together extend right across the tarsus in an irregular transverse plane, between the talus and calcaneum behind and the navicular and cuboid bones in front (Fig. 349). This articular plane is termed the *transverse tarsal joint.*

The anterior two bones involved—navicular and cuboid—are bound together by **dorsal** (Fig. 346) and **plantar cubo-navicular ligaments** between adjacent parts of the corresponding surfaces, and by an **interosseous cubo-navicular ligament** between their contiguous sides (Fig. 349). Sometimes there is a synovial cavity amidst these ligaments, between cartilage-covered facets on the bones, which opens anteriorly into the cuneo-navicular joint.

The remaining intertarsal joints—*cuneo-navicular, intercuneiform*, and *cuneo-cuboid*—frequently share a common synovial cavity, but the cuneo-cuboid may have a cavity separate from that of the others. The intercuneiform and cuneo-cuboid joints are placed between the tarsal segments of the transverse arch of the foot.

Cuneo-Navicular Joint.—This is the joint between the convex anterior surface of the navicular bone and the concave articular surface provided by the posterior ends of the three cuneiform bones. The navicular **articular cartilage** (Fig. 349) is faceted by the opposed cuneiform bones, and is continued on to the medial wall of the cavity of the cubo-navicular joint when such is present.

The joint is surrounded by a **capsular ligament** distinct on all sides except laterally, towards the cuboid bone, where the joint may communicate with the cuneo-cuboid joint and always with a cubo-navicular joint when present. Distally, the joint-cavity forms recesses between the cuneiform bones (Fig. 349). In the upper and medial parts of the capsule there are short bands, relatively weak, passing from the navicular to each cuneiform bone ; these are the **dorsal cuneo-navicular ligaments** (Figs. 345, 346). Similar stronger bands on the under aspect of the joint, inseparable from slips of insertion of the tibialis posterior tendon, constitute the **plantar cuneo-navicular ligaments.**

Intercuneiform Joints.—At the intercuneiform joints the three cuneiform bones are bound together by weak, transverse **dorsal ligaments** and much stronger **interosseous** and **plantar ligaments**. The last two limit, in front, small joint-cavities between articular facets placed behind and above on the contiguous surfaces of the bones. These cavities are continued from that of the cuneo-navicular joint (Fig. 349), and usually the medial intercuneiform joint extends forwards over the interosseous ligament to open into the middle tarso-metatarsal joint.

Cuneo-Cuboid Joint.—This is a joint between oval or circular facets on the lateral cuneiform bone and the cuboid bone. It is surrounded by a weak **dorsal cuneo-cuboid ligament** between the dorsal surfaces of the bones, by a **plantar cuneo-cuboid ligament** (Fig. 348) between their adjacent plantar borders, and by a strong **interosseous cuneo-cuboid ligament** (Fig. 349) which closes the cavity anteriorly. Posteriorly, the joint may or may not open into the cuneo-navicular joint.

The cuboid and cuneiform bones, placed side by side across the distal part of the tarsus, form the tarsal part of the *transverse arch of the foot*. The strong interosseous and plantar intercuneiform and cuneo-cuboid ligaments maintain the segments of the arch in position, and additional strength is obtained from the peroneus longus tendon as it passes across the foot between the two pillars of the arch (Fig. 348).

Nerve-Supply.—The tarsal joints are supplied on the dorsal aspect by the **anterior tibial** nerve, and on the plantar aspect by the **medial** and **lateral plantar** nerves.

Movements in the Tarsus

The movements of dorsi-flexion and plantar-flexion occur at the ankle joint and have been described on page 392. In these movements the talus rotates in the tibio-fibular socket and the tarsus and metatarsus move as a unit. In the other movements of the foot the calcaneum and navicular, carrying with them the more distal tarsal bones (between which movements also occur), move on the talus.

The movements that occur at the tarsal joints produce, in summation, the characteristic changes of inversion and eversion.

In **inversion**, the foot is adducted and twisted so that the medial border is raised and the lateral border depressed until the sole is turned slightly medially (Pl. XXXVI, p. 383, Fig. 1). Inversion is usually accompanied by plantar-flexion, and the composite movement is sometimes referred to as *supination*. In **eversion**, the foot is abducted, the lateral border is raised and the medial border lowered, so that the sole is turned slightly laterally. Eversion is usually accompanied by dorsi-flexion and the total movement is sometimes referred to as *pronation*. Inversion and eversion occur principally at the talo-calcanean and talo-calcaneo-navicular joints, and Inkster (1938) has shown that fixation of the calcaneum greatly limits these movements. The talo-calcanean and talo-calcaneo-navicular joints have a common axis of movement which runs obliquely forwards, upwards and medially through the sinus tarsi, in the region of the ligamentum cervicis (p. 394), and the complicated movements that occur at these joints have been described in detail by Manter (1941). Movement occurs also at the other tarsal and tarso-metatarsal joints during inversion and eversion, but this diminishes in amount in a proximo-distal direction (MacConnaill, 1945).

TARSO-METATARSAL AND INTERMETATARSAL JOINTS

Tarso-Metatarsal Joints (Fig. 349).—The anterior members of the tarsus —the cuboid and three cuneiform bones—articulate with the bases of the metatarsal bones along an irregular line which "presents the outline of an indented parapet both on its tarsal and its metatarsal aspects".

The *first* metatarsal bone articulates only with the anterior surface of the

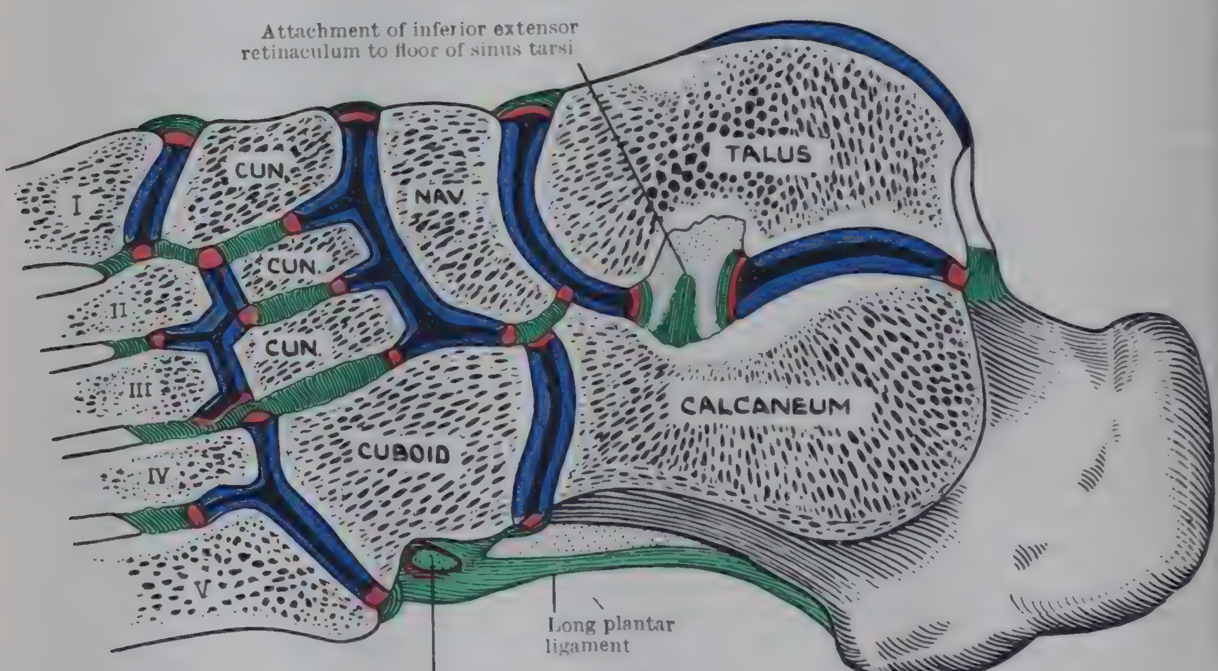

Fig. 349.—Oblique Section of Left Foot to show the Synovial Cavities of the Tarsal and Tarso-Metatarsal Joints.

The foot was in strong inversion when sectioned and does not reveal the communication that exists between the cuneo-navicular and intermediate tarso-metatarsal joints. An unusually large cubo-navicular joint-cavity was present. Articular cartilage, *blue*; synovial membrane, *pink*; ligaments and tendon, *green*.

medial cuneiform bone. The *second* metatarsal articulates in a socket with all three cuneiform bones—the lateral side of the medial bone, the anterior end of the intermediate, and the medial side of the lateral bone. The *third* metatarsal articulates with the lateral cuneiform bone. The *fourth* metatarsal articulates with the cuboid and to a small extent with the lateral cuneiform bone. The *fifth* metatarsal articulates with the cuboid bone only.

The articulations are all synovial joints of gliding type, closed over by dorsal

and plantar ligaments. In addition there are certain interosseous ligaments which delimit three separate synovial cavities.

The **dorsal tarso-metatarsal ligaments** are short slips that pass between the adjoining dorsal surfaces of the tarsal and metatarsal bones, each metatarsal bone receiving a slip from each tarsal bone with which it articulates.

The **plantar tarso-metatarsal ligaments** are similar bands on the under aspect of the joints, but are less regularly disposed. Those for the medial two metatarsal bones are the strongest, but the lateral tarso-metatarsal joints are strengthened underneath by fibres from the long plantar ligament. The tarso-metatarsal joint of the big toe is strengthened below by the insertion into the articulating bones of the tibialis anterior medially and the peroneus longus laterally. Slips from the tibialis posterior tendon are applied to the under aspect of the joints of the middle three metatarsal bones. (See Fig. 348.)

Two strong **interosseous tarso-metatarsal ligaments** are always present (Fig. 349). One passes from the anterior and lateral part of the medial cuneiform bone to the contiguous medial side of the second metatarsal base. The other passes from the antero-lateral angle of the lateral cuneiform to the adjacent medial surface of the fourth metatarsal base. These two ligaments separate **three tarso-metatarsal synovial cavities.**

The **medial** cavity is entirely confined to the joint between the first metatarsal and medial cuneiform bones. The **intermediate** cavity separates the second and third metatarsals from the intermediate and lateral cuneiform bones; this cavity is prolonged forwards for a little way between the second and third, and third and fourth metatarsal bases; posteriorly, it usually communicates, between the medial and intermediate cuneiform bones, with the cuneo-navicular joint. The **lateral** joint-cavity separates the cuboid from the fourth and fifth metatarsal bones, and is prolonged forwards between these two metatarsal bases. Sometimes the intermediate cavity is partially divided by a third interosseous ligament that passes between the adjacent angles of the lateral cuneiform and second metatarsal bones; this band was absent in the specimen drawn in Fig. 349.

The indented nature of the tarso-metatarsal joint line adds strength to the *transverse arch* of the foot. This arch is built of two spans placed side by side, the one formed by the cuboid and cuneiform bones, the other formed by the metatarsal bases. These two spans are interlocked by the indentations and tied together by the ligaments of the tarso-metatarsal joints.

Intermetatarsal Joints.—The intermetatarsal joints are small synovial joints between cartilage-covered facets on the contiguous sides of the bases of the lateral four metatarsal bones. The joint-cavities (Fig. 349) are prolonged from the tarso-metatarsal cavities—that between the fourth and fifth bones from the lateral tarso-metatarsal joint, those on each side of the third bone from the intermediate joint.

Above, below, and in front, the little joints are closed by **dorsal, plantar**, and **interosseous intermetatarsal ligaments**, composed of short, transverse fibres between corresponding surfaces of the bases of the metatarsal bones. The interosseous ligaments are very strong, and play an important part in holding together the metatarsal bases as segments of the metatarsal span of the transverse arch of the foot.

The first metatarsal bone is connected to the second by interosseous fibres only. Sometimes a bursal sac is formed amidst these fibres, between indistinct facets on the bones; its cavity may communicate with the medial tarso-metatarsal joint.

Nerve-Supply.—The tarso-metatarsal and intermetatarsal joints are supplied by twigs from the anterior tibial and the lateral and medial plantar nerves.

Metatarsal Movements.—The interlocking of the bones at the tarso-metatarsal joints and the intermetatarsal interosseous ligaments preclude, except at the first tarso-metatarsal joint, anything beyond small gliding movements of the metatarsal bones by which they contribute very slightly to the inversion and eversion movements of the foot. The fourth and, more particularly, the fifth, owing to the oblique line of their basal joints, have a slight capability of flexion accompanied by adduction. At the first tarso-metatarsal joint a slight rotary movement may occur in addition to a limited amount of up and down gliding. Such movements of the first metatarsal take place during the adaption of the foot to the ground in varying degrees of inversion and eversion.

METATARSO-PHALANGEAL AND INTERPHALANGEAL JOINTS

Metatarso-Phalangeal Joints.—These joints closely resemble the metacarpo-phalangeal joints in the shape of the articular surfaces and the disposition of the

ligaments. At the base of each toe the cupped posterior end of the proximal phalanx is applied to the rounded metatarsal head.

The **capsular ligament**, lined with synovial membrane, is formed at the sides by strong, fan-shaped **collateral ligaments** attached to neighbouring parts of the bones, and, on the plantar aspect, by a thick, pad-like **plantar ligament**; dorsally, the capsule is completed by an expansion of the extensor tendon.

The plantar ligament is grooved by the flexor tendons. In the big toe this ligament has two fairly large sesamoid bones developed in it; they are covered with cartilage on their upper surfaces, which articulate with grooves scored on the under surface of the head of the first metatarsal bone. The plantar ligaments of all the joints are connected by the **deep transverse ligaments of the sole,** which are arranged like the deep transverse ligaments of the palm, except that in the hand this connexion does not involve the joint of the thumb, whereas in the foot the joint of the big toe is linked up with the others.

Nerve-Supply.—The metatarso-phalangeal joints are supplied on their **dorsal** and **plantar** aspects by the corresponding **digital** nerves.

Movements.—The movements of these condyloid joints are similar to the movements at the corresponding joints in the hand but are less extensive. In the foot, however, **extension** of the proximal phalanges can be carried beyond the line of the metatarsal bones; and **abduction** and **adduction** are centred on the second toe because of the slightly different arrangement of the interossei muscles. In **flexion** the toes are at the same time drawn together; in **extension** they are spread apart and inclined slightly in the lateral direction.

Interphalangeal Joints.—The interphalangeal joints also are similar to the corresponding joints in the hand. At each articulation the proximal bone presents a double convexity within the joint and the distal bone a double concavity.

Collateral ligaments at the sides, a thick **plantar ligament** and the expansion of the extensor tendon dorsally complete the **articular capsule**, lined with synovial membrane. The second interphalangeal joint of the little toe is often obliterated by synostosis.

Nerve-Supply.—These joints are supplied by the **dorsal** and **plantar digital** nerves.

Movements.—These are hinge-joints. Movement is limited to **flexion** towards the sole of the foot and **extension** in the opposite direction, around a transverse axis.

Mechanism of the Foot

The foot is specialized to support the body in the erect position, alike in standing and in progression. Its skeletal parts are arranged in arches, longitudinal and transverse, in the manner already described. The presence of the joints in the arches introduces a spring mechanism, so that the arches resemble the half-elliptical springs of a carriage. They yield slightly when weight is put upon them, and recoil when it is removed (Fig. 350). The medial longitudinal arch is higher than the lateral and has more joints, which give to the corresponding part of the foot a greater resilience. This is in accordance with the propulsive function of the medial part of the foot in walking and running, whereas the lateral part of the foot is more concerned with the actual static support of the body. The arched form of the foot is established in early foetal life, but the height of the arches shows considerable individual variation.

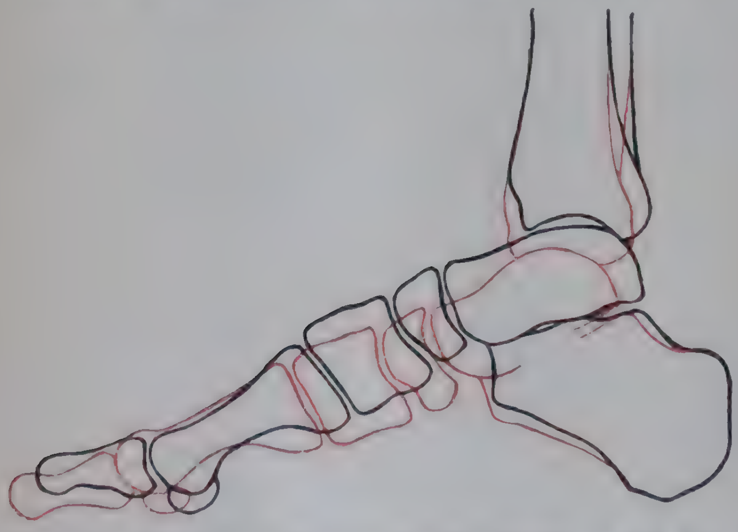

FIG. 350.—TRACING OF RADIOGRAPHS (Pl. XXXVI, p. 383, Figs. **2** and **3**). Superimposed to show the position of the Longitudinal Arch of the Foot during Relaxation (red) and Contraction (black) of the muscles. (See also Fig. 472, Footprints **2** and **3**.)

Attention has been drawn to the ligaments which specially support the arches,

and to the prime importance of the muscles in safeguarding the ligaments from over-stretching. The tendon of the tibialis posterior muscle passes as a sling below the summit of the medial arch, and, because of the insertion of that tendon on the plantar aspect of nearly all the tarsal and metatarsal bones, the contraction of the muscle must tend to increase the general concavity of the sole. The peroneus longus acts similarly as a sling beneath the lateral arch and also as a contractile tie-beam between the extremities of the transverse arch. The tibialis anterior and peroneus tertius muscles pull upon the medial and lateral arches from above. The long flexors of the toes act as contractile ties to the longitudinal arches. The muscles of the sole help to brace all the arches, according to their disposition.

In walking, the weight is first applied to the common posterior pillar of the two longitudinal arches as the heel strikes the ground. As the body moves forward the weight falls on the lateral border of the foot along the lateral arch, is rapidly transferred across the metatarsal heads to the medial arch as the heel leaves the ground, and a final propulsive thrust is obtained by flexion of the joints of the big toe. In running, the weight reaches the ground at the distal ends only of the longitudinal arches, which then act as quarter-elliptical springs, and, by their recoil, reinforce the final thrust derived from flexion of the medial toes.

MYOLOGY

by R. D. Lockhart, M.D., Ch.M.
Regius Professor of Anatomy, University of Aberdeen

The **skeletal muscles** alone are considered in this Section. They constitute the 'red flesh' of the body, and account for 42 per cent of its weight in the male, 36 per cent in the female. They execute movements initiated by the will, for which reason the tissue concerned is known as voluntary muscle. It is termed also **striated** muscle on account of its characteristic transverse striations, alternately dark and pale, seen under the microscope. It differs from the two other varieties of muscle-tissue, namely, **unstriated** or **plain** muscle found in the walls of viscera, blood-vessels, ducts of glands, and elsewhere; and the distinctive type of striated muscle confined to the heart, and hence termed **cardiac** muscle (Fig. 351). Both these varieties are under the control of the involuntary nervous system.

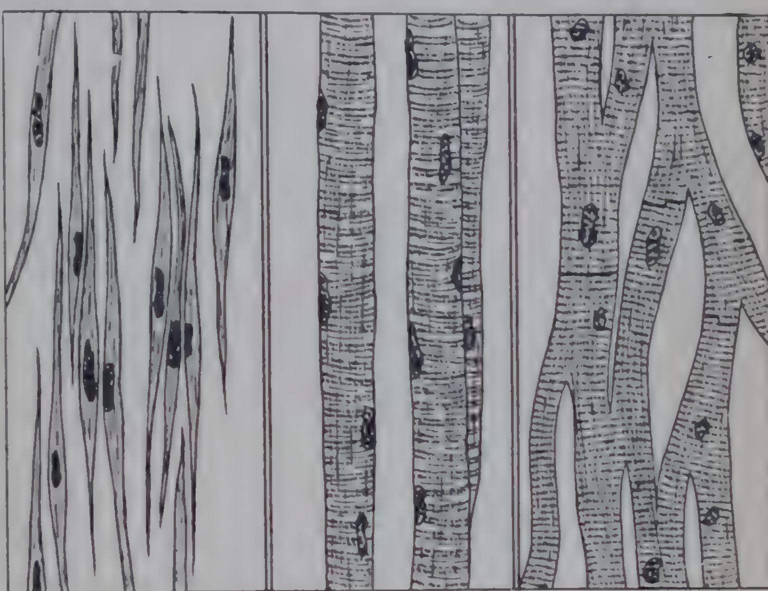

Fig. 351.—The Three Varieties of Muscle-Tissue. (Drawn from human muscle × 250.)

A. Plain muscle-fibres from prostate gland.
B. Striated. C. Cardiac.

All three varieties of muscle-tissue are derived from mesoderm, the cells of which acquire the characteristic power of contractility and become specialized to form muscle-fibres.

A typical skeletal muscle consists of a number of *fasciculi* or muscle-bundles, enveloped in a sheath of fibrous tissue termed *fascia*, and usually connected, at one or both extremities, with bundles of white fibrous tissue which constitute some variety of *tendon*.

Each fasciculus is surrounded and bound to its neighbours by areolar tissue called the **perimysium externum**; and each consists of a number of elongated muscle-fibres, held together in their turn by areolar tissue called the **perimysium internum**. The perimysium internum is connected on the one hand to the **sarcolemma** (or cell-wall of the muscle-fibre) and on the other to the perimysium externum, by which it is brought into connexion with some part of a tendon.

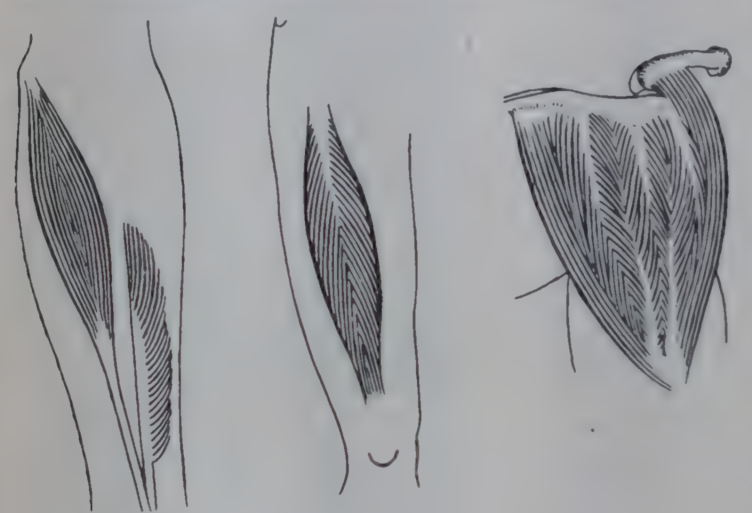
Attachments.—In order that a muscle may effectively exercise its power of contractility, it must possess (1) a relatively fixed point of attachment, termed the **origin**, usually nearer the median plane of the body, or proximal in a limb, and (2) a movable point of attachment, termed the **insertion**, usually farther from the median plane, or distal in a limb. Skeletal muscles are usually attached at both ends to bone, not directly by contractile muscle substance but by intervening non-contractile fibrous tissue. Some muscles have extensive attachments to bands of deep fascia and thereby to the bones, while such varied structures as tendons,

cartilages, fibrous raphes, ligaments, and skin may also be the site of origin or insertion.

Muscular attachments show marked individual variation in their extent and character and may be (1) fleshy, (2) tendinous, or (3) a combination of both. In the first case, *e.g.*, vastus intermedius, the fleshy fibres appear to spring directly from the bone, but the actual union is by perimysium to periosteum. In the second case, a varying extent of white fibrous tissue is interposed between the attachment and the fleshy belly. This intermediary is termed a **tendon**; and the shape and appearance of tendons vary greatly, the extremes being represented by the narrow, ribbon-like tendon of the palmaris longus and the broad, sheet-like tendon of the obliquus externus abdominis. A sheet-like tendon is usually referred to as an **aponeurosis.**

In some cases a muscle consists of two bellies connected by an *intermediate tendon.* Such muscles are termed "digastric" or "biventral". The fleshy bellies may be set at an angle to each other (*e.g.*, digastric and omo-hyoid), and in that event the intermediate tendon is anchored to some part of the skeletal system by a fascial sling. On the other hand, the two bellies may be placed in the same line.

The tendon, whether of origin or insertion, usually sends prolongations into the substance of the muscle—an arrangement which is not only efficient, but is also economical in the use of highly specialized tissue such as muscle, since it obviates the need for long muscle-fibres when the required movement may be produced by short fibres.



A B C

FIG. 352.—DIAGRAMS OF TYPES OF MUSCLES.

A. Fusiform (flexor carpi radialis) and Unipenniform (flexor pollicis longus). Cf. Fig. 421, p. 494.
B. Bipenniform (rectus femoris). Cf. Fig. 448, p. 522.
C. Multipenniform (deltoid).

Muscular Form.—The phylogeny and the function of a muscle determine its general form, and its detailed structure depends upon the number, arrangement, and length of its fibres. The greater the range of movement produced the longer are the fibres in the muscles concerned (Jansen, 1913). Various statements have been made regarding the length of muscle-fibres, from 1 mm. to 15 cm., but it seems probable that fibres may run the whole length of a muscle. Fibres of the adult sartorius 34 cm. long—and incomplete at that—have been isolated by dissection and fibres have been found to run from the tendon of origin to the tendon of insertion in the sartorius at birth and in the eye-muscles of the adult. (Lockhart & Brandt, 1938.) The more powerful a muscle the greater is the number and the shorter the length of its fibres; and the more extensive also is the use of tendinous fibres for their attachment. For example, the arrangement in the **penniform** types permits a greater number of fibres to be used and confers greater power.

In **unipenniform** muscles, the fibres are placed parallel to one another but not to the long axis of the muscle. This arrangement permits the use of short powerful fibres, and the longer the muscular belly the greater the number of these fibres, and the stronger the muscle (*e.g.*, vastus medialis). In **bipenniform** (*e.g.*, rectus femoris) and **multipenniform** muscles (*e.g.*, deltoid) still greater power is obtained by modifications of the same arrangement. In some muscles the fibres run parallel (or nearly parallel) to the long axis. They are termed **fusiform.** When the points of attachment of a fusiform muscle are widely separated, a long tendon of insertion is provided—again an efficient arrangement economical of muscle-tissue (Fig. 352).

Nomenclature of Muscles.—Muscles have received their names from a variety of circumstances, such as—their shape, *e.g.*, trapezius, quadratus; their structure, *e.g.*, triceps, digastric; their situation, *e.g.*, pectoralis, tibialis; their points of attachment, *e.g.*, sterno-mastoid, pubo-coccygeus; their direction, *e.g.*, rectus, obliquus; or their function, *e.g.*, flexor, abductor, etc. The names of most muscles combine two characteristics, *e.g.*, pronator teres, flexor digitorum sublimis. It is an interesting (and instructive) exercise for the student, as he studies Myology, to note the reasons for the names of individual muscles.

Variations.—The muscular system is remarkable for the numerous variations in its members. Individual muscles may possess additional heads of origin, *e.g.*, the biceps brachii; some muscles are frequently absent, *e.g.*, palmaris longus; while, in addition to the variations of muscles which we speak of as 'normal', a large number of 'abnormal' muscles or muscular slips have been described. Many of the latter, on account of the regularity of their position and attachments, have received special names. In a student's text-book it is not possible to deal with this aspect of Myology; but references to a few of these anomalous muscles will be found at the appropriate places in the description of the 'normal' muscles. Those who desire further information should consult Bryce (1923) or the special work of Le Double (1897).

Types of Muscle-Fibres.—Human muscles and the muscles of all other vertebrates are composed of several kinds of fibres:—(1) Pale, thin, rapidly contracting, easily fatigued, and metabolically expensive fibres—the first to be called upon in the production of active movements; (2) red, thick, slowly contracting, difficult to fatigue, and metabolically inexpensive fibres, that are harnessed in the work to increase and maintain the effort; (3) several intermediate types of fibres. Invertebrates and some vertebrates (*e.g.*, the rabbit) possess muscles composed exclusively of either the first or second types of fibre; but in man the fibres are mixed, though the red kind are considered to predominate in certain muscles, for example, the soleus, and the pale in others, for example, the gastrocnemius. Fibres of the same speed of contraction are usually grouped together. The deeper heads of a muscle are said to have more of the slowly contracting fibres.

Slight stimuli (caused, for example, by a stretching of the muscle) conveyed by its sensory nerves to the central nervous system produce a reflex state of contraction or muscle-tone *via* the motor nerves to the muscle. Red and pale fibres both function in this respect in maintaining *tone* and *posture*. There is no example of a purely postural muscle in Man. The greater the stimulus, the more fibres are called to function; and there is no basic difference in the production of the contraction maintaining postural tone, and that causing any active voluntary movement.

Contraction of Muscle-Fibres.—The amount of shortening which any muscle undergoes is directly proportional (nearly 1 : 2) to the length of its constituent fibres. Haines (1934) states that a muscle-fibre contracts by about 57 per cent of its length when fully stretched. If all the fibres of a given muscle are the same length and run from the tendon of origin to the tendon of insertion, then the extent of the muscle's contraction may be associated with the range of movement possible at a joint or joints; Haines considers that in movements not habitual, such as full flexion at the knee with full extension at the hip, the fibres of certain muscles, *e.g.*, the long head of the biceps femoris, are too short to perform the dual movements fully, and consequently that such muscles can act fully on only one joint at a time.

MUSCULAR ACTION

The essential virtue of muscle—its contractility—is displayed in producing movements of the body. Muscular action is therefore the basis of physical culture, an underlying principle of treatment in orthopædic surgery, and very frequently the secret of diagnosis in affections of the nervous system when the muscles are made to yield tell-tale evidence of the condition of their nerve-supply. Physical fitness may be assessed by the general tone of the muscular system; for example,

the poise of the shoulders, which depends mainly on the trapezius muscles, is a good general indication of well-being. Great emphasis must therefore be placed on the value of practical and experimental study of the function of muscles in the living human body. The following paragraphs dealing with the action of muscles should, indeed, be frequently consulted throughout the study of Myology. For discussion beyond the scope of this text see the detailed yet engrossing works of Duchenne (1867) and Beevor (1904).

Most skeletal muscles function by producing movements at the joint or joints over which they pass on their way from origin to insertion; and it is important to note that the muscles most powerfully concerned may act either by contraction or by relaxation, according to whether the movement is made against gravity or resistance, or with gravity in the absence of resistance. For example, the deltoid contracts when the arm is raised, but in Fig. 1, Pl. XLI, p. 512, the lengthening muscle is still firm and active, as shown by the weight riding upon it, while the arm is being lowered. The deltoid thus controls the gravitational descent of the arm, as a crane would pay out rope in lowering a weight, but when the arm is being lowered against resistance, as in Fig. 2, Pl. XLI, such activity of the deltoid is useless; other muscles, antagonists to the deltoid, such as the pectoralis major and the latissimus dorsi, have to pull the arm downwards, and the deltoid itself becomes flaccid, as is shown by the weight sinking into it. It is therefore essential to consider the influence of gravity and resistance in determining muscular action, and to note that the relaxation of muscles is as important as their contraction; modern physical training methods exercise both functions to obtain harmony in development.

The terms '**concentric action**' and '**excentric action**' are sometimes used in this connection to distinguish the shortening and lengthening respectively of a muscle as it works. It must be emphasized that a muscle may work equally hard in each kind of action, *i.e.*, there may be '*active* lengthening' as well as the more obvious 'active shortening'. On the other hand, a muscle may shorten or lengthen, in co-operation with more active muscles, without working hard at all; this may be termed '*adaptive* shortening or lengthening'.

Muscular relaxation may be the important feature in certain exercises. For example, the hip joint may be fully flexed, and then again the knee joint may be fully extended, but not both together unless the "hamstring" muscles acquire a special power of relaxation through practice; extreme relaxation of the hamstrings is essential for the accomplishment of the 'high kick', and a lesser degree is required in touching the toes without bending the knees.

Muscles may be voluntarily contracted without movements occurring and without appreciable shortening. This condition is known as **isometric contraction**, and occurs, for example, in the quadriceps femoris maintaining the erect posture, when the knee joint is held extended against the flexing force of gravity. The length remains constant but the tension is increased. In the opposite condition, **isotonic contraction,** the muscle shortens but its tension is constant. This occurs in voluntary movements.

The more powerful the action of a muscle the greater is the number of fibres stimulated to function. It is not necessary for all the fibres of a muscle to contract at the same time for gentle movements; indeed, muscle-fibres work by groups in relays to avoid fatigue. When examining a patient, the physician, in order to bring more fibres into play, adopts the method of **reinforcing** muscular action by opposing the patient's movements; this is a practice which will afford the student of anatomy also, as he carefully palpates living limbs, valuable practical information concerning muscles.

When a muscle contracts, its insertion is, as a general rule, approximated to its origin, but when both attachments are movable, the insertion may on occasion be relatively more fixed than the origin. Thus, in Fig. 1, Pl. XL, p. 457, in which the subject pulls down a weighted rope towards the body, the insertion of the latissimus dorsi into the arm is brought towards its origin from the trunk; but if the subject were to raise the body by means of the rope, the origin would be approximated to the insertion.

Most skeletal muscles utilize the bones as levers, and in the limbs the muscles are usually attached just beyond the joint upon which they mainly act; one advantage of this is that a small movement at the knee or the elbow, for instance, produces, with economy of muscle-contraction, a much wider excursion of the foot or the hand. The particular action of any muscle is a problem in mechanics, depending on the position of the two attachments and the relation of the muscle to the axes of the movements which are possible at the joint or joints over which it passes. Thus, in the case of the elbow joint where movements occur around a transverse axis only, all muscles which pass anterior to the joint can act as flexors, and all muscles which pass posterior to the joint can act as extensors. But such questions are not of great importance.

Movements, and not individual muscles, are represented in the cerebral cortex—that is, we are aware of the execution of a movement but not of the executive muscles. In fact, we may hardly even be aware of certain movements that initiate or are accessory to the chief movement. Even the simplest movements require the co-ordinated action of many muscles in different functional capacities to ensure precision of performance. Although some persons may appear to have the power to contract a particular muscle at will, probably other muscles are also employed, and it is justifiable to say that, from a functional point of view, there is no such thing as the isolated action of a muscle. Control of the muscles producing any given voluntary movement is an automatic function of the central nervous system.

The different capacities in which individual muscles may function in any given movement are as follows:—1. Prime movers; 2. Antagonists; 3. Fixation muscles; 4. Synergists; but the same muscles appear in different capacities for different movements.

The **prime movers**, as the term implies, are the muscles which by their active contractions, and the consequent approximation of their attachments, are responsible for the actual movements which take place. When the fist is clenched, for example, the prime movers are the flexors of the fingers and the thumb.

The **antagonists** in any movement are those muscles which are capable by contraction of producing the reverse movement, and by their relaxation enable the movement to be effected. The extensors of the fingers and thumb, for example, would prevent the clenching of the fist, but for the law of *reciprocal innervation* between two groups which causes antagonists to relax as prime movers contract. It has been shown experimentally that the same areas of the motor cortex of the brain are responsible for the contraction of the one and the inhibition or relaxation of the other. The term 'antagonists' belies the function of muscles in that capacity, for they do everything to secure harmony in the movement, 'paying out' just as much as, and no more than, is required, thus securing guidance and precision. For example, the deltoid remains taut when the arm is lowered against slight resistance but becomes flaccid when severe resistance is encountered.

Precision in the performance of any desired movement, or effective action against resistance, is possible only if the muscles concerned have a stable basis from which to act. It is the function of **fixation muscles** to provide this stable basis by steadying a part or a joint. For example, if the scapula is not adequately steadied and guided by the trapezius and serratus anterior muscles, disharmony in elevation of the arm by the deltoid will result. The trapezius and serratus anterior are prime movers in securing the rotation of the scapula upon the chest-wall necessary for elevation of the arm, but are also fixation muscles in providing a firm base upon which the humerus is turned by muscles of the arm. During the exercise, in the supine position, of raising both legs from the floor, the rectus abdominis, though it does not act upon the limbs, soon becomes painfully cramped, because of the heavy and exhausting work required of it in fixing the pelvis for the pull of the limb-muscles and the support of the weight of the limbs.

Synergists [σύν (syn) = together, ἔργειν (ergein) = to work] might well be classed as special examples of fixation muscles, since they control the position of intermediate joints so that prime movers which pass over several joints may exert their power in a desired movement of a distal joint. In clenching the fist the synergists are the extensors of the wrist. If the wrist were not held extended,

then the flexors of the fingers would be powerful enough to produce flexion of the wrist. Now, flexion of the wrist added to flexion of the fingers stretches the tendons of the extensors of the fingers until they can yield no more, whereupon the continued flexion at the wrist causes the fingers to open out and the grip to slacken. This is the explanation of the success of the common trick of forcibly flexing an opponent's wrist to compel him to drop a weapon from his hand. Similarly the synergic action of the flexor carpi ulnaris and the extensor carpi ulnaris, acting together as adductors of the wrist, is essential for the apparently simple movement of abducting the thumb.

Group-Action of Muscles.—A movement may require the simultaneous co-operation of teams of muscles from all four of the above classes, namely prime movers, antagonists, fixation muscles and synergists, and such activity is sometimes cited as an example of the group-action of muscles. But the term is more accurately applied to the common or related action of a group of muscles usually with common sources of nerve-supply ; for example, the muscles that flex the ankle work together as a team, and surgeons, appreciating this fact, are careful to select a muscle from the same team when they try to mitigate the disability due to paralysis of a muscle, by transplanting another member of the team to act as substitute. Obviously, a muscle transferred from a rival side would be by nature an antagonist, although, eventually, it might be trained to play a new part among its former opponents. Such reversal is more efficient in the upper limb than in the lower. In the lower limb, individualism is suppressed in the well-nigh automatic group-actions of locomotion, and such a practice as replacing a paralysed tibialis anterior by an antagonist —the peroneus longus—is usually unsatisfactory. In the upper limb, however, with its universal movements and more diverse and refined functions, muscles are more accustomed to the need for varied uses and individual specialization, and an extensor can be educated to take the part of a flexor (a normal action of the extensors upon the pronated forearm, p. 492) much more easily than in the lower limb (Dunn, 1920).

Associated Actions.—Muscles of one region may act in harmony with remote muscle-groups ; in walking, as the foot leaves the ground, the post-vertebral muscles of that side and the gluteus medius and minimus of the opposite side can be felt contracting to maintain the balance of the body. Again, in turning to look backwards we are mainly conscious of the movement of the head, and seldom realize the harmonious activity of the muscles of the eyes, trunk, limbs and feet ; indeed every large movement is preceded and accompanied by movements of which we are not aware until we study the concerted action carefully and analyse its different phases. Owing to these associations, paralysis of a single muscle affects the general co-ordination as well as the chief movement in which it is concerned. The defect resulting from paralysis of a muscle is not necessarily a full indication of its action as a component of the movement.

Dual Action of Muscles.—Apart from voluntary actions, some striated muscles also perform involuntary movements ; and in certain lesions of the central nervous system it is a point of clinical interest that a muscle, though intact, cannot execute its voluntary movement although it may retain its function for involuntary *bilateral* acts—*e.g.*, a paralysed upper limb is moved with its fellow in the stretching that accompanies a yawn, and a latissimus dorsi, paralysed for voluntary unilateral movement, contracts in the instinctive bilateral act of coughing (Beevor, 1904). Further, a muscle which participates in more than one voluntary movement (*e.g.*, biceps, flexor and supinator) may be paralysed for the one movement and not the other, as the movements are not represented in the same part of the cerebral cortex.

Ligamentous Action of Muscles.—The ligaments of a joint would require to be much stronger and bulkier were it not for the aid given by muscles. All the activities of muscles, from gentle muscle-tone to vigorous contraction, prevent undue strain being thrown on the ligaments ; and, indeed, ligaments stretch rapidly when the muscular safeguard is removed or diminished. But muscles have a more truly ligamentous effect through their inability to relax sufficiently to allow free movement of a joint in all circumstances. For example, when the

knee is straight the hamstring muscles, unable to relax enough to permit full flexion of the hip joint, play the part of restraining ligaments at that joint (cf. pp. 529, 543).

Postural Action.—Even at rest, during consciousness, all voluntary muscles are under slight tension, called *tone* or *tonus*. This is well marked in muscles which habitually maintain and regain the normal posture of the body against gravity, and such muscles, sometimes termed the anti-gravity muscles, may be said to possess a postural function. For the main part, the extensor muscles of the lower limb, trunk and neck exercise this function which may be easily demonstrated by the following methods. Stand erect with one hand placed upon the back, lean slightly forwards, and the increased tension of the extensors to maintain the balance will be felt at once. Instead of leaning forwards, the mere raising of one arm forwards, disturbs the delicate postural balance and produces the same effect upon the extensors. In the erect position, a slight inclination forwards and then backwards causes alternate tension and relaxation of the extensors and flexors of the trunk easily detected by one hand on the back and the other on the abdomen. Other instances of postural muscular activity—a function, be it noted, which is carried out for long periods without appreciable signs of fatigue—are the sitting posture, the clenched position of the teeth by the elevators of the mandible, the suspension of the upper limb by supraspinatus (aided by infraspinatus, teres minor and subscapularis) and the action of the deep muscles of the calf not only in helping to keep the posture erect but also in maintaining the arches of the foot.

The student must be careful to appreciate that this postural play upon particular muscles is controlled by the central nervous system through reflexes in the spinal cord, initiated by impulses from other muscle-groups, the skin, the labyrinth and higher centres in the brain. Slowly contracting muscles are not radically different from their fellows except for the predominance of their red fibres as against the pale fibres in the rapidly contracting muscles. In some groups the superficial muscles may be of the pale type and the deep of the red variety; for example, the superficial, pale, rapidly contracting gastrocnemius and the deep, red, slowly contracting postural soleus. As both gastrocnemius and soleus act posturally as well as in rapid and exhausting voluntary movement, there is no vital difference between the types.

Action-Currents in Muscle.—The activity of a muscle produces action-currents which may be recorded by electrical apparatus—a valuable method of determining the active and inactive muscles in a movement; the activity of the internal intercostal muscles in expiration has been demonstrated in this way.

Nerve-Supply.—Each muscle is supplied by one or more nerves, which in their course through it separate into smaller and smaller branches. Ultimately their terminal filaments (axons) give off numerous collaterals, each of which forms a special end-plate in relation to a muscle-cell.

It has been estimated that of the fibres contained in a nerve of supply to a muscle three-fifths are motor and two-fifths are sensory; the reciprocal action of these has already been described under muscle-fibres. In addition, all muscles receive sympathetic nerve-fibres, which have been shown to diminish and delay the occurrence of fatigue in skeletal muscle, but the details of their action are not yet fully determined.

Vascular Supply.—*Blood-vessels* enter muscles with the nerves along a line which is frequently definite enough to receive the name of *neuro-vascular hilum* (Brash, 1947). Striated muscles may be said not to possess *lymph-vessels* since these are not found between the individual fibres. But a capillary network is present in the sheath of a muscle and between the fasciculi. (Aagaard (1913) states that there is a lymph-capillary plexus around the fibres of striated muscle.)

FASCIÆ AND SYNOVIAL SHEATHS AND BURSÆ

Beneath the skin there are two layers of connective tissue to be considered in relation to the muscular system—the superficial fascia [panniculus adiposus] and the deep fascia. The panniculus carnosus (rudimentary in man) lies in the substance of the superficial fascia.

The cells of the mesoderm, not differentiated into muscles, vessels, and bones are utilized to form connective tissue or fascia which ensheaths these structures.

Superficial Fascia.—The superficial fascia is a continuous sheet of areolar tissue which underlies the skin of the whole body. It is closely adherent to the corium; and, except beneath the skin of the eyelids, penis, and scrotum, it is usually more or less impregnated with fat. The fat of the superficial fascia is scanty in the healthy adult male, but tends to increase on the abdomen, breast, and buttocks; it forms a thicker subcutaneous layer in women and children, and is thus mainly responsible for the more rounded contours of their bodies. Its relative amount is indeed a secondary sex-character, since in the average it accounts for about 18 per cent. of the body-weight in men and 28 per cent. in women. The cutaneous vessels and nerves ramify in this fascia; and its deep surface—membranous in character—is in loose connexion with the deep fascia. It is chiefly in this layer that dropsical effusions occur.

Deep Fascia.—Underneath the skin and superficial fascia there is a fibrous membrane, bluish-white in colour, devoid of fat, and in closest relation to skeleton, ligaments, and muscles. This is the deep fascia. It covers and invests the various muscles, and in some cases is the means of their attachment. It has a special tendency to become attached to all subcutaneous bony prominences, and to be continuous with the ligaments. Laminæ from its deep surface extend inwards among the deeper structures; these sheets enclose glands and viscera, provide nerves and vessels with sheaths, and form **intermuscular septa** which separate groups of muscles and individual muscles—affording them additional means of attachment.

In the distal portions of the limbs, where the various joints are close to one another, special thickenings of the deep fascia called **retinacula** are present for the purpose of retaining the tendons in position when their muscles contract. These fascial bands act as pulleys round which the tendons work, and they serve to prevent waste of power. There is a further modification on the flexor aspects of the digits for the same purpose; the fibrous bands are connected to one another and to the phalanges in such a way as to form osteo-fascial tunnels in which the tendons lie.

It is important for the student to appreciate the function of the undifferentiated mesoderm which remains as a living packing-material to embed those structures (vessels, muscles, bones) that are of mesodermal origin. This conception clarifies the fact that where muscles or vessels cross each other, or lie in contact, the fascial bed makes a common wall for the separate tunnel or tube each structure occupies. This arrangement of the investing fascia, the texture of which may vary from a dense sheet to a thin membrane, is evident in the living subject; but in the dissecting-room a wrong impression may be obtained from the preserved subject by an artificial cleavage that splits up the fascial bed, like a slate slab, into numerous planes and sheaths. These points should be kept in mind particularly in dealing with the fasciæ of the neck and pelvis (cf. Fig. 380).

Synovial Sheaths.—In the situations just described, where tendons are retained in place by localized thickenings of the deep fascia, synovial sheaths are provided to facilitate their movements. Such sheaths may be related to one or more tendons. They are always closed sacs, with a parietal layer lining the walls of the space in which the tendon lies and a ‘visceral’ layer closely applied to the tendon itself, so that the two synovial surfaces are in apposition with each other.

In the digital synovial sheaths, continuity is established between the parietal and visceral layers by means of **vincula tendinum** (p. 496), as well as at the extremities of the sheaths. The vincula tendinum transmit small blood-vessels, and they may be regarded as incomplete ‘meso-tendons’.

Synovial Bursæ.—Simple, closed synovial sacs are placed between a tendon (or an aponeurosis) and a bony point or ligament over which it plays, or between the distal ends of two or more tendons, when they are inserted in close proximity to one another.

DESCRIPTION OF THE MUSCLES

In the study of the muscular system it is necessary to note the following characters in reference to each individual muscle: (1) The *shape* of the muscle—flat, cylindrical, triangular, rhomboidal, etc.; and the character of its extremities—membranous, tendinous, or fleshy. (2) The *attachments* of the muscle. (3) The *relations* of the surfaces and borders of the muscle to bones, joints, muscles, and other important structures. (4) Its *vascular* and *nervous supply*. (5) The *movements* in which it takes part.

The skeletal muscles may be divided into two series: axial and appendicular. The **axial muscles** comprise the muscles of the trunk, neck, head, and face; they are more or less segmental in arrangement, and are grouped around the axial skeleton. The **appendicular muscles** are the muscles of the limbs; they are grouped around the appendicular skeleton, and they are not segmental in arrangement.

AXIAL MUSCLES

MUSCLES OF VERTEBRAL COLUMN

The muscles of the vertebral column are arranged in two main groups—post-vertebral and prevertebral—on the dorsal and ventral aspects of the column respectively. The post-vertebral or dorsal group is by far the more extensive and the more complex in its attachments. It extends from the sacrum to the head, forming a cylindrical fleshy column in the loin, filling up the vertebral groove in the thoracic region, and giving rise to the muscular mass at the back of the neck. It is attached not only to the vertebral column but also to the pelvic girdle below, the posterior part of the base of the skull above, and, by means of numerous slips of its component parts, to all the ribs.

The prevertebral or ventral group, on the other hand, is interrupted. It extends from the base of the skull, in front of the foramen magnum, to the upper thoracic region, and reappears again in the lumbar region as the psoas major and minor.

It is evident that the physiological antagonists of the powerful dorsal group, whose main action, taken as a whole, is to extend the vertebral column, are to be found not merely in the true prevertebral group directly in relation to the vertebral column, but also and mainly in the ventral and lateral muscles of the abdominal wall, which, through their attachments to the thorax, are in a position to bend the vertebral column forwards on the pelvis.

The muscles of the back, from the topographical point of view, may be conveniently divided into two main groups—(1) the *superficial* and (2) the *deep*.

The **superficial muscles of the back** are described with the muscles of the upper limb, which they connect to the axial skeleton.

DEEP MUSCLES OF BACK

The **deep muscles of the back**—the post-vertebral or dorsal group of the vertebral column—may be classified according to their attachments in three series — vertebro-costal, vertebro-cranial, and intervertebral. It is, however, more convenient to describe them as they are met with in irregular strata in the dissection of the back. On this basis, and having regard to serial repetition of attachments and the general direction taken by the muscular fibres, the greater part of this complex musculature—so bewildering at first to the student, subdivided as it has been into many parts, separately named and largely artificial—may be resolved into two main systems: a superficial, longitudinal *sacro-spinalis* system and a deeper, oblique *transverso-spinalis* system. These form the basis of the first two of the following three groups into which the deep muscles of the back may be divided: (1) the sacro-spinalis system and the splenius muscle; (2) the transverso-spinalis system (semispinalis thoracis and cervicis, multifidus and rotatores) with

the semispinalis capitis; and (3) the interspinal, intertransverse, and suboccipital, muscles.

The general regional disposition as indicated in Figs. 353, 354, should be studied rather than the details of attachments.

It should be noted that the component parts of the more superficial group are arranged in more or less separate longitudinal columns and stretch between their attachments over many vertebræ; the component parts of the deeper muscles are shorter, passing over fewer vertebræ; and in the deepest layer the attachments of the individual parts are between contiguous vertebræ only.

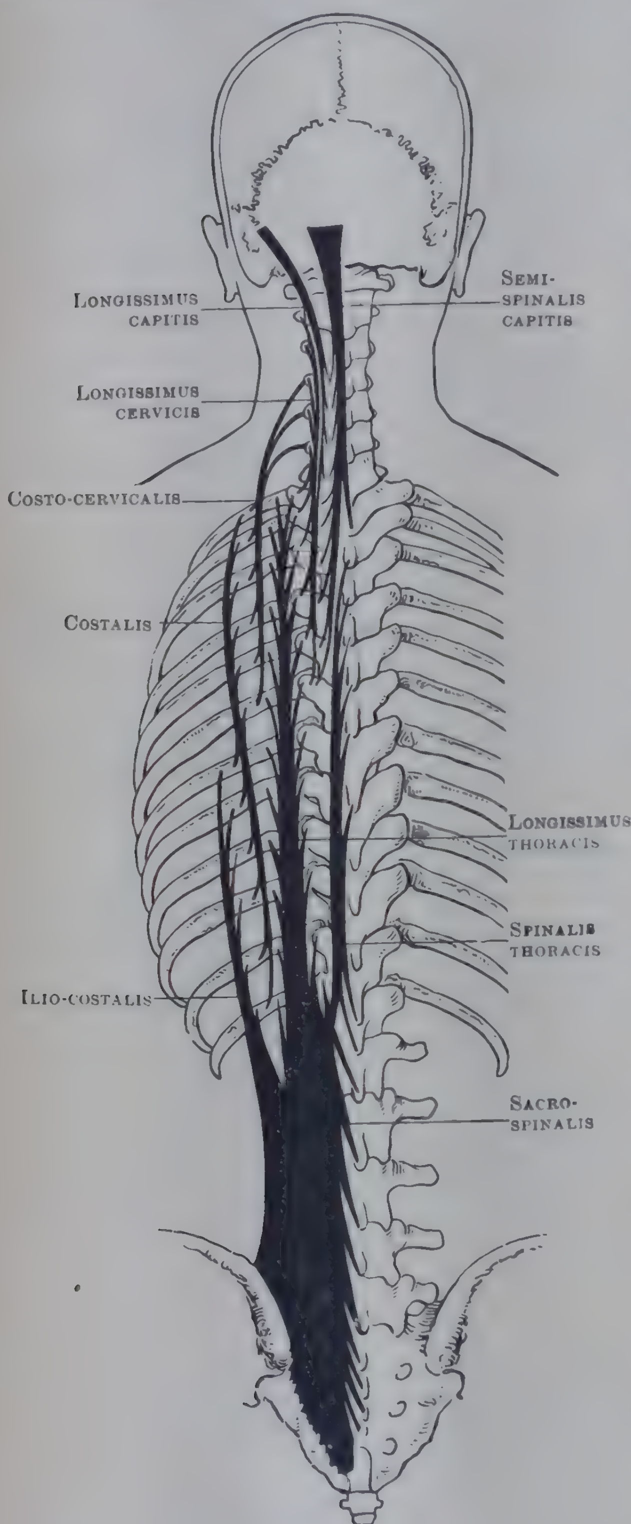


Fig. 353.—Schematic Representation of the Parts of the Left Sacro-Spinalis Muscle.

In general also, the differentiation of the muscular systems described increases from below upwards. All three groups are continued to the head, and, in the cervical region, portions of each become definitely individualized in relation to the finer movements of the head and the cervical part of the vertebral column as compared with the more generalized movements of the column as a whole.

Two small muscles called the *serrati posteriores, superior* and *inferior*, situated between the superficial and the deep muscles of the back, are described with the muscles of the thorax, to which they properly belong.

First Group

This group includes the sacrospinalis with the spinalis thoracis (usually described as its medial column), and the splenius (capitis and cervicis) muscle, which lies in a more superficial plane in the upper thoracic and cervical regions.

Splenius.—The splenius muscle, situated in the back of the neck and the upper part of the thoracic region, is a broad band which straps down the underlying muscles. It **arises** from the ligamentum nuchæ (from the level of the fourth cervical vertebra downwards) and from the spines of the last cervical and higher (four to six) thoracic vertebræ.

Its fibres extend upwards and laterally into the neck, separating in their course into an upper and a lower part. The upper part is the **splenius capitis**, which is **inserted** into the mastoid portion of the temporal bone and the lateral part of the superior nuchal line of the occipital bone (Fig. 356). The lower part is the **splenius cervicis**, which is **inserted** into the posterior tubercles of the transverse processes of the upper three or four cervical vertebræ, under cover of the origin of the levator scapulæ.

The greater part of the muscle is concealed by the trapezius and the sterno-mastoid, but a portion of the splenius capitis appears between them in the floor of the posterior triangle of the neck. It is covered also by the rhomboid muscles, levator scapulæ, and serratus posterior superior, and, itself, helps to conceal the cervical prolongations of the sacro-spinalis and the semispinalis capitis.

Sacro-Spinalis.—The sacro-spinalis possesses vertebral, vertebro-cranial, and vertebro-costal attachments. It is an elongated mass composed of separate slips extending from the sacrum to the skull. Simple at its origin, it becomes more and more complex as it is traced upwards towards the head, its continuity as a whole being maintained at higher levels by relays of fibres arising as the lower fibres are inserted.

Its primary origin is: (1) by a strong tendinous sheet fused with the posterior layer of the lumbar fascia and continuous below, as it narrows to a pointed extremity, with the posterior sacro-iliac, the sacro-tuberous, and the sacro-coccygeal ligaments, from the iliac crest and posterior superior iliac spine, the transverse tubercles and spinous crest of the sacrum and the lumbar and lower two thoracic spines; and (2) by fleshy fibres massed beneath the lateral border of the tendon just above the posterior superior iliac spine, where they obtain a powerful direct attachment to the upper half of the iliac tuberosity and to the inner lip of the iliac crest. Below this level the tendon is spread over the underlying multifidus muscle, which is separated from it for the most part by a layer of areolar tissue containing some fat. The sacro-spinalis muscle extends upwards through the loin, in which it forms the main muscular mass posterior and lateral to the multifidus, and it splits into three columns—**a lateral,** called the **ilio-costo-cervicalis,** derived from the lateral part of the fleshy origin, an **intermediate,** called the **longissimus,** and a **medial,** called the **spinalis thoracis.**

Ilio-costo-cervicalis.—The **ilio-costalis** is **inserted** by six slender slips into the lower six ribs.

Medial to the insertion of each of these slips is the origin of the **costalis** which, **arising** from the lower six ribs medial to the ilio-costalis, is **inserted** in line with it by similar slips into the upper six ribs.

The **costo-cervicalis arises** in the same way by six slips from the upper six ribs, medial to the insertions of the costalis. It forms a narrow band that extends into the neck to be **inserted** into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ behind the scalenus posterior.

The three subdivisions of the ilio-costo-cervicalis form together a continuous muscular column, and constitute the most lateral group of the component elements of the sacro-spinalis.

Longissimus.—The longissimus is the largest element in the sacro-spinalis system. Mostly tendinous on the surface at its **origin,** it becomes fleshy in the upper part of the loin. It is thickest in the loin, and becomes thinner as it passes upwards in the back, as the longissimus thoracis, between the columns formed by the ilio-costo-cervicalis laterally and the spinalis thoracis medially. It is continued up into the neck as the longissimus cervicis and longissimus capitis.

The **longissimus thoracis** is **inserted** by two series of slips—laterally into nearly all the ribs, and medially into the transverse processes of the thoracic vertebræ and the accessory processes of the upper lumbar vertebræ.

The **longissimus cervicis** has an **origin** from the transverse processes of the upper six thoracic vertebræ, medial to the insertions of the longissimus thoracis. Extending upwards into the neck, it is **inserted** into the posterior tubercles of the transverse processes of the second, third, fourth, fifth, and sixth cervical vertebræ. In the neck it is concealed by the costo-cervicalis and splenius cervicis muscles.

The **longissimus capitis arises,** partly by an origin common to it and the previous muscle, from the transverse processes of the upper six thoracic vertebræ, and partly by an additional origin from the articular processes of the lower four cervical vertebræ. Separating from the longissimus cervicis, the muscle ascends through the neck as a narrow band which is **inserted** into the mastoid portion of the temporal bone, deep to the splenius capitis muscle. In the neck the muscle is placed between the splenius capitis and semispinalis capitis.

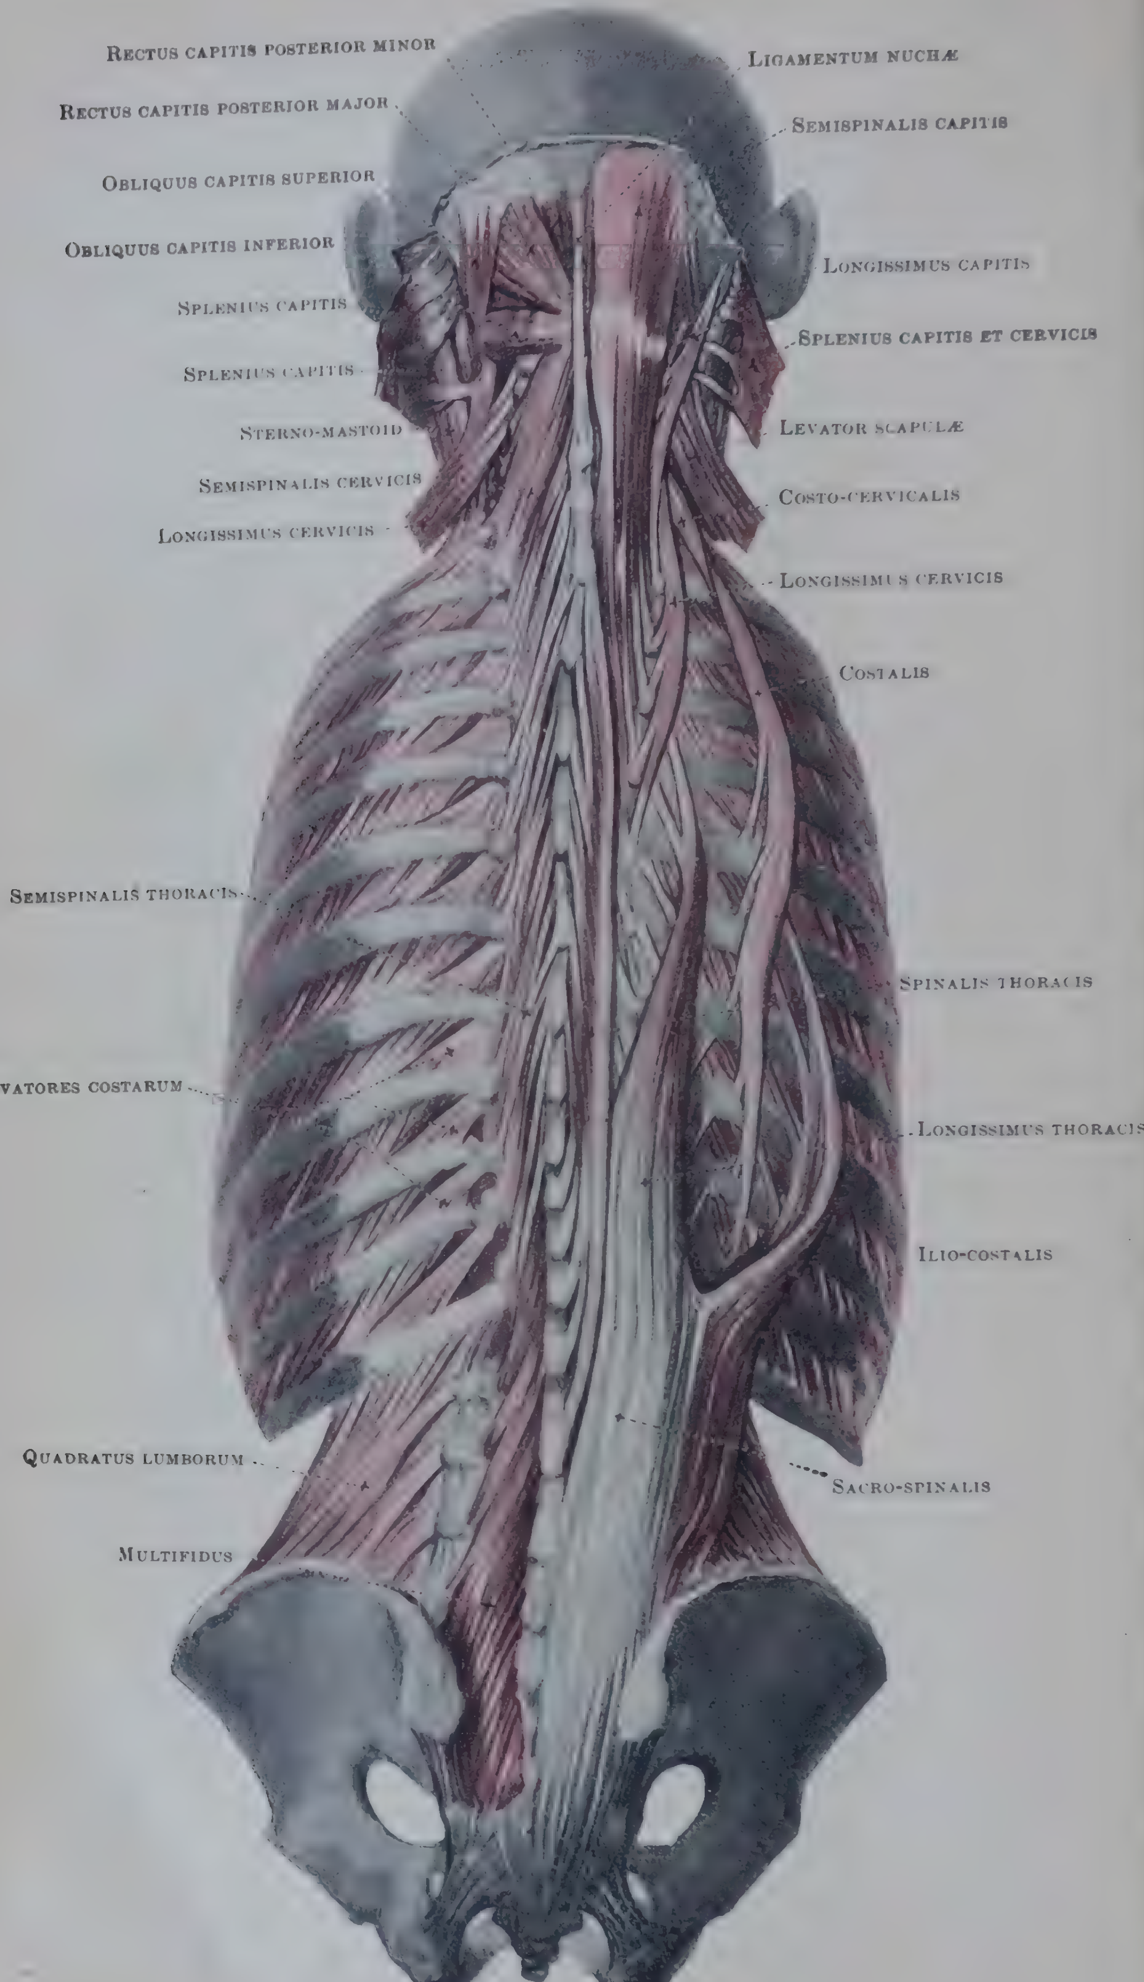

Fig. 354.—Deep Muscles of the Back.

Spinalis Thoracis.—The spinalis thoracis **arises** by tendinous fibres from the lower two or three thoracic and upper two or three lumbar spines, the lower slips being in common with the upper origins of the longissimus thoracis.

It is a narrow muscle which lies close to the thoracic spines medial to the longissimus thoracis, and it is **inserted** into the upper four to eight thoracic spines. It is not as a rule prolonged into the neck, though a **spinalis cervicis** and a **spinalis capitis** (joining the semispinalis) may both be present.

Second Group

This group comprises the multifidus (with the deep-lying rotatores) and the semispinales muscles (thoracis, cervicis, and capitis). The multifidus occupies the

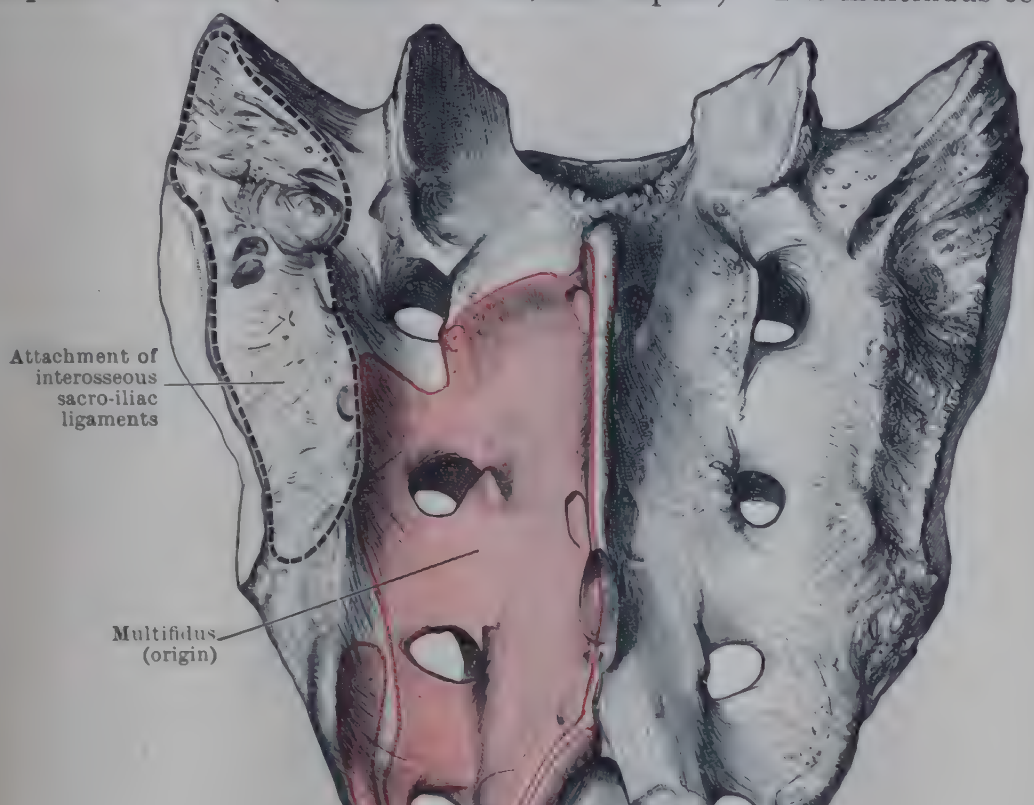

Fig. 355.—Muscle-Attachments to the Sacrum (Dorsal Surface).

The tendinous origin of the sacro-spinalis is represented by the thick line on the medial and lateral sides of the area of the origin of the multifidus.

whole length of the vertebral furrow; it is under cover of the sacro-spinalis below, while in the upper thoracic and cervical regions the semispinales form more superficial and overlapping strata partially concealed by the splenius. The more superficial muscles have the longer fibres; the fibres of the multifidus pass over fewer vertebræ.

In general, these muscles extend obliquely upwards from the transverse processes to the spines, thus constituting a "transverso-spinal" system; the semispinalis capitis, related to this system as the splenius is to the sacro-spinalis, with a similar origin, but extending to the base of the skull, is a corresponding "transverso-occipital" muscle. The general contrast between the directions of the fibres of this and the previous group should be noted as an indication of a real distinction between them; the fibres of the sacro-spinalis system pass upwards and laterally from spines to transverse processes, while those of the transverso-spinalis system pass upwards and medially from transverse processes to spines.

Semispinalis.—The semispinalis muscle extends from the loin to the skull. It is described as three muscles—the **semispinalis thoracis**, the **semispinalis cervicis**,

and the **semispinalis capitis**—but the separation between S. thoracis and S. cervicis is artificial.

The **semispinalis thoracis arises** from the transverse processes of the lower six thoracic vertebræ and is **inserted** into the spines of the first four thoracic and last two cervical vertebræ.

The **semispinalis cervicis arises** from the transverse processes of the upper six thoracic and the articular processes of the lower four cervical vertebræ, and it is **inserted** into the spines of the cervical vertebræ from the second to the fifth.

The **semispinalis capitis** is very similar in its attachments to the longissimus capitis, but it is a very much larger muscle and the direction of its fibres is different. It takes **origin** from the transverse processes of the upper six thoracic and the articular processes of the lower four cervical vertebræ medial to the longissimus

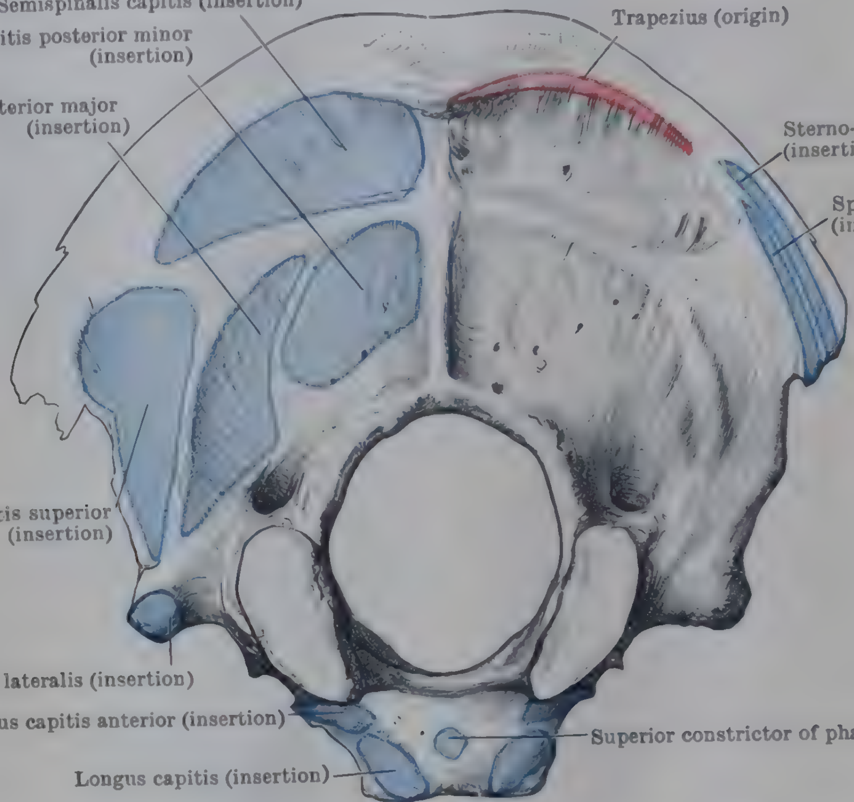

Fig. 356.—Muscle-Attachments to the Occipital Bone.

cervicis and longissimus capitis. It may have an origin also from a variable number of the spines of the lower cervical and upper thoracic vertebræ (**spinalis capitis**).

It forms a broad muscular sheet which extends upwards in the neck to be **inserted** into the medial impression between the superior and inferior nuchal lines of the occipital bone (Fig. 356). The medial portion of the muscle is separate; it consists of upper and lower muscular parts with an intervening tendon placed vertically in contact with the ligamentum nuchæ; this tendon is not to be confused with a tendinous intersection which may traverse the upper portion (Fig. 354). The muscle, covered by trapezius and, deep to that, mainly by the splenius and longissimus capitis muscles, forms the muscular mass that bounds the nuchal furrow. It conceals the semispinalis cervicis and the medial part of the suboccipital triangle, and its vertical fibres are usually visible at the upper angle of the posterior triangle of the neck above the splenius capitis.

Multifidus.—The multifidus differs from the semispinalis in extending from the sacrum to the second cervical vertebra, and in the shortness of its fasciculi, which pass over fewer vertebræ to reach their insertion.

It **arises** successively from the sacrum (Fig. 355) under cover of the tendon of the sacro-spinalis, from the posterior sacro-iliac ligaments, from the mamillary processes of the lumbar vertebræ, from the transverse processes of the thoracic vertebræ, and from the articular processes of the lower four cervical vertebræ. It is **inserted** into the spines up to and including the second cervical.

Lying in contact with the vertebral laminæ and, in the thoracic region, with the rotatores, the muscle is covered in the neck and back by the semispinalis, and in the loin by the sacro-spinalis muscle.

Rotatores.—The rotatores are eleven pairs of small muscles that occupy the vertebral groove in the thoracic region, deep to the multifidus, of which they form the deepest fibres. Each is a small slip which **arises** from the transverse process of one vertebra and is **inserted** into the lamina of the vertebra directly above.

Third Group

This group comprises several series of small muscles which are vertebro-cranial or intervertebral in their attachments, and include the special group of sub-occipital muscles.

Interspinales.—The interspinales are bands of muscular fibres that connect

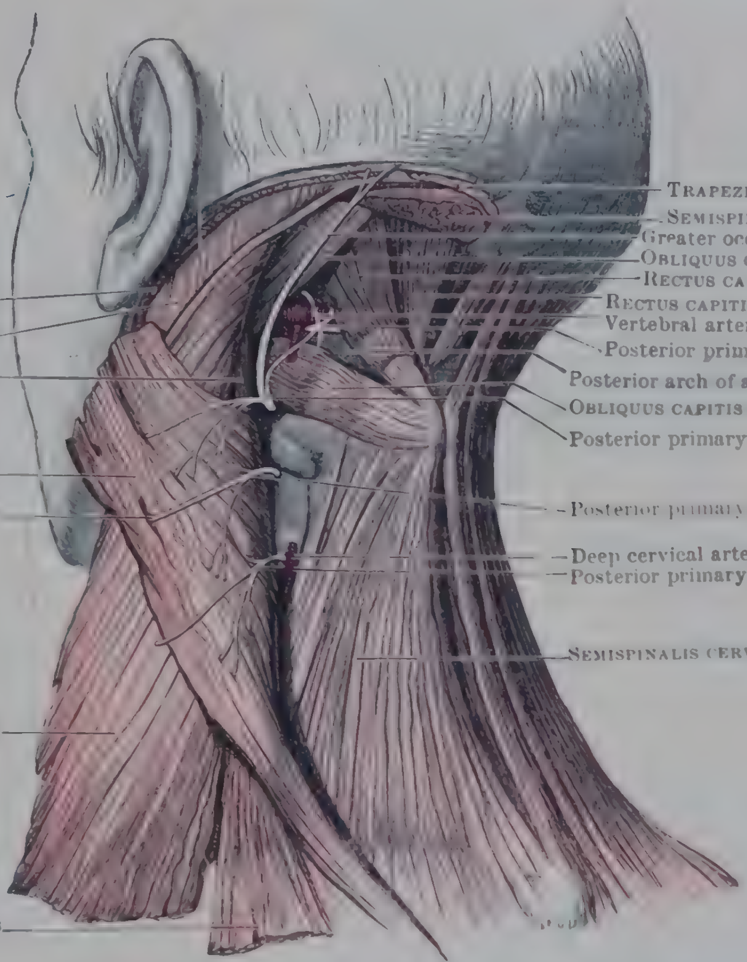

FIG. 357.—SUBOCCIPITAL TRIANGLE OF THE LEFT SIDE.

together the spines of the vertebræ from the second cervical downwards. They are well-developed in the cervical and lumbar regions, where they lie one on each side of the corresponding interspinous ligament, but they are poorly developed and may be absent in the thoracic region.

Intertransverse Muscles.—The intertransverse muscles are slender slips that extend between the transverse processes.

In the cervical region, with certain exceptions, an anterior intertransverse muscle extends from costal element to costal element in front of the emerging anterior primary ramus of the corresponding spinal nerve, and a posterior intertransverse muscle extends from transverse element to transverse element behind the nerve. Above the atlas, the rectus capitis lateralis is in series with the posterior intertransverse muscles, and the rectus capitis anterior may represent the anterior group. Between the atlas and the second cervical vertebræ, the posterior muscle is well developed and is situated, like the rectus capitis lateralis, posterior to the emerging nerve, but the anterior muscle in this space is frequently absent.

In the thoracic region the intertransverse muscles are absent, except in the lower three or four intervals, where their arrangement corresponds to that found in the lumbar region.

In the lumbar region lateral and medial intertransverse muscles are present. The lateral pass between the extremities of the transverse processes, while the medial connect the mamillary tubercles to the accessory tubercles of the vertebræ above.

Suboccipital Muscles.—These muscles are four in number—obliquus capitis inferior and superior, and rectus capitis posterior major and minor (Fig. 357). They are concealed by the semispinalis capitis, longissimus capitis, and splenius capitis, and enclose a triangular space (the suboccipital triangle) which contains the vertebral artery, the posterior primary ramus of the first cervical nerve, the posterior arch of the atlas, and the posterior atlanto-occipital membrane.

The **obliquus capitis inferior,** the stoutest of the group, **arises** from the spine of the axis vertebra and passes upward and laterally to be **inserted** into the transverse process of the atlas. The greater occipital nerve curls round the inferior border of this muscle.

The **obliquus capitis superior arises** from the transverse process of the atlas and passes backwards, upwards and medially to be **inserted** into the occipital bone, deep and lateral to the semispinalis capitis, above the inferior nuchal line (Fig. 356). The upper border of the muscle is closely related to the posterior belly of the digastric at its origin, and the occipital artery runs backwards between them.

The **rectus capitis posterior major arises** from the spine of the axis and **is inserted** into the occipital bone, deep to the obliquus capitis superior and semispinalis capitis, below the inferior nuchal line (Fig. 356).

The **rectus capitis posterior minor arises** deep to the preceding muscle from the posterior tubercle of the atlas and **is inserted** into the occipital bone below the inferior nuchal line, medial and deep to the rectus major (Fig. 356).

Nerve-Supply.—The deep muscles of the back are, in general, all supplied by the **posterior primary rami** of the **spinal nerves** according to their situation. The medial intertransverse muscles in the lumbar and lower thoracic region are supplied by posterior primary rami, but (as exceptions to the general statement) the lateral intertransverse muscles in the same regions, and both anterior and posterior intertransverse muscles in the cervical region, are supplied by **anterior primary rami.**

The four suboccipital muscles are supplied by branches of the **posterior primary ramus** of the **first cervical nerve.**

Actions of the Deep Muscles of the Back.—These muscles act upon the vertebral column, head, ribs, and pelvis, producing, according to circumstances, flexion, extension, lateral bending and rotation. It is of special importance, in connection with the many disabilities that arise from faulty posture, injuries to the back, "muscular strains", etc., to remember that they are in constant action against gravity in maintaining the erect and sitting postures. Like all other muscles they pass readily into reflex contraction to prevent painful movements; the difficulty experienced in performing *any* muscular action efficiently when the muscles of the back are thus in rigid contraction emphasizes strongly the principle of the co-operation of all the muscles of the body in the simplest action.

The deep muscles of the back not only control the gravitational descent of the body in bending forwards (flexion), but also act powerfully in regaining the erect position (extension). The extensor muscles of the vertebral column are therefore twice as massive as the flexors—just the opposite of the proportions found in anthropoid apes (Fick, 1911). If extension is continued beyond the erect position—backward bending (Pl. XXIX, p. 342, Fig. 2)—the important action is the relaxation of the sterno-mastoid and the abdominal and prevertebral groups to permit and control the movement. If flexion of the column is resisted, or is performed against gravity as in getting up from the supine position, then the prevertebral muscles, to which the sterno-mastoid and the abdominal groups functionally belong, are called into action. Gravitational control is again concerned in lateral flexion. The oblique parts of the post-vertebral and prevertebral muscles, the oppositely-directed fibres of the two sides working in unison, produce rotation—a movement that occurs also in the lumbar region. The muscles that produce lateral flexion act with those that produce rotation, which must also occur during side-bending. Although relaxation of the post-vertebral group secures forward bending (flexion) of the body, it should be noted that the greater part of this movement is executed not so much by the vertebral column as by relaxation of the hamstring muscles to allow flexion of the hip.

The association of the post-vertebral muscles with the limb-muscles in walking (p. 408) and also their postural action (p. 409) have already been mentioned. The muscles acting upon the head, particularly those of the suboccipital group, may be associated

with the muscles of the eyeballs; for example, when the eyes are turned to one side, the head also is turned to that side.

The student will appreciate therefore that the following statement of isolated muscle actions is merely a summary of mechanical deductions and is of little clinical value.

Splenius cervicis—Extension and lateral flexion of vertebral column to the same side.
Splenius capitis—Extension of head, and lateral flexion and rotation to the same side.
Sacro-spinalis, multifidus and semispinalis—Extension, lateral flexion, and rotation of column; extension and lateral movement of pelvis in walking.
Longissimus capitis and semispinalis capitis—Extension, lateral flexion and rotation of the head.
Inferior oblique—Extension, lateral flexion and rotation of the atlas (with the head) on the axis.
Superior oblique—Extension, lateral movement and rotation of the head on the atlas.
Rectus capitis posterior major—Extension, lateral flexion and rotation of the head.
Rectus capitis posterior minor—Extension and lateral flexion of the head.

FASCIÆ OF THE BACK

The **superficial fascia** of the back is thick and tough, and contains a quantity of granular fat.

The **deep fascia** is attached to the superior nuchal line of the occipital bone and in the median plane to the ligamentum nuchæ, and, below this level, to the supraspinous ligaments and vertebral spines—thus extending from the skull to the back of the sacrum and coccyx. Its fibres are mainly transverse. It ensheaths the superficial muscles of the back and becomes continuous with the fascia of the neck, axilla, thorax, and abdomen (cf. Fig. 412, p. 483). In the shoulder region it is attached to the spine and acromion of the scapula and to the clavicle, and sweeps over the deltoid into the arm. Below and laterally it is attached to the iliac crest.

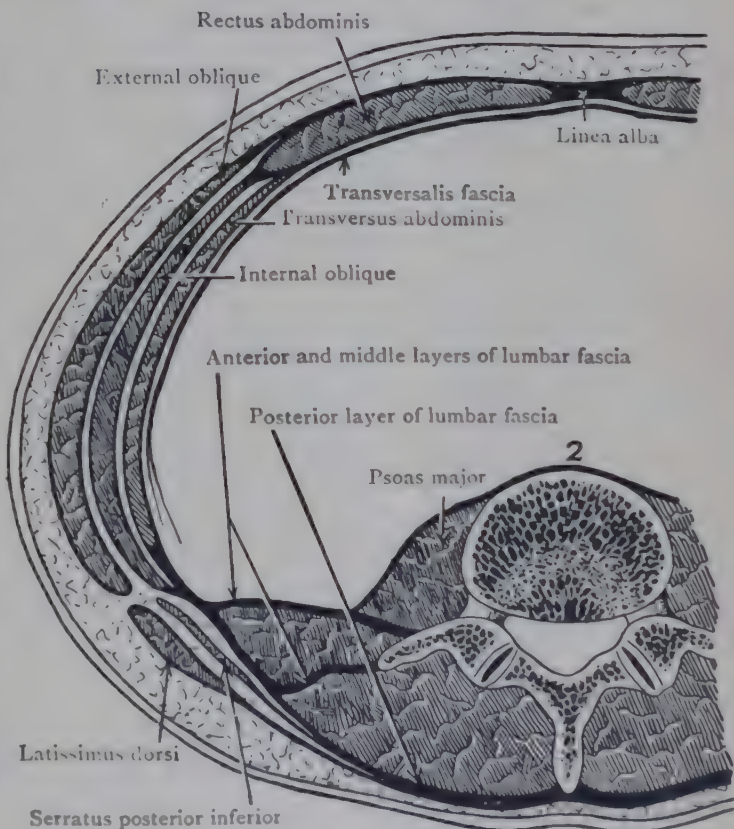

FIG. 358.—TRANSVERSE SECTION THROUGH THE ABDOMEN AT LEVEL OF SECOND LUMBAR VERTEBRA.

In the loin, the deep fascia is specially named the **lumbar fascia** and is divided into three layers—posterior, middle, and anterior—which enclose muscles between them; but the posterior layer is the only one of the three that is continuous with the deep fascia above the loin. In the course of development the deep muscles of the back, within their fascial sheaths, become covered by muscles derived from myotomes developed in other situations, for example, by the trapezius, rhomboid and latissimus dorsi muscles. The sheet that covers the posterior surface of the deep muscles of the back therefore runs upwards under the superficial muscles, becomes attached to the angles of the ribs lateral to the ilio-costo-cervicalis, and blends with the aponeurosis of serratus posterior superior in its course. In the sacral and lumbar regions, because of the interweaving of this sheath with the tendinous expansion of the latissimus dorsi and serratus posterior inferior, it becomes a strong, glistening aponeurosis termed the **posterior layer of the lumbar fascia**. This layer is attached medially to the lumbar and sacral

spines and supraspinous ligaments, laterally to the iliac crest; it covers the sacro-spinalis muscle, and is continuous round the lateral border of this muscular column with another fascial plane—the **middle layer of the lumbar fascia.** The middle layer is the continuation of the posterior aponeurosis of the transversus abdominis. It extends medially to be attached to the tips of the lumbar transverse processes. It covers the posterior surface of the quadratus lumborum and separates its medial part from the sacro-spinalis. Its upper border, between the twelfth rib and the first lumbar transverse process, blends with the lumbo-costal ligament. The **anterior layer** is the thinnest of the three. It covers the front of the quadratus lumborum and separates its medial part from the psoas major. Medially, it is attached to the fronts of the lumbar transverse processes. Laterally, it blends with the middle layer at the lateral margin of the quadratus to form a narrow band that stretches from the last rib to the iliac crest. Its upper border, between the twelfth rib and the first lumbar transverse process, forms the lateral arcuate ligament, which gives origin to part of the diaphragm and behind which the subcostal nerve and vessels pass from the thoracic to the abdominal wall.

MUSCLES AND FASCIÆ OF HEAD AND NECK

Deep Lateral and Prevertebral Muscles of Neck

There are three series of muscles in this group: (1) vertebro-costal (scalenus anterior, medius and posterior), (2) vertebro-cranial (longus capitis and rectus capitis anterior and lateralis), and (3) intervertebral (longus cervicis). They clothe the antero-lateral borders of the cervical portion of the vertebral column, and are in relation anteriorly with the pharynx and œsophagus, and the large vessels and nerves of the neck.

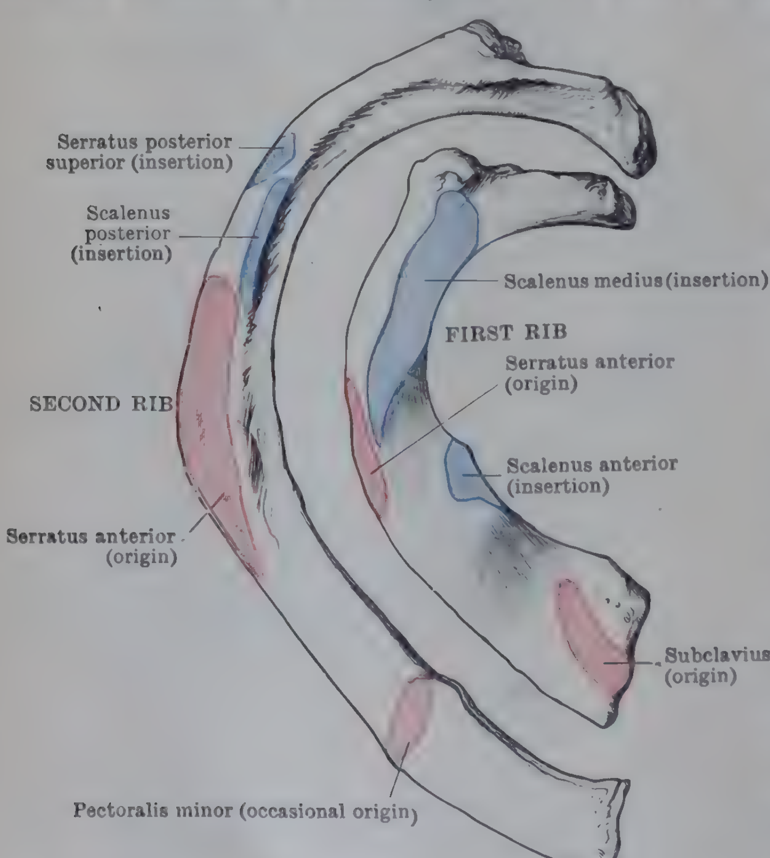

Fig. 359.—Muscle-Attachments to Upper Surface of First Rib and Outer Surface of Second Rib (Right Side).

Scalenus Anterior.—The scalenus anterior **arises** from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ. It runs downwards and laterally to be **inserted** into the scalene tubercle and ridge on the first rib (Figs. 359, 360, 381).

The phrenic nerve is formed at the upper part of the lateral border of the scalenus anterior, runs vertically downwards on its anterior surface, and leaves its medial border a little above its insertion. The pre-vertebral fascia covers the muscle and binds down the phrenic nerve to its surface. With the exception of its insertion, which lies behind the clavicle, the muscle is completely covered by the sterno-mastoid, but the inferior belly of the omo-hyoid and the internal jugular vein intervene between them. It is separated posteriorly from the scalenus medius by the roots of the brachial plexus and the subclavian artery, while just anterior to its insertion the subclavian vein grooves the rib. Spasm of

the scalenus anterior with consequent elevation of the first rib may cause irritation of the fibres of the plexus that cross the rib, and section of the tendon has been successful in relieving the symptoms.

Scalenus Medius.—The scalenus medius **arises** from the posterior tubercles of the transverse processes of all the cervical vertebræ—occasionally omitting the first or the seventh. It descends in the posterior triangle, behind the brachial plexus and the subclavian artery, to be **inserted** into the rough impression on the first rib behind the subclavian groove (Fig. 359). The nerve to the rhomboids and the upper two roots of the nerve to the serratus anterior pierce the muscle, and descend on its lateral aspect under cover of the fascia.

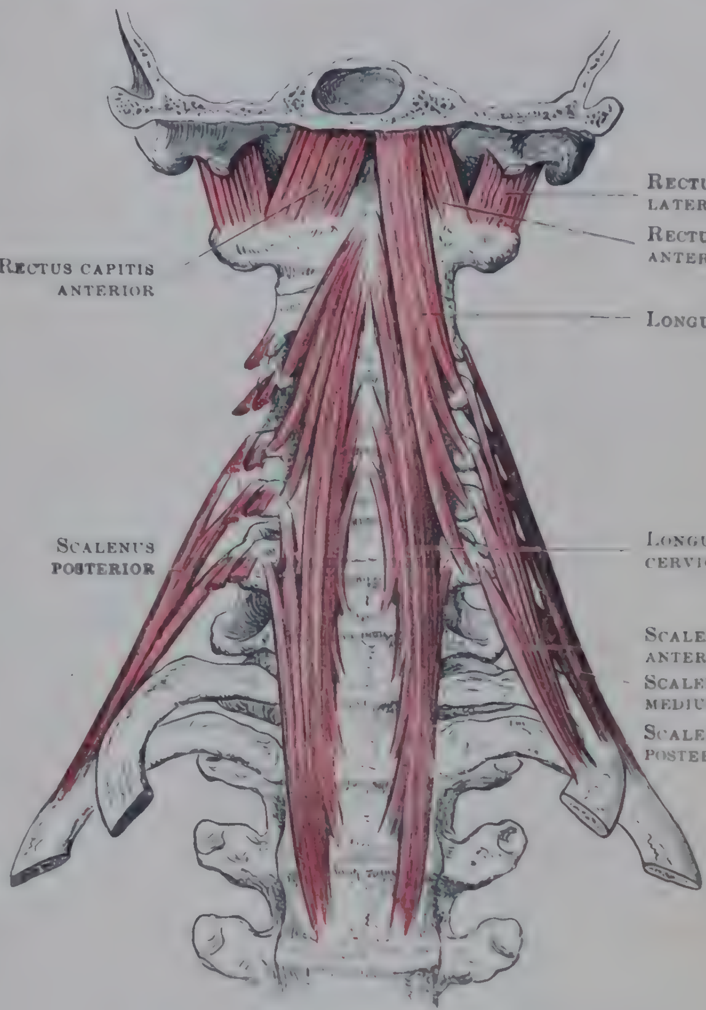

Fig. 360.—Prevertebral Muscles of the Neck.

Between these scalene muscles laterally and the longus cervicis medially, there is a pyramidal space into the base of which the pleura projects, capped by a fascial membrane that may be strengthened by a few slips from the scalene muscles and their fascial sheaths. The vertebral vessels run to the apex of this pyramid.

Scalenus Posterior.—The scalenus posterior **arises**, behind the scalenus medius, from the posterior tubercles of the fourth, fifth, and sixth cervical transverse processes. It is **inserted** into an impression on the outer side of the second rib behind the origin of serratus anterior.

At first completely hidden by the scalenus medius, the scalenus posterior appears in the lowest part of the floor of the posterior triangle in the angle between the scalenus medius and the levator scapulæ muscles.

Longus Capitis.—The longus capitis **arises** from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ. It is a flat, triangular muscle which is directed upwards, behind the carotid sheath, and overlapping the upper oblique part of the longus cervicis muscle, to be **inserted** into an impression on the inferior surface of the basilar part of the occipital bone, anterior and lateral to the pharyngeal tubercle (Fig. 356).

Rectus Capitis Anterior.—The rectus capitis anterior **arises**, under cover of the longus capitis, from the lateral mass of the atlas. It is **inserted** into the basilar part of occipital bone between the longus capitis and the occipital condyle (Fig. 356).

Longus Cervicis.—The longus cervicis is a flattened muscular band which extends from the third thoracic vertebra to the atlas. It is divisible into three portions—a vertical, an inferior oblique, and a superior oblique portion. The **vertical portion** of the muscle **arises** from the bodies of the first three thoracic and the last three cervical vertebræ. Passing vertically upwards, it is **inserted** into the bodies of the second, third, and fourth cervical vertebræ (Fig. 360). The **inferior oblique portion arises** from the bodies of the first three thoracic vertebræ and is **inserted** into the anterior tubercles of the transverse processes of

the fifth and sixth cervical vertebræ. The **superior oblique portion arises** from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ and is directed upwards to be **inserted** into the anterior tubercle of the atlas.

Rectus Capitis Lateralis.—The rectus capitis lateralis, in series with the posterior intertransverse muscles in the neck, **arises** from the transverse process of the atlas, and is **inserted** into the inferior surface of the jugular process of the occipital bone. It is placed alongside the rectus capitis anterior, separated from it by the anterior primary ramus of the first cervical nerve, and is covered anteriorly by the internal jugular vein.

Nerve-Supply.—All the muscles of this group are supplied by branches from the **anterior primary rami** of the **cervical nerves**—the recti from the loop between the first two, the longus capitis from the first four, the longus cervicis from second to eighth, and the scaleni from the lower five or six.

Actions.—The muscles of this group act together with, and as antagonists to, the cervical postvertebral muscles in movements of the neck and head. Against gravity and resistance they are flexors of the cervical vertebral column and of the head upon the column (including lateral flexion), according to their attachments. They also take part in movements of rotation; the lower oblique part of the longus cervicis, for example, may help to produce rotation to the opposite side. The *scalene* muscles, in addition to their action as lateral flexors of the vertebral column, are important accessory muscles of respiration as elevators of the first and second ribs.

MUSCLES OF THE HEAD

The muscles of the head are divisible into three separate groups: superficial (cutaneous) muscles, muscles of the orbit, and muscles of mastication.

Superficial Muscles

The superficial muscles are those of the scalp and face, and the platysma (which lies chiefly in the neck).

Muscles of the Scalp

The muscles of the scalp are the occipito-frontalis muscle and the extrinsic muscles of the auricle.

Occipito-Frontalis—The occipito-frontalis is a muscle with two pairs of bellies —frontal and occipital—united by a tendinous sheet, called the epicranial aponeurosis, which stretches uninterruptedly across the median line of the cranium. Each **occipital belly arises** as a broad flat band from the lateral two-thirds of the superior nuchal line of the occipital bone. The **frontal bellies** have no bony attachments. Each **arises** from the epicranial aponeurosis about the level of the coronal suture and passes downwards to the supra-orbital arch, where it interlaces with the orbicularis oculi muscle and is **inserted** into the skin. The two frontal bellies extend across the full width of the forehead and blend with each other in the median plane.

The **epicranial aponeurosis,** extending between the frontal and the occipital fleshy bellies, caps the dome of the skull, and has been termed the galea aponeurotica (from *galea*, a leather helmet). Posteriorly, it is attached to the superior nuchal line—its medial part directly, and its lateral part indirectly through the occipital bellies. Anteriorly, it joins the frontal bellies, sending a short slip between them; and a fascial layer beneath that is fixed to the supra-orbital margin. Laterally, it gives origin to the superior and anterior auricular muscles, and is continued downwards as a thin sheet that blends with the temporal fascia a short distance above the zygomatic arch. The superficial surface is bound to the skin of the scalp by dense fibrous strands with enmeshed fatty granules, but the deep surface is connected with the pericranium only by loose areolar tissue.

The attachments of the aponeurosis limit effusions beneath it which may extend forwards to the supra-orbital margin and downwards almost to the zygomatic arch. The mobility of

the scalp as a whole accounts for the readiness with which it may be torn away from the pericranium and for the scalp-hunter's dexterity in removing his victim's scalp by cutting through the aponeurosis.

The **extrinsic muscles of the auricle** are three in number: posterior, superior, and anterior. They are rudimentary and usually functionless, though variable in development and capable of training.

The **auricularis posterior** is a narrow fleshy slip which **arises** from the surface of the mastoid part of the temporal bone and is **inserted** into the cranial surface of the auricle. It bridges across the groove between the mastoid part of the temporal bone and the auricle, and conceals the posterior auricular vessels and nerve.

The **auricularis superior** is a fan-shaped muscle and is the largest of the three.

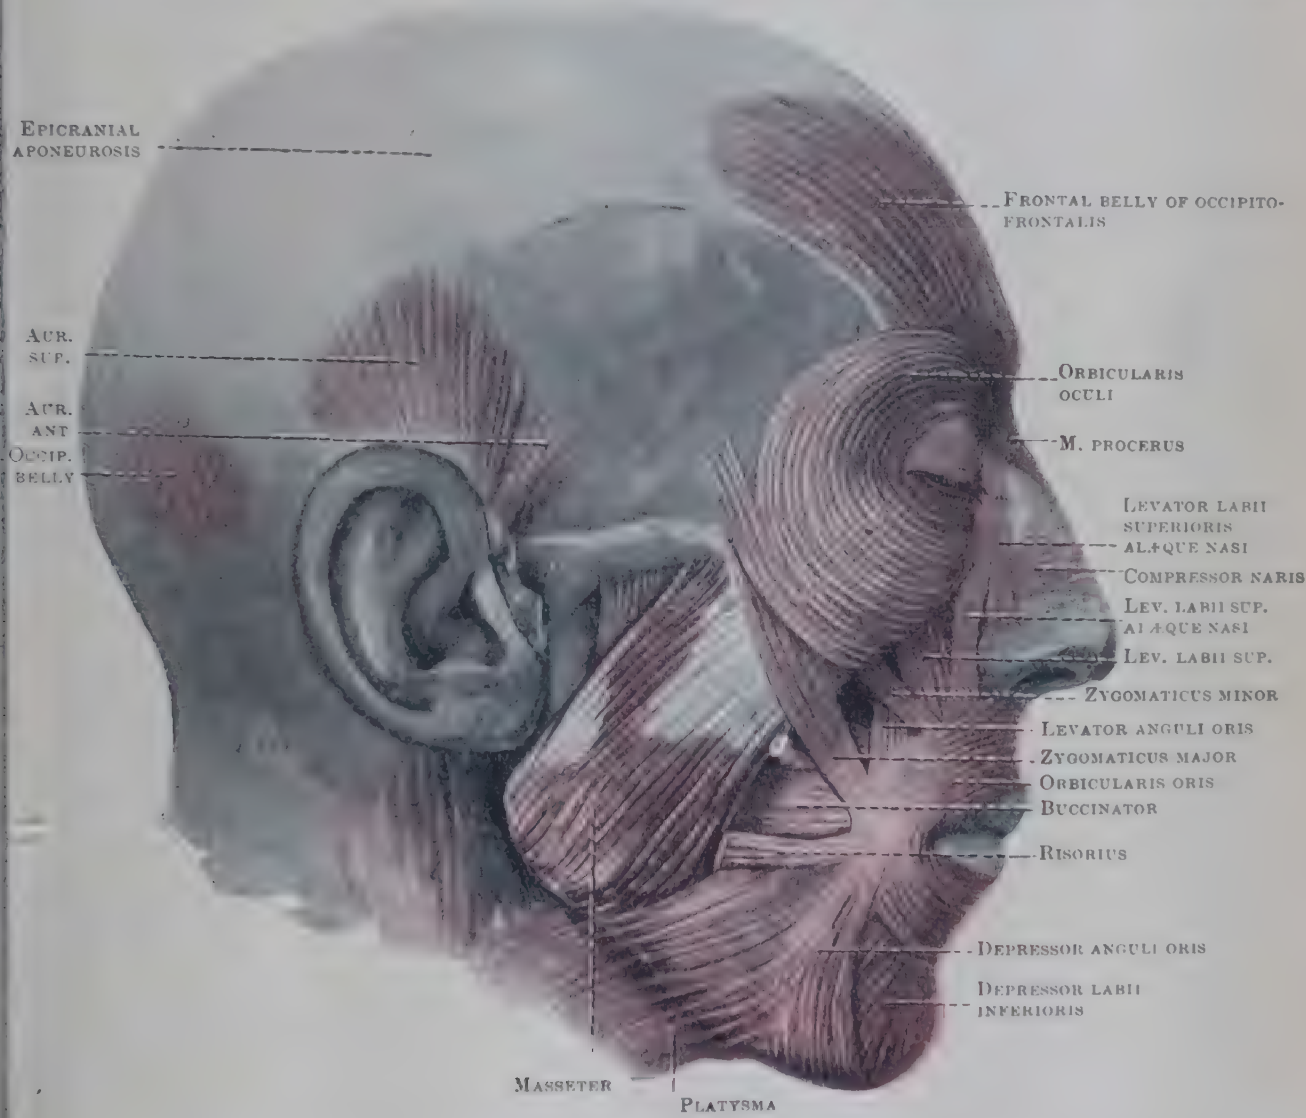

FIG. 361.—MUSCLES OF FACE AND SCALP (Muscles of Expression).

It **arises** from the epicranial aponeurosis and the temporal fascia, and descends to be **inserted** into the medial surface of the auricle opposite the fossa of the antihelix.

The **auricularis anterior** is a small muscle placed in front of the auricularis superior; it stretches obliquely from the temporal fascia to the anterior part of the medial surface of the helix.

The intrinsic muscles of the auricle and the small muscles of the tympanic cavity (tensor tympani and stapedius) are described with the Ear as an Organ of Sense.

Muscles of the Face

The facial muscles are divided into groups associated with the eyelid, the external nose, and the mouth.

1. The **muscles of the eyelids** are the orbicularis oculi, and the levator palpebræ superioris—which is described with the orbital muscles (p. 428).

Orbicularis Oculi.—The orbicularis oculi is a transversely oval sphincter muscle that surrounds and occupies the eyelids (Fig. 361). It is divisible into two parts which differ in action. The peripheral, **orbital part** has red, thick fibres, spreads on to the forehead, temple, and cheek, and closes the eyes forcibly; the central, **palpebral part** has pale, thin fibres, is situated beneath the skin of the eyelids, and closes the eyes gently.

The **orbital part** is attached to the medial orbital margin between the supra-orbital notch and the infra-orbital foramen—the medial palpebral ligament, also a source of origin, interrupting this bony attachment. Fibres arch from the site above the ligament round the upper lid and then return round the lower lid to the site below the ligament, without interruption laterally. (Some authors describe interlacing of the fibres of both lids laterally.) A deep bundle (*corrugator supercilii*), inseparable from the orbital fibres and arising from the medial part of the supra-orbital margin, runs, intermingling laterally with the superficial fibres, to be inserted into the skin of the medial half of the eyebrow.

The **palpebral part** has two origins—a superficial origin from the medial palpebral ligament and adjacent bone, and a deep origin from the crest of the lacrimal bone. The superficial fibres (preseptal) arch round the peripheral (septal) portions of the eyelids, while the deep fibres (pretarsal) pass across the tarsal plates; both sets interlace at the lateral angle to form the *lateral palpebral raphe*. The deep fibres, termed the *lacrimal part*, enclose the lacrimal canaliculi and run posterior to the lacrimal sac. A slip of delicate fibres, called the *ciliary bundle*, runs from the palpebral part along the free margin of each lid behind the eyelashes.

2. The **muscles of the nose**, small and feeble, are the procerus, compressor naris, dilator naris, and depressor septi.

Procerus.—The muscles of the two sides are united. **Arising** from the fascia covering the lower parts of the nasal bones, they broaden to be **inserted** into the skin between and above the eyebrows, interlace with the frontal bellies of the occipito-frontalis, and draw down the skin at the root of the nose and produce transverse wrinkling of the skin in this area.

Compressor Naris.—This muscle **arises** from the upper end of the canine eminence and is **inserted** with its fellow into an aponeurosis on the cartilaginous part of the nose. It compresses the nostril in the production of certain sounds, and its action is well seen in the crying infant.

Dilator Naris.—The dilator naris **arises** from the maxilla above the lateral incisor tooth and is **inserted** into the lateral part of the lower margin of the ala of the nose. It dilates the nostril.

The **depressor septi** is a flat quadrangular muscle that **arises** with the medial fibres of the dilator and is **inserted** into the mobile part of the nasal septum. It draws the septum downwards and narrows the nostril.

3. The **muscles of the mouth** are bilaterally placed, except for orbicularis oris. They are:—(1) orbicularis oris; (2) levator labii superioris alæque nasi; (3) levator labii superioris; (4) zygomaticus minor; (5) levator anguli oris; (6) zygomaticus major; (7) risorius; (8) depressor anguli oris; (9) depressor labii inferioris; (10) mentalis; (11) buccinator. With them may be considered the platysma, as it is a prolongation downwards into the neck of the same superficial sheet.

Orbicularis Oris.—The orbicularis oris is a sphincter formed by contributions from muscles converging on the mouth; it arches around the two lips, its constituent fibres partly interlacing at the angles of the mouth, thereby forming a nodule that may be felt in the living subject. Lying between the skin and mucous membrane of the lips, it is limited superiorly by the nose, and inferiorly by the junction of the lower lip and chin. The deeper fibres in the upper lip are derived from the buccinator muscle, reinforced by the *superior incisive* bundles. This pair of little bands arises from the nasal septum and from the maxilla above the lateral incisor teeth, and each passes laterally towards the angle of the mouth. The more superficial fibres are continued upwards from the depressor anguli oris and are inserted into the skin of the central part of the lip. A similar arrangement is found in the orbicularis oris in the lower lip. The deeper fibres are derived from the buccinator, but they are reinforced on each side by an *inferior*

incisive bundle, which runs laterally from the mandible below the canine tooth. The more superficial fibres are continued downwards from the levator anguli oris to be inserted into the skin of the median part of the lip.

Levator Labii Superioris Alæque Nasi.—With the dual action implied in its name, this is a narrow band that **arises** from the root of the frontal process of the maxilla, and descends along the side of the nose to be **inserted** partly into the ala of the nose and partly into the skin of the naso-labial groove, blending with the orbicularis oris.

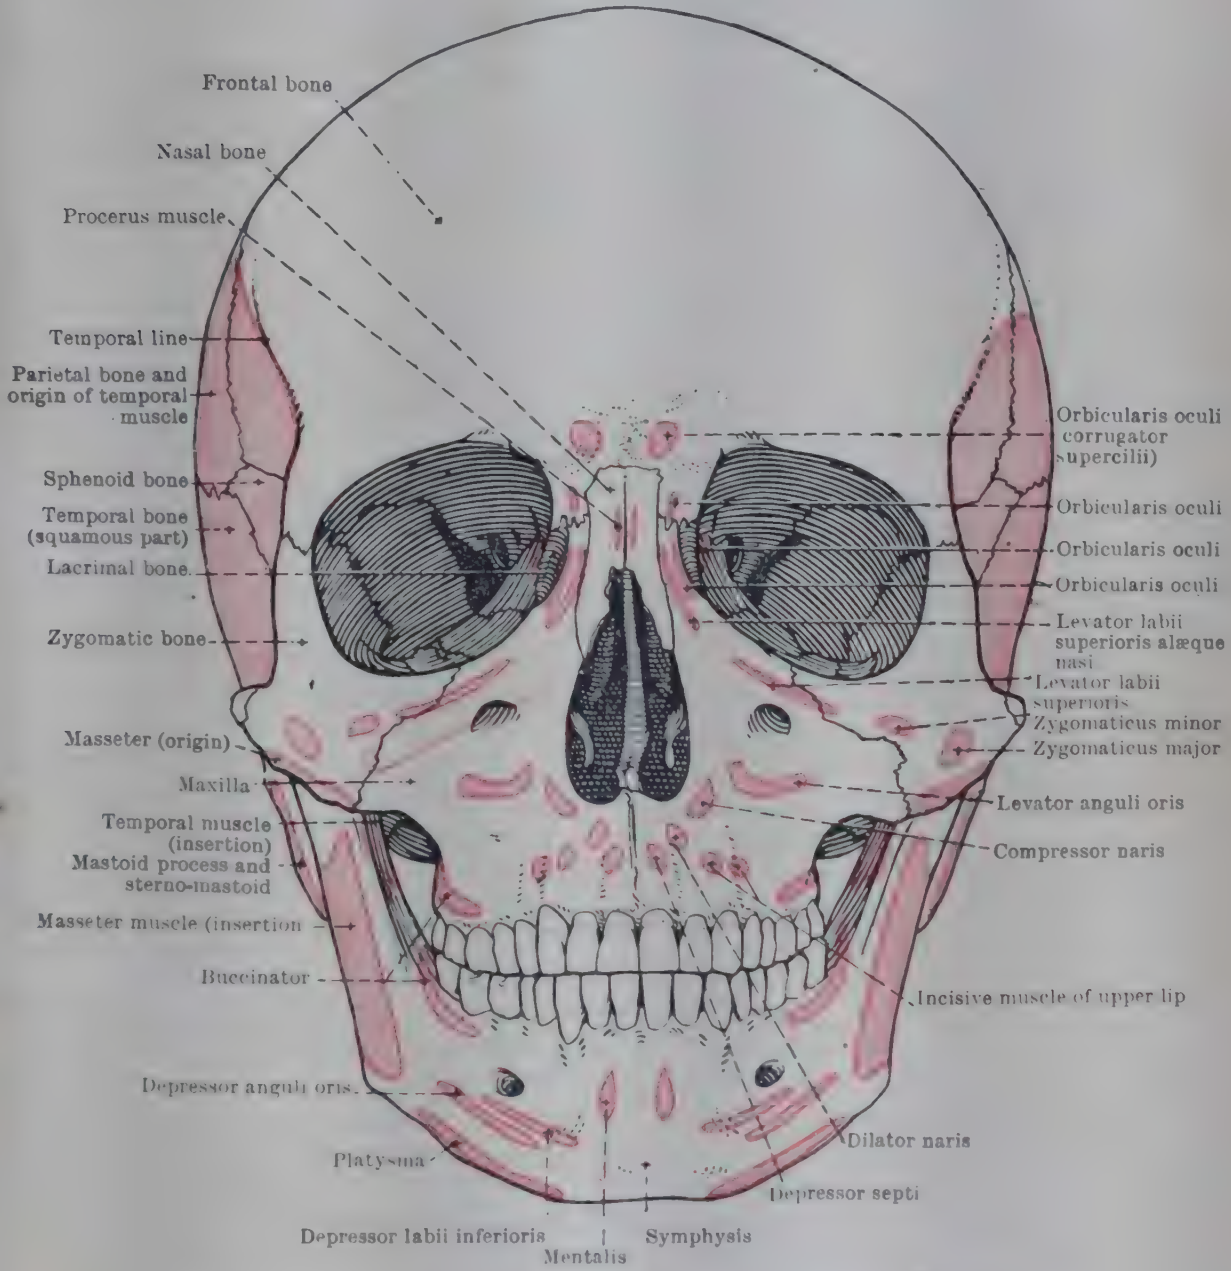

FIG. 362.—ANTERIOR VIEW OF SKULL, SHOWING THE MUSCULAR ATTACHMENTS.

Levator Labii Superioris.—The levator labii superioris **arises** from the maxilla immediately above the infra-orbital foramen, and it is **inserted** into the skin of the naso-labial groove; it conceals the infra-orbital vessels and nerve.

Zygomaticus Minor.—This slender slip **arises** from the zygomatic bone and is often continuous near its origin with the orbicularis oculi; it is **inserted** into the skin of the naso-labial groove and upper lip.

Levator Anguli Oris.—The levator anguli oris **arises** from the maxilla below the infra-orbital foramen and under cover of the zygomaticus minor. It is directed laterally and downwards, to be **inserted** into the orbicularis oris and the skin at the angle of the mouth, some fibres arching into the lower lip.

Zygomaticus Major—This narrow muscular band **arises** from the zygomatic portion of the zygomatic arch and passes to the angle of the mouth to be **inserted**

partly into the skin, partly into the orbicularis oris. When this muscle is involved in tetanus its spasm produces the facial appearance known as 'risus sardonicus'.

Risorius.—The risorius is a thin flat muscle which is in part a continuation of the platysma on the face, and in part a separate muscle, with an **origin** from the parotid fascia. It passes transversely forwards to be **inserted** into the skin at the angle of the mouth.

Depressor Anguli Oris—This muscle **arises** from the oblique line of the mandible and is continuous with the platysma (Fig. 361). It is triangular in form, its fibres converging on the angle of the mouth, where they are **inserted** into the orbicularis oris and the skin. Some of the fibres reach the upper lip through the orbicularis muscle.

Depressor Labii Inferioris—The depressor of the lower lip **arises** from the lateral surface of the mandible deep and medial to the depressor anguli oris (Fig. 362). It is quadrilateral in form and is directed upwards to be **inserted** into the orbicularis oris and the skin of the lower lip. Its lateral fibres are overlapped by the depressor anguli oris, and its medial fibres join with those of the opposite muscle.

Mentalis.—This small muscle **arises** from the mandible below the incisor teeth and passes downwards to be **inserted** into the skin of the chin.

Buccinator.—The buccinator muscle lies in the side-wall of the mouth, and is in series posteriorly with the constrictor muscles of the pharynx. **It arises** from the outer surfaces of the maxilla and mandible opposite the sockets of the molar teeth (Fig. 362), and from the pterygo-mandibular ligament. Its fibres are directed forwards to the angle of the mouth, where they blend with the corresponding (upper and lower) portions of the orbicularis oris muscle. The *middle fibres* of the muscle decussate at the angle of the mouth—the lower set passing to the upper lip, the upper set to the lower lip (cf. orbicularis oris, p. 424). Where the decussation occurs a firm node may easily be felt by gripping the angle between the finger and thumb. The buccinator is covered on its deep surface with the mucous membrane of the mouth. Towards its insertion it is concealed by the muscles which converge on the angle of the mouth; and it is covered behind by the masseter, from which it is separated by the buccal pad of fat. It is pierced by the duct of the parotid gland, and by branches of the buccal nerve. A small gap between the fibres arising from the maxilla and those arising from the pterygo-mandibular ligament transmits the tendon of the tensor palati as it bends round the pterygoid hamulus to gain the soft palate.

Platysma.—The platysma is a thin, quadrilateral sheet that **arises** in the upper pectoral and deltoid regions by scattered bundles from the superficial fascia and the skin, and extends from the chest over the side of the neck between the superficial and deep fasciæ to the face (Fig 361 and Pl. XXXVII, p. 456, Fig. 1).

It is directed upwards and forwards, and is partly **inserted** (by its intermediate fibres) into the lower border of the mandible, becoming connected with the depressor labii inferioris and depressor anguli oris muscles (Figs. 361, 362). The more anterior fibres pass across the median plane and decussate with those of the opposite side for a variable distance below the chin. The posterior fibres sweep over the angle of the jaw and become continuous with the risorius muscle.

Nerve-Supply.—The facial and scalp muscles are all innervated by the **facial nerve**. The *posterior auricular branch* supplies the posterior auricular muscle and the occipital belly of occipito-frontalis; the branches into which the facial nerve breaks up in the parotid gland supply the frontal belly, the superior and anterior auricular muscles, the several muscles associated with the apertures of the orbit, nose, and mouth (including the buccinator), and the platysma (cervical branch). The facial nerve conveys motor fibres to these muscles, and sensory fibres from them which gain the nucleus of the fifth nerve (Wakeley & Edgeworth, 1933); there is a similar arrangement in the innervation of the ocular muscles (p. 430) and probably also for the muscles of mastication and the muscles of the tongue.

Actions.—The almost infinite variety of facial expression is produced partly by the action of these muscles, partly by their inactivity, or by the action of antagonising muscles (antithesis). Joy is betrayed by the action of one set of muscles, while grief is accompanied by the contraction of an opposing set. Determination or eagerness is accom-

panied by a fixed expression due to a combination of muscles acting togeth ; and despair is expressed by a relaxation of muscular action.

The frontal belly of **occipito-frontalis** raises the eyebrows as in surprise, contraction of the occipital and frontal bellies moves the scalp backwards and fo ternate The **auricular** muscles may be capable of moving the auricle upwards and backwards. rds.

The **procerus,** assisting the upper deep part of the orbital portion of orbicularis ocu in wrinkling the skin at the root of the nose and adjacent part of the forehead, is s li habitually in use in some people as to be almost involuntary in its action. The **orbicularis oculi** contracts in protecting the eye from intense light and injury. The **orbital part** closes the lids firmly; the **palpebral part** closes the lids gently and keeps them applied to the eyeball, but it acts also reflexly—contracting periodically to moisten and clean the eye. This it does by drawing the eyelids medially and thereby wiping the tears across the eyeball to the lacus lacrimalis where they drain into the puncta. The *lacrimal part* is important because its destruction, *e.g.*, in operations on the lacrimal sac, results in the lower lid falling away from the eyeball (ectropion—seen also in facial paralysis). This portion also probably dilates the lacrimal sac and canaliculi. The levator palpebræ superioris and occipito-frontalis are antagonists of the orbicularis oculi. The **muscles of the nose** take part in contraction and dilatation of the nostrils. Their tonic action supports the alæ nasi, which do not move during ordinary respiration; but in deep and laboured respiration a visible movement of elevation and expansion takes place with each inspiration. In enfeebled states, on the other hand, owing to the diminution of the tonic action, the alæ nasi are drawn in with each inspiration giving a characteristic 'sharp' appearance to the nose. Of the muscles of the mouth, the **orbicularis oris** has a complex action, depending on the degree of contraction of its component parts, producing compression, contraction, and protrusion. The **zygomaticus major** and **risorius** are associated with mirth, the **depressor anguli oris** with grief, while the **mentalis** raises the skin of the chin and protrudes the lower lip.

The muscles of the lips are concerned in the production of speech, and they have an important function in retaining food during mastication. The delicate co-ordination between the **buccinator** and the tongue muscles in keeping food poised between the grinding teeth may be appreciated by the infrequency of the accident of biting either the inside of the cheek or the tongue. Apart from retracting the angles of the mouth as antagonists of the orbicularis oris, the buccinators control the expulsion of air from the distended cheeks (*buccinator*—a trumpeter). With the orbicularis protruding the lips the buccinators cave in the cheeks, producing a suctorial action. The **platysma** (Pl. XXXVII, p. 456, Fig. 1) retracts and depresses the angle of the mouth. Its contraction when the head is extended produces longitudinal ridging of the skin, well seen in violent stages of athletic effort, and the view has been advanced that its contraction prevents the retraction of the soft tissue at the root of the neck which would press on the veins and impede the return of blood to the heart in violent inspiratory effort. Its action is evident in sudden fear. It depresses the mandible, but only against resistance.

When the muscles of one side of the face are paralysed because of injury to the facial nerve (peripheral paralysis) the face is twisted to the opposite side by the unopposed pull of the sound muscles of that side; and, on the opposite side, the lines of the features are smoothed out, the eye cannot be closed and tears run down the cheek because the lacrimal puncta are not kept close to the eyeball through the lower lid falling away (see above). The lips are open upon the active side and slightly closed towards the affected side. Food and saliva cannot be retained by the affected cheek, and escape from between the lips on that side.

For further information, see Lightoller (1925); Huber (1931); Bell (1847); Duchenne (1867); and Darwin (1872).

Fasciæ and Muscles of Orbit

The eyeball, with its muscles, vessels, and nerves, is lodged in a mass of soft and yielding fat within the cavity of the orbit. The eyeball is surrounded by a fascial cup called the **fascial sheath of the eyeball**, which is loosely connected with the sclera by easily cleft *episcleral tissue.* The fascial cup accompanies the eyeball in its wider excursions, but there is a slight play of the eyeball within the cup. Anteriorly the sheath is adherent to the overlying conjunctiva, and to the sclera close to the corneal margin while more posteriorly it is pierced by the muscles, vessels, and nerves of the eyeball and is continuous with the sheath of the

...scial cup is thickened at the points where the muscles pierce it, ...ckwards over them as tightly-adherent sleeves, so that the fascial ...t anchor by the fascial expansions or **check ligaments** that extend ...the muscle-sheaths to the orbital walls; the strongest of these ligaments ...ing from the sheaths of the medial and lateral rectus and are called the medial

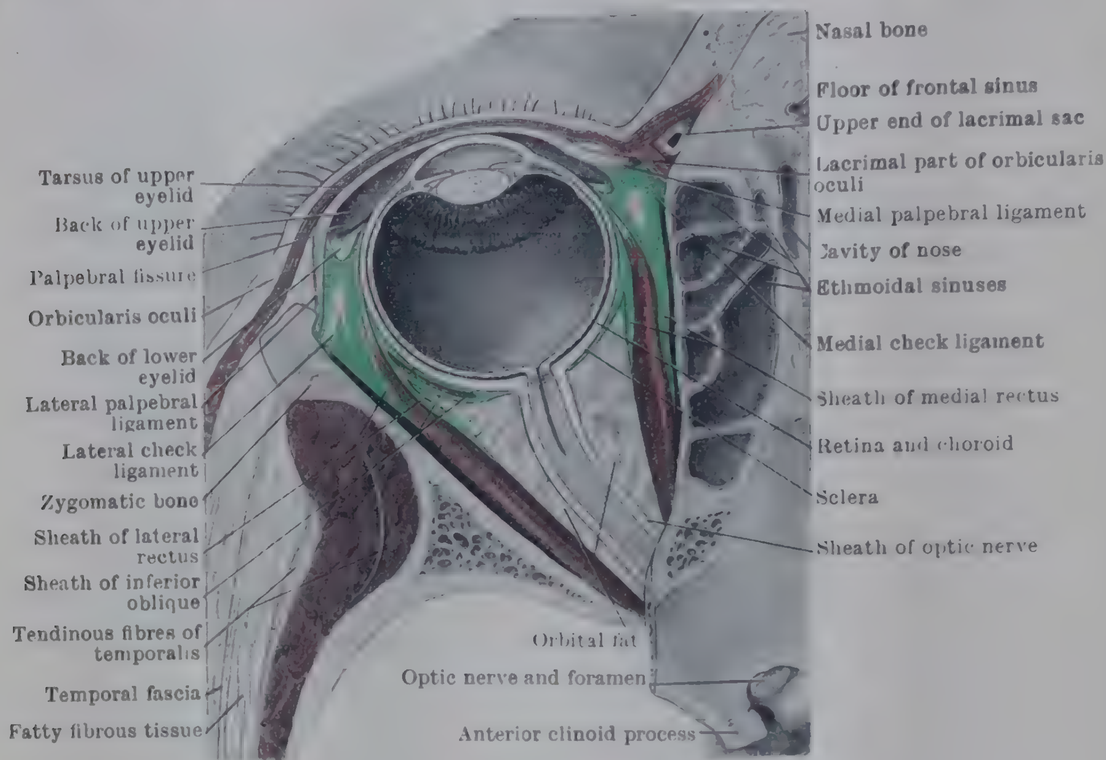

Fig. 363.—Horizontal Section through Left Orbit to show Arrangement of Fascial Sheath of Eyeball and Check Ligaments.

and lateral check ligaments. The *medial check ligament* is attached (1) just behind the crest of the lacrimal bone, (2) to the palpebral fascia behind the pars lacrimalis muscle, (3) to the caruncle and medial conjunctival fornix. The *lateral check ligament* is attached to (1) the orbital tubercle of the zygomatic bone at the mid-point of the orbital margin, (2) the lateral palpebral ligament and the lateral conjunctival fornix (Fig. 363). In the case of the inferior rectus, these expansions, sweeping towards the medial and lateral check ligaments, form a hammock—*suspensory ligament of the eyeball*—that holds the eyeball up in position and must therefore be preserved in surgical removal of the floor of the orbit. The fascial sheath helps to form a socket for an artificial eye when the eyeball is removed, and after this operation the muscles cannot retract far because of their tight adherence to the fascial sleeves.

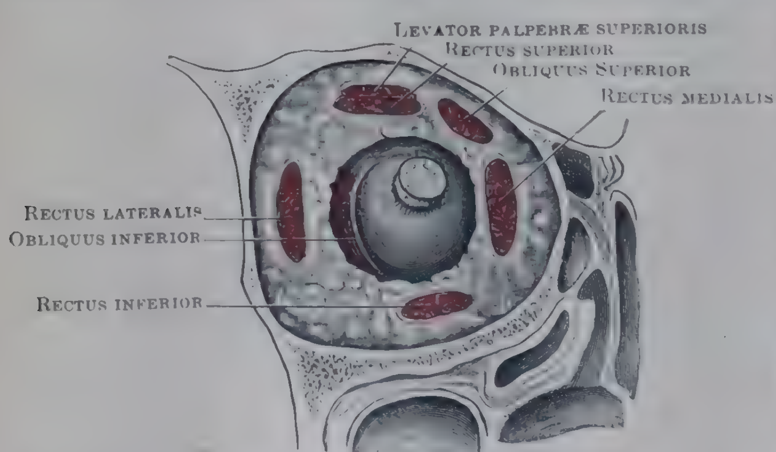

Fig. 364.—Coronal Section through Left Orbit behind the Eyeball to show Arrangement of Muscles.

The muscles of the orbit (Figs. 364-367) are seven in number: one, the levator palpebræ superioris, belongs to the upper eyelid; the other six are extrinsic muscles of the eyeball.

Levator Palpebræ Superioris.—The levator palpebræ superioris lies immediately beneath the roof of the orbit and covers the superior rectus muscle. It has a narrow **origin** from the roof of the orbit in front of the optic foramen. It

expands as it passes forwards to be **inserted**, in relation to the upper lid, into a membranous expansion. This aponeurosis has the following attachments: (1) arching from side to side over the eyeball, its ends, or horns, are fixed to the mid-points of the medial and lateral orbital margins; (2) a superficial layer of fibres from the anterior edge of the aponeurosis runs downwards into the eyelid to become attached to the front of the tarsus, and into the skin of the eyelid with the orbicularis; (3) a layer of plain (involuntary) muscle-fibres **arises** from the deep surface of the aponeurosis and is **inserted** into the upper border of the tarsus of the upper eyelid. The muscle has an additional attachment through its fascial sheath; anteriorly, the sheath is thickened by fusion with the sheath of the rectus superior, and is then attached to the superior fornix of the conjunctiva, so that the fornix also is pulled up when the lid is elevated.

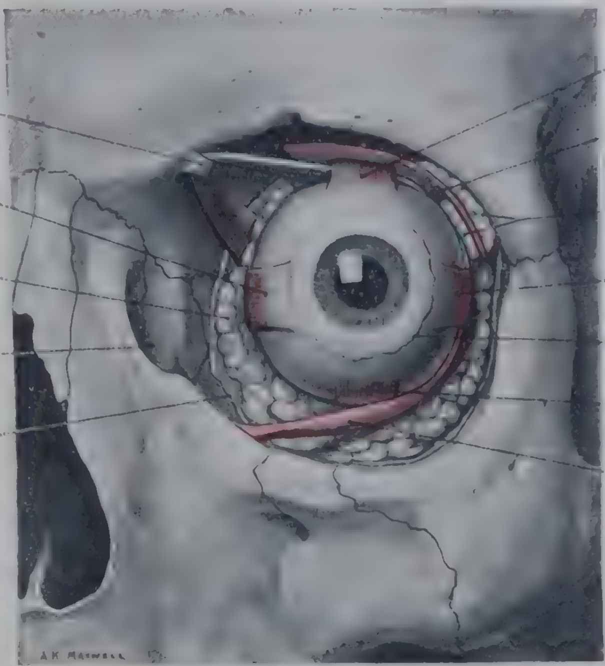

FIG. 365.—DISSECTION OF LEFT ORBIT FROM THE FRONT.

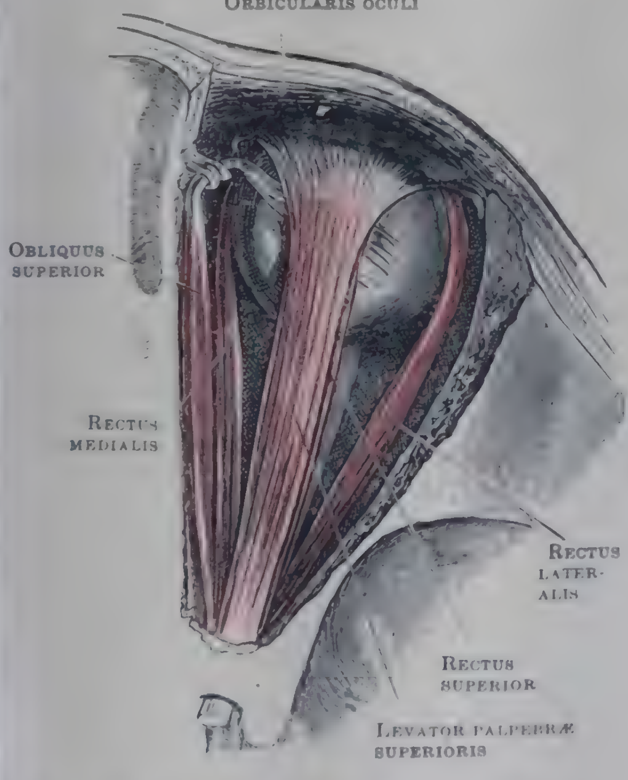

FIG. 366.—MUSCLES OF RIGHT ORBIT (from above).

Non-striated muscle is present in the eyelids of land mammals, but in the seal striated slips run from the recti to the eyelids, a condition partly represented in Man by the striated part of the elevator of the upper lid.

Mm. Recti.—The recti muscles are four in number—**superior, inferior, medial, and lateral**—and they all **arise** from a *common tendinous ring* (Fig. 896, p. 1024). Medially and superiorly the ring is attached around the optic foramen; laterally it bridges across the superior orbital fissure to be fixed to a tubercle on its lower margin. The part of the ring that gives origin to the rectus lateralis transmits the two divisions of the oculomotor nerve, the naso-ciliary nerve, and the abducent nerve between the two heads of origin. Forming flattened bands which lie in the fat around the optic nerve and eyeball, the four muscles end in tendons which pierce the fascial sheath and are **inserted** into the sclera about eight millimetres behind the margin of the cornea.

The **superior** and **inferior recti** are inserted in the vertical plane slightly medial to the vertical axis of the eyeball; the **lateral** and **medial recti** in the transverse plane of the eyeball; and all are attached in front of the equator of the eyeball.

Superior Oblique.—The superior oblique **arises** near the margin of the optic foramen supero-medial to the origin of the rectus medialis. It passes forwards, as a narrow muscular band, medial to the rectus superior, and at the anterior part of the orbit it forms a narrow tendon which passes (invested by a synovial sheath) through a special fibro-cartilaginous pulley (trochlea) attached to the roof of the orbit (the pulley is sometimes palpable in the living subject). Its direction is then altered, and, passing laterally and backwards between the tendon of the superior rectus and the eyeball, it is **inserted** into the sclera between the superior and lateral recti, midway between the margin of the cornea and the entrance of the optic nerve.

Inferior Oblique.—The inferior oblique **arises** from the floor of the orbit immediately lateral to the naso-lacrimal canal. It is a slender, rounded slip which passes laterally and backwards below the inferior rectus tendon and curves upwards between the lateral rectus and the eyeball to be **inserted** into the sclera between the superior and lateral recti, and farther back than the superior oblique muscle.

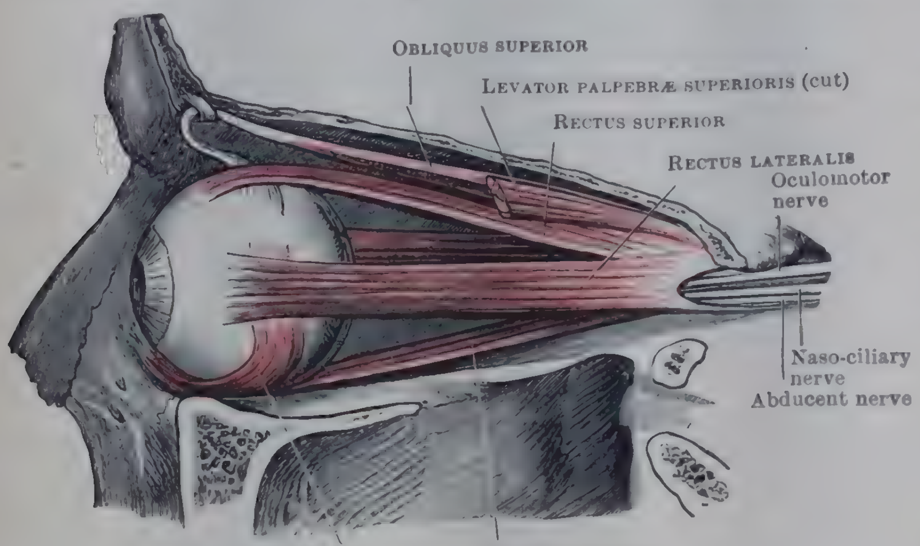

Fig. 367.—Muscles of Left Orbit (from lateral aspect).

The superior oblique muscle occasionally arises from the site of the pulley. This is normal in lower vertebrates, where the muscle is the counterpart of the inferior oblique; in mammals, a posterior belly develops; the two bellies join, and the pulley and tendon are the remains of the original anterior belly.

M. orbitalis is a rudimentary bundle of plain muscular fibres that bridges across the inferior orbital fissure and infra-orbital groove. It is supplied by sympathetic fibres, and it has been suggested that contraction of the muscle compresses the veins, producing congestion that causes the protrusion of the eyeball seen in hyperactivity of the sympathetic nervous system.

Nerve-Supply.—The muscles of the orbit are supplied by the third, fourth, and sixth cranial nerves. The **trochlear (fourth) nerve** supplies the obliquus superior; the **abducent (sixth) nerve** supplies the rectus lateralis; the **oculomotor (third) nerve** supplies the others—the levator palpebræ superioris and rectus superior by its superior division; the rectus medialis and inferior, and the obliquus inferior by its inferior division. The afferent fibres from the ocular muscles run in the third, fourth, and sixth nerves to the nucleus of the fifth nerve (Woollard, 1931; Tarkhan, 1934) (cf. p. 426). The plain muscle-fibres of the eyelids are supplied by the sympathetic system, and the upper lid is retracted or dropped in conditions that stimulate or paralyse this system (Fig. 890, p. 1017).

Actions.—The lateral and medial recti, by virtue of their insertions in front of the equator, rotate the eyeball so as to make the pupil look laterally or medially, respectively. As their insertions extend equally on to the upper and lower quadrants of the sclera, they produce no rotation around the transverse axis of the eyeball.

The superior and inferior recti rotate the eyeball so as to make the pupil look upwards and downwards, respectively; but, as the line of pull of each muscle passes by the medial side of the vertical axis of the eyeball, a slight degree of medial rotation accompanies the primary movement.

The superior and inferior oblique muscles, by virtue of their insertion behind the equator of the eyeball and because their pull is exerted from the forepart of the orbit, rotate the eyeball so as to make the pupil look downwards and upwards, respectively. As in the case of the superior and inferior recti, the lines of pull pass by the medial side of the vertical axis of the eyeball, but, as the pull is exerted from in front instead of from behind, the opposite effect—viz., lateral rotation—is added to the primary movement.

When the eyeball is rotated so as to make the pupil look directly downwards, the

superior oblique and the inferior rectus act together and the lateral rotation caused by the obliquus is counteracted by the medial rotation caused by the rectus. In a similar way the inferior oblique and the superior rectus act together to produce a purely upward direction of the pupil.

Combinations of rotation around the vertical and transverse axes of the eyeball are brought about by the combined actions of the superior oblique with the inferior and medial recti, or with the inferior and lateral recti, or by the combined actions of the inferior oblique with the superior and medial recti, or superior and lateral recti.

The levator palpebræ superioris elevates the upper eyelid and antagonizes the action of the palpebral part of the orbicularis oculi muscle. The plain muscle of the upper lid attached to the aponeurosis of the levator palpebræ superioris and the upper border of the tarsus raises the lid involuntarily.

Muscles of Mastication

The muscles of mastication are the masseter, the temporal, and the two pterygoid muscles—lateral and medial.

Masseter.—The masseter (Fig. 361), flat, quadrangular and the most superficial of these muscles, has an origin which is partly tendinous and partly fleshy. It arises in two parts: (1) superficially from the lower border of the zygomatic arch in its anterior two-thirds, and (2) more deeply from the deep surface of the zygomatic arch in its whole length. The superficial fibres, directed downwards and backwards towards the angle of the mandible, and the deeper fibres, directed vertically downwards, blend anteriorly but are separated behind by a slight cleft. The muscle is **inserted** by fleshy and tendinous fibres into the lateral surfaces of the coronoid process, ramus and angle of the mandible. The deepest fibres blend with the subjacent fibres of the temporal muscle. A "sub-masseteric space" that extends obliquely forwards across the ramus from above downwards has been

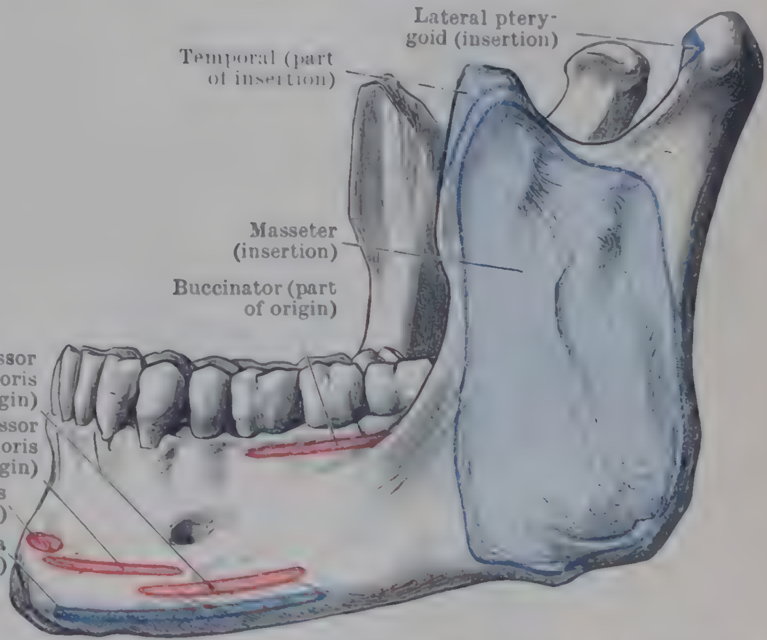

Fig. 368.—Muscle-Attachments to Superficial Surface of Mandible.

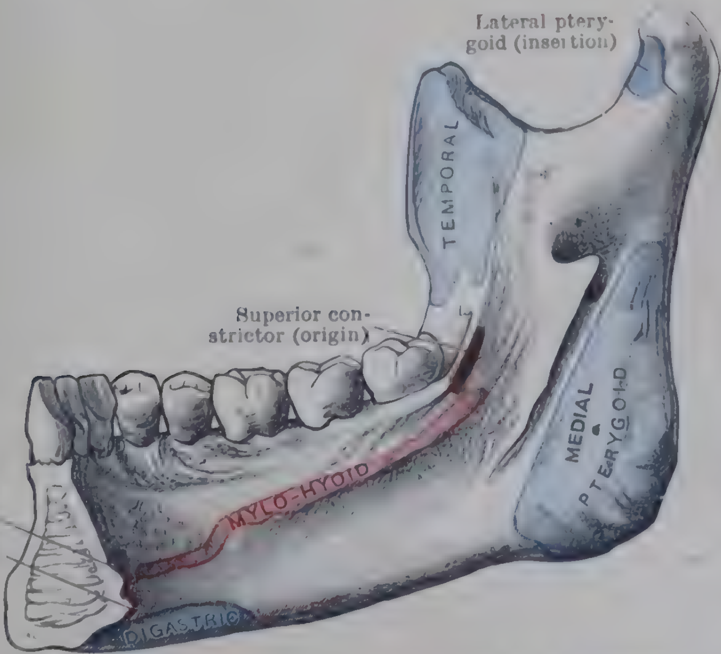

Fig. 369.—Muscle-Attachments to Deep Surface of Mandible.

described as separating the insertions of the deep fibres above and the superficial fibres below (Bransby-Zachary, 1948).

The muscle is partially concealed by the parotid gland, the accessory parotid gland, and the parotid duct; by the anterior facial vein; by the branches of the facial nerve; and by the zygomaticus major and platysma muscles. It conceals the ramus of the mandible, and, anteriorly, is separated from the buccinator muscle by the buccal pad of fat. The masseteric nerve and vessels reach its deep surface through the mandibular notch. When the teeth are clenched the parotid

FIG. 370.—RIGHT TEMPORAL MUSCLE. (The zygomatic arch and the masseter muscle have been removed.)

duct may be rolled under the finger against the contracted muscle as the duct turns round the anterior border of the masseter to pierce the buccinator.

Temporal Muscle.—This is a fan-shaped muscle that **arises** from the whole of the floor of the temporal fossa and also from the temporal fascia, which covers it. Although thin at its origin, its converging fibres form a thick tendon as they pass medial to the zygomatic arch—the anterior fibres vertically, the posterior horizontally and then curved—to be **inserted** into the apex and deep surface of the coronoid process, and into the anterior border of the ramus of the mandible, almost as far as the last molar tooth, its lower fibres becoming continuous with the buccinator.

As the muscle passes to its insertion it is concealed by the zygomatic arch, the masseter muscle, and the coronoid process of the mandible. The maxillary artery usually passes between it and the lateral pterygoid muscle. The masseteric nerve and vessels appear at its posterior border; the buccal nerve and vessels at its anterior border.

Lateral Pterygoid Muscle.—The lateral pterygoid muscle is deeply placed in the infratemporal fossa. It **arises** by two heads—upper and lower. The *upper head* is attached to the infratemporal surface of the greater wing of the sphenoid;

the *lower head* takes origin from the lateral surface of the lateral pterygoid plate. The muscle is directed laterally and backwards to be **inserted** into the front of the neck of the mandible (Figs. 368 and 369), and the capsule of the mandibular joint.

This muscle is covered by the lower part of the temporal muscle and the coronoid process of the mandible, and its lower head is usually crossed by the maxillary artery. It conceals the mandibular branch of the trigeminal nerve, the pterygoid origin of the medial pterygoid muscle, and the spheno-mandibular ligament.

Medial Pterygoid Muscle.—The medial pterygoid muscle has a double **origin**—(1) from the medial surface of the lateral pterygoid plate and the posterior surface of the tubercle of the palatine bone, and (2) by a small slip from the tuberosity of the maxilla. Its two heads of origin embrace the inferior fibres of the lateral pterygoid muscle. It is quadrilateral in form, and is directed downwards, laterally, and backwards to be **inserted** into a triangular impression on the medial surface of the mandible between the mylo-hyoid groove and the angle (Fig. 369).

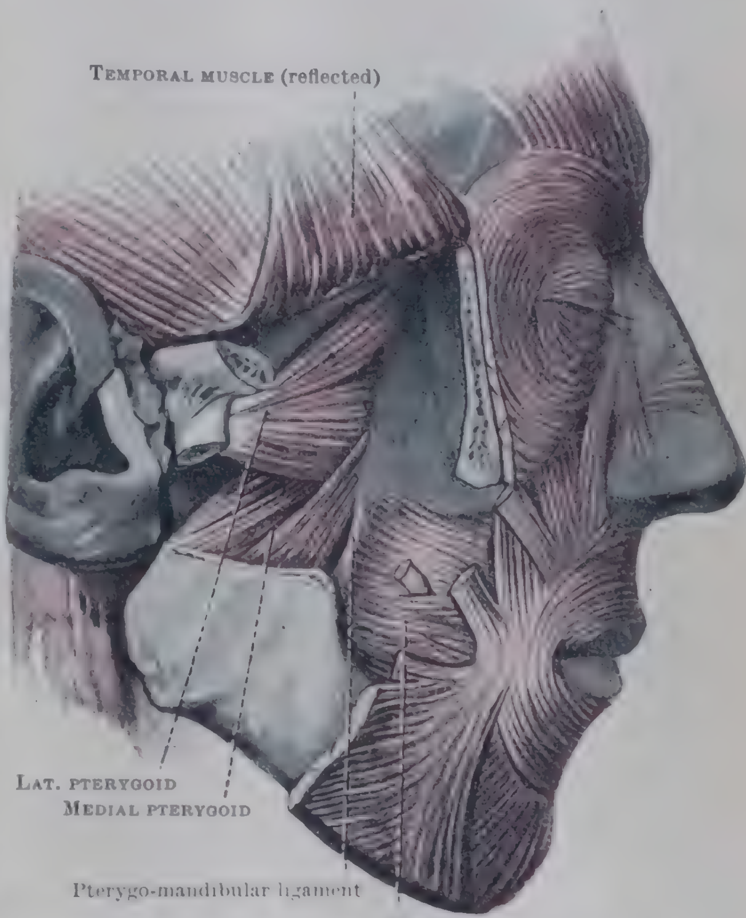

FIG. 371.—PTERYGOID MUSCLES OF THE RIGHT SIDE.

Lateral to the muscle there are the ramus of the mandible, the temporal and lateral pterygoid muscles, the maxillary vessels with their inferior dental branches, the inferior dental and lingual nerves, part of the parotid gland, and the spheno-mandibular ligament; the deep surface, at its origin, is separated from the pharyngo-tympanic tube and levator palati by the tensor palati, and, lower down, from the superior constrictor of the pharynx by the stylo-glossus and stylo-pharyngeus.

Nerve-Supply.—The mandibular division of the trigeminal (fifth cranial) nerve supplies all the muscles of mastication. The medial pterygoid muscle is supplied by the nerve before it divides; the other muscles are innervated by the anterior division.

Actions.—The temporal, masseter, and medial pterygoid muscles raise the jaw and have great power in keeping the teeth clenched. (But it is important to note that in the dislocated jaw their contraction increases the opening of the mouth.) The muscles that raise the mandible are also good examples of antigravity or postural muscles (see p. 409). The mouth opens by the relaxation of these muscles and the weight of the mandible, and, against resistance, by the contraction of the suprahyoid and infrahyoid groups and the platysma, and the lateral pterygoids. When the teeth are tightly clenched, the hyoid bone will be found firmly fixed. (See action of hyoid muscles, p. 438.)

The lateral pterygoids protrude the jaw and pull the articular discs forward; the temporal muscles retract the jaw.

The co-ordinated alternate action of the right lateral pterygoid with the elevators of the left side, and of the left one with the elevators of the right side, produces chewing movements.

MUSCLES OF THE NECK

In addition to the muscles included among those of the vertebral column (p. 411), the following muscles lie wholly or chiefly in the neck: (1) sterno-(cleido-)mastoid; (2) the muscles of the hyoid bone (suprahyoid and infrahyoid); (3) the muscles of the tongue (extrinsic and intrinsic); (4) the muscles of the pharynx and soft palate; and (5) the intrinsic muscles of the larynx. The last group is described with the larynx itself (p. 695).

Sterno-Mastoid.—The sterno-mastoid muscle lies obliquely in the side of the neck between the anterior and posterior triangles, and stands out prominently when thrown into action (Pl. XXXVII, p 456, Figs. 3, 4; Pl. XL, p. 457, Fig. 3). It **arises** by two heads—(1) a narrow, tendinous, *sternal* head from the anterior surface of the manubrium sterni (Fig. 407, p. 479), and (2) a broader, *clavicular* head, partly tendinous, partly fleshy, from the upper surface of the clavicle in its medial third. The clavicular head ascends to blend with the deep surface of the sternal head forming a thick belly which is **inserted** by a short, strong tendon into the anterior border and tip of the mastoid process, and the lateral surface of the mastoid portion of the temporal bone, and by a thin tendinous expansion into the lateral half of the superior nuchal line of the occipital bone (Fig. 356, p. 416).

Relations

The careful dissection of the relations of this muscle provides a good guide to the disposition of most of the structures in the neck. It is seen and felt superficially throughout its extent, but its upper part is overlapped anteriorly by the parotid gland; the external jugular vein descends over its surface; and, curving round its posterior border, there are the lesser occipital nerve, the great auricular nerve, the anterior cutaneous nerve of the neck, and the medial and intermediate supraclavicular nerves—all, except the first two, covered by the platysma. Its deep surface is related to a large number of structures. Its lower third is in relation with the scalenus anterior, the phrenic nerve, the transverse cervical and suprascapular arteries, and, at its posterior border, with the brachial plexus; farther forward, the infrahyoid muscles (along with the anterior jugular vein, which crosses them superficially above the clavicle) separate the muscle from the common carotid artery, the subclavian artery and the internal jugular vein, the lower part of the vein being opposite the depression between the two heads of the muscle. The middle third is in relation with the internal jugular, the common facial and lingual veins, the external and internal carotid arteries (with the vagus posteriorly), the descending branch of the hypoglossal nerve, the nervus descendens cervicalis, and deep cervical lymph-glands. The upper third is related to the cervical plexus, the scalenus medius, the levator scapulæ, the posterior belly of the digastric, and, near its insertion to the splenius capitis and longissimus capitis. The occipital artery runs upwards and backwards along the lower border of the digastric; and the accessory nerve, escaping from under cover of that muscle, descends to sink into the sterno-mastoid. A group of lymph-glands forms a chain along its posterior border.

Nerve-Supply.—The muscle is innervated by the **accessory (eleventh cranial) nerve** and also by branches from the **second cervical nerve** which are said to be afferent.

Actions.—Figs. 1 and 2, Pl. XLI, p. 512, show the left sterno-mastoid in action as it turns the head to the opposite side. The two muscles acting together can flex the head, but do so only against resistance or against gravity when the subject is supine. They function also as muscles of forced inspiratory effort—raising the thorax when the head is fixed.

Muscles of Hyoid Bone

There are two groups of these muscles: (1) infrahyoid muscles, which connect the hyoid bone to the scapula, the wall of the thorax, and the thyroid cartilage; (2) suprahyoid muscles, which connect it to the mandible, cranium, and tongue. The middle constrictor muscle of the pharynx also is attached to the hyoid bone.

The **infrahyoid muscles** are the omo-hyoid, sterno-hyoid, sterno-thyroid, and thyro-hyoid.

Omo-Hyoid.—The omo-hyoid is a muscle with two bellies—superior and inferior. The *inferior belly* **arises** from the upper margin of the scapula and the suprascapular ligament (Fig. 211, p. 243). It is a narrow muscular band which passes obliquely forwards and upwards across the scalene muscles to end in an

intermediate tendon under cover of the sterno-mastoid muscle. From this tendon the *superior belly* proceeds upwards across the carotid sheath to be **inserted** into the lower border of the body of the hyoid bone, lateral to the sterno-hyoid. A sling of the deep cervical fascia binds down the tendon and the inferior belly to the clavicle and the first rib.

Sterno-Hyoid.—The sterno-hyoid muscle **arises** from the posterior surface of the manubrium sterni, from the posterior sterno-clavicular ligament, and from the medial end of the clavicle. Converging slightly towards its fellow, it ascends along the medial border of the omo-hyoid and superficial to the sterno-thyroid muscle to be **inserted** into the medial part of the lower border of the body of the hyoid bone. Near its origin it is covered by the sternum, clavicle, and sternal head of the sterno-mastoid, but the greater part of the muscle is superficial.

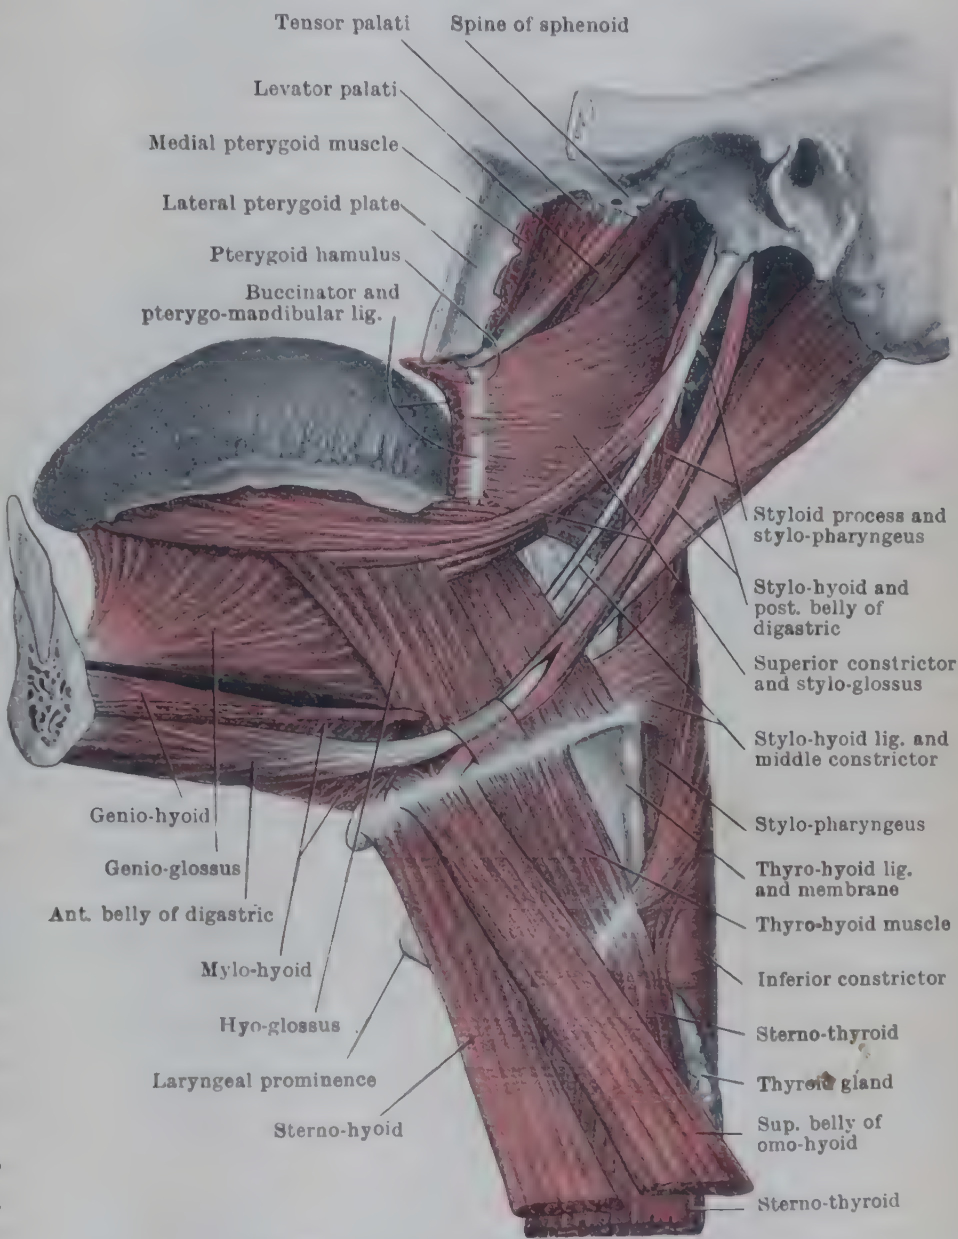

FIG. 372.—MUSCLES OF THE TONGUE, HYOID BONE, AND PHARYNX.

Sterno-Thyroid.—The sterno-thyroid muscle **arises** from the back of the manubrium and first costal cartilage. Broader than the preceding muscle, and diverging from its fellow, it passes upwards in front of the trachea and thyroid gland, and deep to the sterno-mastoid, omo-hyoid, and sterno-hyoid muscles. It is **inserted** into the oblique line of the thyroid cartilage. The muscle may show an oblique tendinous intersection in the middle of its length.

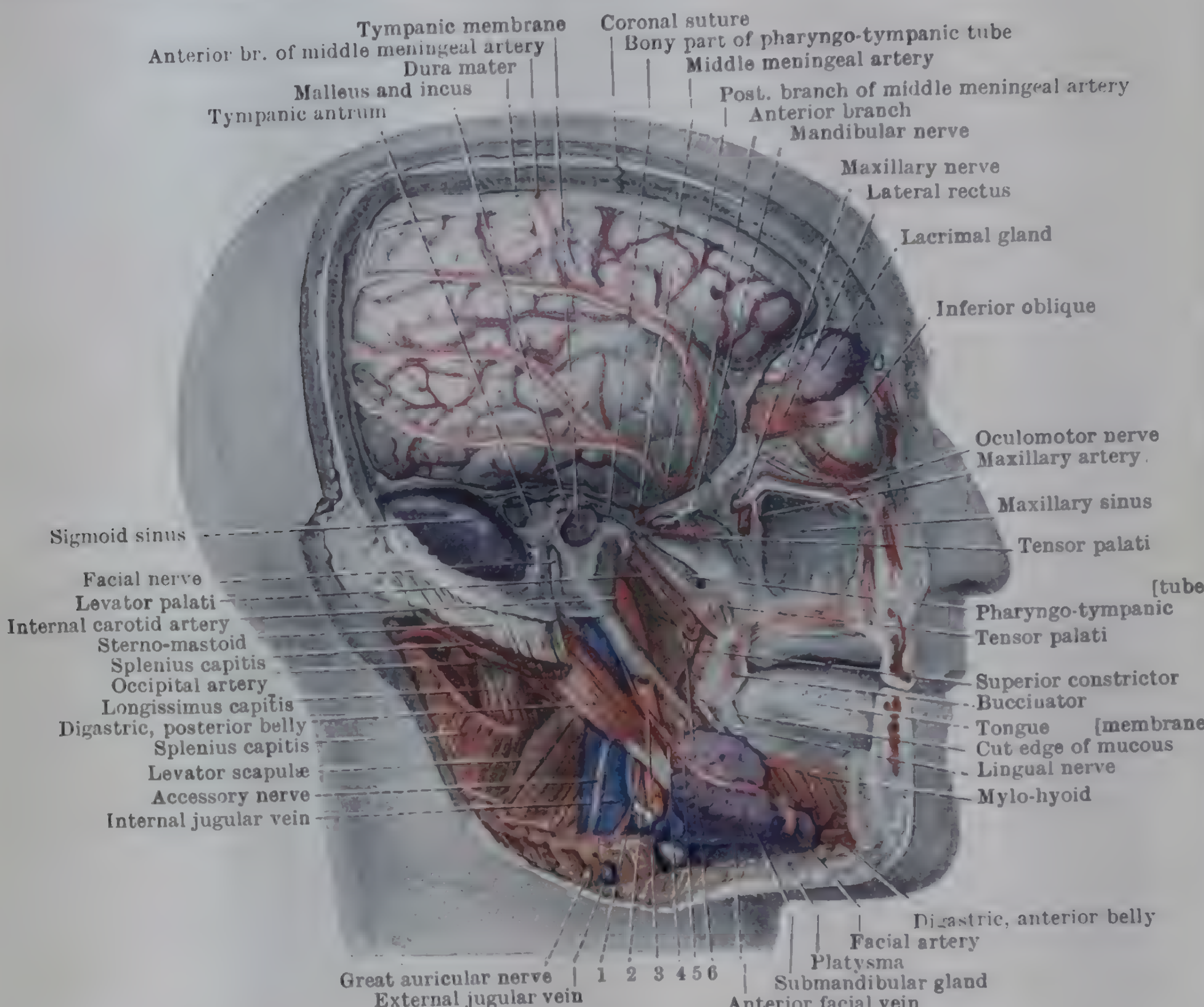
Thyro-Hyoid.—The thyro-hyoid muscle continues the line of the preceding muscle to the hyoid bone. Short and quadrilateral, it **arises** from the oblique line of the thyroid cartilage. Passing over the thyro-hyoid membrane, deep to the omo-hyoid and sterno-hyoid, it is **inserted** into the lower border of the body and adjacent part of the greater horn of the hyoid bone.

The **levator glandulæ thyreoideæ** is an occasional unpaired slip that stretches between the hyoid bone and the isthmus or the pyramidal lobe of the thyroid gland.

The **suprahyoid muscles** are the digastric, stylo-hyoid, mylo-hyoid, and

genio-hyoid; and also two muscles—the genio-glossus and hyo-glossus—which will be described along with the extrinsic muscles of the tongue.

Digastric Muscle.—The digastric muscle, as its name implies, has two bellies—anterior and posterior. The *posterior belly* **arises** from the mastoid notch of the temporal bone. It is directed forwards and downwards, in company with the stylo-hyoid muscle, to end in an intermediate tendon which passes through the stirrup-like insertion of the stylo-hyoid, and is connected by a sling of fascia to the body of the hyoid bone. The *anterior belly* is directed forwards and slightly upwards from the tendon and often from the body of the hyoid bone, and is **inserted** into the lower border of the mandible close to the symphysis (Fig. 369).



1. Sterno-mastoid artery.
2. Hypoglossal nerve.
3. External carotid artery.
4. Stylo-hyoid.
5. Stylo-glossus.
6. Ascending palatine artery.

FIG. 373.—DISSECTION OF HEAD SHOWING THE RELATIONS OF MUSCLES AT ITS JUNCTION WITH THE NECK. For enlargement of part of this illustration, see Fig. 378, p. 443.

The muscle forms the inferior boundary of the space occupied by the submandibular gland. The posterior belly, in company with the stylo-hyoid, crosses lateral to the transverse process of the atlas, the accessory nerve, the internal jugular vein and carotid arteries. The occipital artery runs backwards along its lower margin, and the parotid gland covers its upper border. The hypoglossal nerve emerges from under cover of the muscle just above the tendon. The anterior belly lies on the lower surface of the mylo-hyoid muscle.

Stylo-Hyoid.—The stylo-hyoid muscle **arises** from the posterior border of the styloid process of the temporal bone near its root. Extending downwards and forwards, along with the posterior belly of the digastric muscle, it is **inserted** into the upper surface of the greater horn near the body of the hyoid bone by two slips which enclose the tendon of the digastric muscle.

Mylo-Hyoid.—The mylo-hyoid muscle forms with its fellow a diaphragm in the floor of the mouth. It **arises** from the mylo-hyoid ridge of the mandible

(Fig. 369). It is directed downwards and medially to be **inserted** into the body of the hyoid bone, and, more anteriorly (along with the opposite muscle), into a median raphe that extends from the hyoid bone nearly to the chin.

The muscle is in contact, on its superficial surface, with the digastric muscle, the submandibular gland, the mandible, and the mylo-hyoid vessels and nerve. Its deep surface is partially covered by the mucous membrane of the floor of the mouth, and is separated from the muscles of the tongue by the submandibular duct and the deep part of the gland, the sublingual gland, the lingual and hypoglossal nerves and the vena comitans of the hypoglossal nerve.

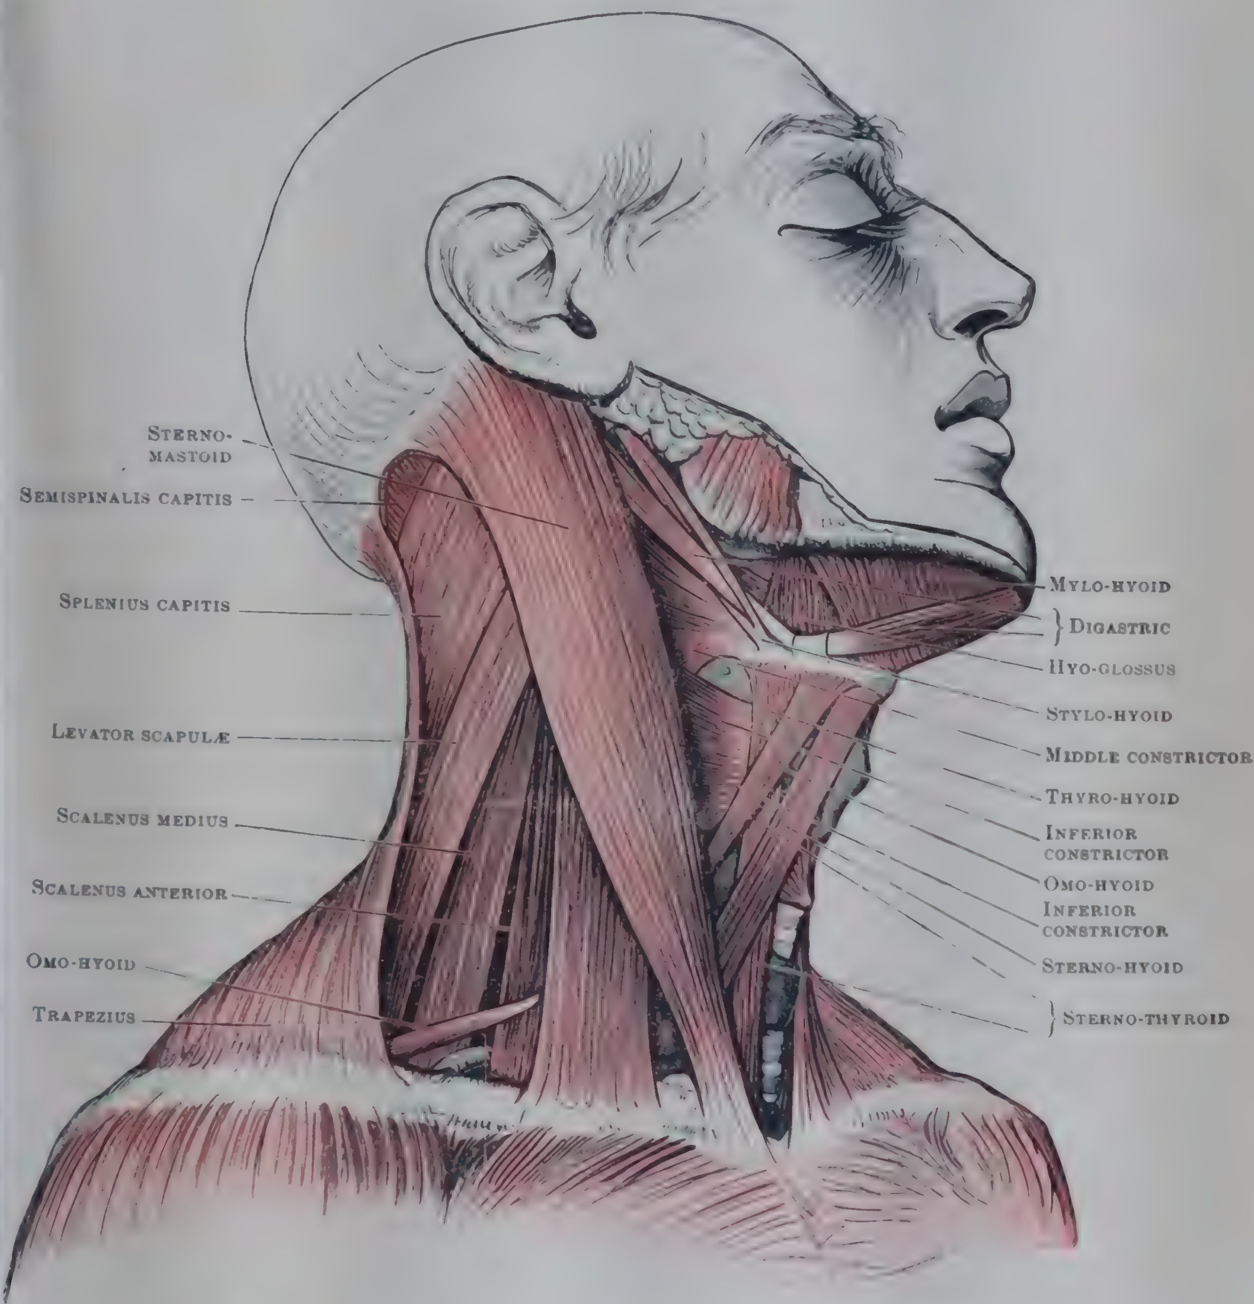


FIG. 374.—MUSCLES OF SIDE OF NECK (anterior and posterior triangles).

Genio-Hyoid.—The genio-hyoid muscle **arises** from the inferior genial tubercle of the mandible (Fig. 369). It is directed backwards and slightly downwards, between the mylo-hyoid and the genio-glossus (Fig. 372), to be **inserted** into the body of the hyoid bone. The muscles of opposite sides are often fused together.

Nerve-Supply.—The sterno-hyoid, sterno-thyroid, and omo-hyoid are supplied by the *ansa hypoglossi*, through which the muscles are innervated by fibres ultimately derived from the **first three cervical nerves.** The ramus descendens hypoglossi is derived from the loop between the **first two cervical nerves,** and the ramus descendens cervicalis springs from the second and third. These two trunks combine to form the ansa. The thyro-hyoid muscle is innervated (through the hypoglossal) from the loop between the **first and second cervical nerves** (Fig. 909, p. 1044).

Three cranial nerves are concerned in the supply of the suprahyoid muscles — an indication of their diverse developmental origins. The posterior belly of the digastric and the stylo-hyoid are supplied by branches from the trunk of the **facial nerve**; the anterior belly of the digastric and the mylo-hyoid by the **trigeminal** through the mylo-hyoid branch of the inferior dental nerve; and the genio-hyoid is supplied by the **hypoglossal nerve**. From the point of view of nerve-supply, the genio-hyoid is a link between the infrahyoid muscles and the muscles of the tongue, since its nerve can be traced back to the communication between the first two cervical nerves and the hypoglossal.

Actions.—The hyoid bone is steadied by the suprahyoid and infrahyoid muscles, as a ship rides when anchored fore and aft. The hyoid bone, through its muscles, provides a fulcrum for the action of the tongue, and plays a part in mastication, deglutition, and phonation—with the associated muscle-groups. The suprahyoid and infrahyoid groups act in concert, and, whether the bone is being raised by one group or lowered by the other, the opposing group steadies the bone like a guy-rope. Descent of the hyoid is not usually an active movement. Both hyoid groups relax slightly as the jaws are closed against resistance. In the first stage of swallowing, the mylo-hyoid and genio-hyoid raise the hyoid bone and the floor of the mouth (the digastric and stylo-hyoid assisting, while the infrahyoid group steadies the bone); the tongue is pressed against the palate and the food is forced backwards; the hyoid bone then regains its resting position. Though not attached to the hyoid bone, the sterno-thyroid, in concert with the thyro-hyoid, depresses the bone. When the upper end of the thyro-hyoid is fixed, the muscle pulls the larynx upwards in the production of high notes; the sterno-thyroid pulls down the larynx markedly when low notes are produced. During high and low notes, the hyoid bone is relatively fixed by the action of the appropriate muscles. During deglutition, the thyro-hyoid pulls the larynx upwards and slightly backwards, probably assisting the synchronous sphincteric action of the laryngeal muscles as they approximate the arytenoid cartilages and the tubercle of the epiglottis.

Muscles of Tongue

The substance of the tongue consists mainly of muscular fibres arranged symmetrically on each side of a median fibrous septum, and interlacing with one another in three main directions—longitudinal, transverse, and vertical. They belong to two sets of muscles—(1) the **intrinsic** muscles, proper to the tongue itself; and (2) the **extrinsic** muscles, arising outside the tongue (from the mandible, the hyoid bone, and the styloid process) and inserted into it.

Intrinsic Muscles of the Tongue.—There are four pairs of intrinsic muscles—the superior and inferior longitudinal, the transverse and vertical muscles.

The **superior longitudinal muscle** extends from the back of the tongue to its tip, and is united to its fellow of the opposite side without the intervention of the median septum at this level. It is placed immediately under the mucous membrane, into which many of its fibres are inserted. The **inferior longitudinal muscle** is a cylindrical band of muscular fibres that lies in the lower part of the tongue, in the interval between the genio-glossus and the hyo-glossus. Posteriorly, some of its fibres extend to the hyoid bone. The **transversus linguæ** arises from the median septum and radiates to the dorsum and sides of the tongue, intermingling with the extrinsic muscles and the fibres of the vertical muscle. The **verticalis linguæ** arises from the mucous membrane of the dorsum of the tongue, and sweeps downwards and laterally to its sides, intermingled with the fibres of the transversus and the extrinsic muscles. The transverse and vertical muscles form a very considerable part of the muscular substance of the organ.

Extrinsic Muscles of the Tongue.—There are three pairs of these muscles: genio-glossus, hyo-glossus, and stylo-glossus. The palato-glossus, also attached to the tongue, is described with the muscles of the soft palate (p. 443).

The **genio-glossus muscle** (Fig. 372) is an extrinsic muscle of the tongue as well as a suprahyoid muscle. It is a fan-shaped muscle that **arises** by its apex from the upper genial tubercle of the mandible (Fig. 369, p. 431) and radiates into the tongue. The lowest fibres are directed downwards and backwards, to be **inserted** into the body of the hyoid bone; the highest fibres curve forwards, to be attached to the tip of the tongue; the intermediate fibres end in the

substance of the tongue in its whole length. The muscles of opposite sides are separated only by the median septum of the tongue. Laterally, each is related to the inferior longitudinal muscle, the stylo-glossus, the hyo-glossus, the lingual artery, and the sublingual gland.

The **hyo-glossus muscle** also is an extrinsic muscle of the tongue as well as a suprahyoid muscle. It is a quadrilateral sheet that **arises** from the body and greater horn of the hyoid bone and is directed upwards and forwards to be **inserted** into the side of the tongue, its fibres interlacing with the fibres of the longitudinalis inferior medially, and the stylo-glossus laterally (Fig. 372).

With the exception of its posterior portion, the muscle is hidden by the mylo-hyoid and the structures that lie on its surface partly between the two muscles. A little above the greater horn of the hyoid bone the tendon of the digastric, the hypoglossal nerve and its accompanying vein lie on the muscle; at a higher level there are the submandibular duct, the deep part of the submandibular gland, the submandibular ganglion, and the lingual nerve. The uppermost part of the hyo-glossus is separated from the mylo-hyoid by the mucous membrane of the floor of the mouth. The deep surface of the hyo-glossus is in contact with the genio-glossus in front, and with the glosso-pharyngeal nerve and the middle

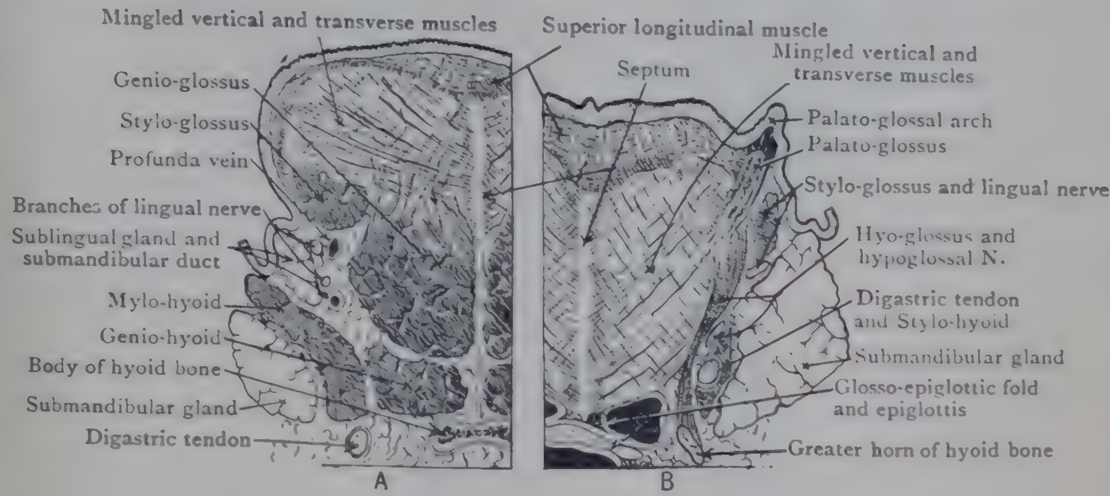

FIG. 375.—A. SECTION THROUGH TONGUE AND BODY OF HYOID BONE.
B. SECTION THROUGH TONGUE AND GREATER HORN OF HYOID BONE.

constrictor of the pharynx arising from the stylo-hyoid ligament behind, but the lingual vessels intervene between it and these muscles.

The **chondro-glossus** is a small separated slip of the hyo-glossus, not always present. It arises from the lesser horn of the hyoid bone.

The **stylo-glossus muscle arises** from the anterior border of the styloid process near its tip and from the stylo-hyoid ligament. It sweeps forwards and medially, at first on the stylo-pharyngeus, and then on the lower and anterior part of the superior constrictor muscle of the pharynx, by which it is separated from the tonsil; finally it runs inferior to the mandibular attachment of the superior constrictor muscle. It is **inserted** into the side of the tongue, its fibres spreading out to mingle with those of the palato-glossus and hyo-glossus beneath the mucous membrane of the tongue.

Nerve-Supply.—All the muscles of the tongue, except the palato-glossus, are supplied by the **hypoglossal nerve.**

Actions.—The intrinsic muscles alter the shape of the tongue. The extrinsic muscles alter the shape and also produce changes in its position. The tongue is protruded by the action of the posterior fibres of the genio-glossus, retracted by the anterior fibres aided by the stylo-glossus and hyo-glossus. The stylo-glossus and palato-glossus are elevators of the tongue, while the genio-glossus and hyo-glossus are depressors. The tongue is active during speech, and in the mastication and swallowing of food.

Muscles of Pharynx

The muscular wall of the pharynx is composed of two strata. The *external* or *circular layer* consists of the three constrictor muscles; the *internal* or *longitudinal layer* consists of the fibres of the stylo-pharyngeus and palato-pharyngeus muscles. (The palato-pharyngeus is described with the muscles of the soft palate.) The outer surface of the muscular wall is covered with a thin layer of fascia, called

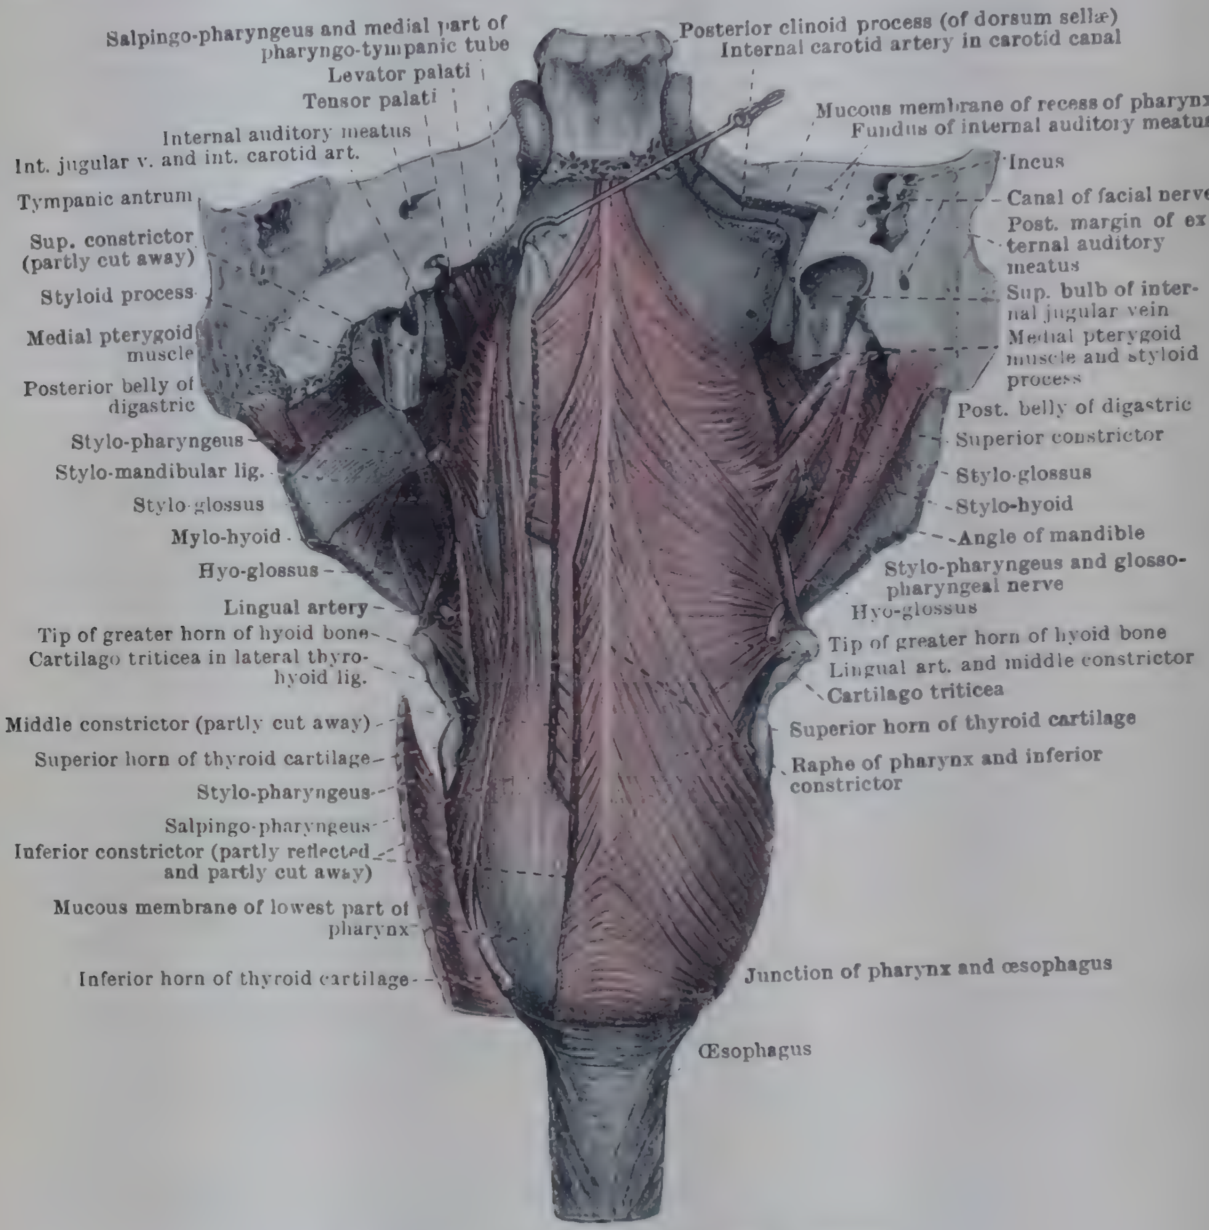

Fig. 376.—Muscles of Pharynx from Behind.
The constrictors of the left side have been cut to show the deeper muscles.

the *bucco-pharyngeal fascia*, which extends forwards to cover the buccinator also. The inner surface is lined with the *pharyngo-basilar fascia*, which is very thin inferiorly but thickens as it approaches the skull.

Superior Constrictor.—The superior constrictor muscle **arises** successively from the lower half of the posterior border of the medial pterygoid plate, from the pterygo-mandibular ligament, from the mylo-hyoid line of the mandible, and from the musculature of the side of the tongue and adjacent mucous membrane of the mouth.

The muscular fibres radiate backwards and medially, and are **inserted**, for the most part, into a median raphe in the posterior wall of the pharynx; the highest fibres are attached to the pharyngeal tubercle of the occipital bone (Fig. 356). A band of fibres from the anterior and lateral part of the palatine aponeurosis sweeps backwards lateral to the levator palati to blend with the pharyngeal

surface of the superior constrictor near its upper border. It forms a "palato-pharyngeal sphincter" (Whillis, 1930) and produces the ridge of pharyngeal mucous membrane known as Passavant's ridge (see pp. 445 and 593). This band is highly developed in cases of complete cleft palate. Between the upper border of the muscle and the base of the skull there is a crescentic interval which is occupied by the pharyngo-basilar fascia and transmits the levator palati muscle and the pharyngo-tympanic tube.

Posteriorly and laterally it is overlapped from below by the middle constrictor. Anteriorly it is continuous with the buccinator through the pterygo-mandibular ligament. A triangular gap filled with fibrous tissue is seen between its lower border, the posterior border of the hyo-glossus and the upper border of the middle constrictor. Here, the stylo-pharyngeus insinuates itself between the superior and middle constrictors; and the glosso-pharyngeal nerve and the stylo-hyoid ligament cross the gap (Figs. 372, 379).

Middle Constrictor.—The middle constrictor muscle **arises** from the lower part of the stylo-hyoid ligament and from both horns of the hyoid bone, and it spreads fanwise backwards and medially to be **inserted** into the median raphe. The upper fibres overlap the superior constrictor; the lower fibres are concealed posteriorly by the inferior constrictor muscle. Between its lower border and the upper border of the inferior constrictor there is a triangular gap. This gap is bounded in front by the thyro-hyoid muscle, and is occupied by the posterior part of the thyro-hyoid membrane and the lower part of the stylo-pharyngeus. The internal laryngeal nerve and the superior laryngeal vessels pierce the thyro-hyoid membrane in this region.

Inferior Constrictor.—The inferior constrictor muscle **arises** from the oblique line of the thyroid cartilage, from the area behind that line, from the side of the cricoid cartilage, and from the fascia on the posterior part of the crico-thyroid muscle.

Its fibres curve backwards and medially to be **inserted** into the median raphe of the pharynx. The upper fibres incline markedly upwards and overlap the middle constrictor; the lowest fibres are horizontal, and blend with the circular muscular fibres of the œsophagus. Under cover of the lower border of the muscle, the inferior laryngeal artery and recurrent laryngeal nerve pass up behind the crico-thyroid joint to enter the larynx.

Stylo-Pharyngeus.—The stylo-pharyngeus **arises** from the root of the styloid process on its medial side, and passes downwards between the external and internal carotid arteries. It enters the wall of the pharynx in the interval between the superior and middle constrictor muscles, accompanied by the glosso-pharyngeal nerve which has curved round the lateral aspect of the muscle. Spreading out internal to the middle constrictor muscle, the greater horn of the hyoid bone, and the thyro-hyoid membrane, it is **inserted** into the superior and posterior borders of the thyroid cartilage and into the wall of the pharynx itself, becoming continuous posteriorly with the palato-pharyngeus.

Muscles of Soft Palate

The soft palate and uvula consist of a fold of mucous membrane enclosing a fibrous aponeurosis and several muscles. The fold hangs down from the hard palate between the pharynx and the mouth.

The muscular substance is composed of five pairs of muscles—the palato-pharyngeus, musculus uvulæ, levator palati, tensor palati, and palato-glossus (Fig. 377). In its anterior part the fold contains the **palatine aponeurosis**, which is attached in front to the posterior border of the bony palate and on each side to the pharyngo-basilar fascia and fades away posteriorly. The palatine aponeurosis is derived mainly from the tendons of the two tensor muscles; the other muscles, with the exception of the palato-glossus, are inserted into it.

Palato-Pharyngeus.—The palato-pharyngeus extends from the soft palate to

the pharyngeal wall and is covered by the mucous membrane of the palato-pharyngeal arch. In the soft palate it is arranged in two layers which enclose the levator palati and the musculus uvulæ. The postero-superior layer is thin; it lies under the mucous membrane of the back of the soft palate, and blends with its companion of the opposite side. A thicker, antero-inferior layer lies between the levator and tensor palati muscles, joins with its fellow in the median plane and **arises** from the palatine aponeurosis and the posterior border of the bony palate. At the postero-lateral part of the soft palate the two layers blend and are joined posteriorly by the **salpingo-pharyngeus** muscle, which is a slender slip that descends

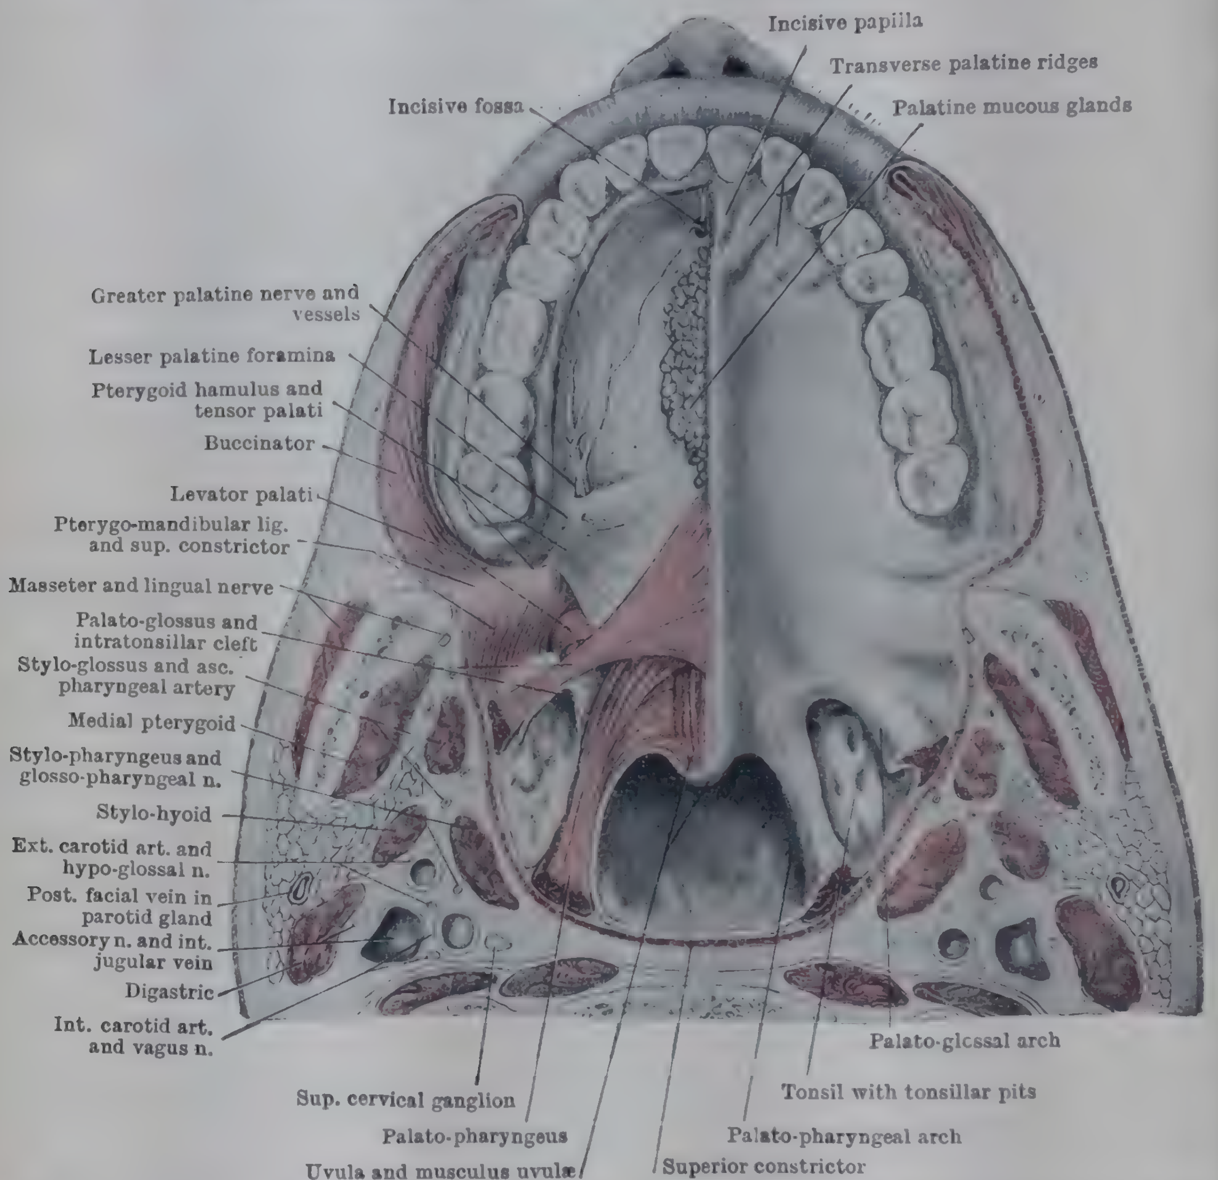

FIG. 377.—HORIZONTAL SECTION AT LEVEL OF ORAL FISSURE SEEN FROM BELOW WITH RIGHT SIDE DISSECTED TO SHOW MUSCLES OF SOFT PALATE.

from the pharyngeal end of the pharyngo-tympanic tube in close relation to the salpingo-pharyngeal fold. The united muscles run downwards along the postero-medial margin of the stylo-pharyngeus, and their fibres spread out in a thin sheet to be **inserted** into the posterior border of the thyroid cartilage, and, behind that, into the pharyngo-basilar fascia. The muscle is covered by the middle and inferior constrictors and decussates with its fellow in the lower part of the pharyngeal wall.

Musculus Uvulæ.—This slender bundle lies alongside its fellow, between the layers of the palato-pharyngeus and above the levator palati. Both bundles **arise** from the posterior nasal spine and the palatine aponeurosis, and they unite as they proceed backwards to end in the mucous membrane of the uvula.

Levator Palati.—The levator palati is a rounded muscle with a double **origin**: (1) from the quadrate area of the lower surface of the petrous portion of the

temporal bone, and (2) from the medial side of the cartilaginous portion of the pharyngo-tympanic tube. Passing obliquely downwards and medially, across the medial side of the upper border of the superior constrictor muscle, it descends in front of the salpingo-pharyngeus and enters the soft palate between the two layers of the palato-pharyngeus muscle to be **inserted** by its anterior fibres into the palatine aponeurosis, but mainly by its posterior fibres becoming continuous with those of the opposite muscle.

It is separated from the tensor palati muscle (1) by the pharyngo-tympanic tube, (2) by the upper fibres of the superior constrictor, and (3) by the deeper layer of the palato-pharyngeus muscle.

Tensor Palati.—The tensor palati is a flat, triangular muscle which **arises**

FIG. 378.—REGION OF PHARYNGO-TYMPANIC TUBE AND TYMPANIC ANTRUM SHOWING THE LEVATOR AND TENSOR PALATI MUSCLES. Enlargement of part of Fig. 373, p. 436.

(1) from the scaphoid fossa and the spine of the sphenoid bone, and (2) from the lateral side of the cartilaginous part of the pharyngo-tympanic tube.

Tapering by the vertical descent of its anterior border, and the oblique descent of its posterior border, the muscle ends in a tendon which hooks round the pterygoid hamulus, a bursa intervening, and passes through a gap in the origin of the buccinator muscle (p. 426) to enter the soft palate. The tendon spreads out below the lower layer of the palato-pharyngeus to be inserted into the posterior border of the hard palate and into the palatine aponeurosis. It is related *medially* to the medial pterygoid plate, the pharyngo-basilar fascia, the pharyngo-tympanic tube, and the upper origin of the superior constrictor. Its lateral surface is related to the otic ganglion, the mandibular and chorda tympani nerves, the middle meningeal vessels, and the medial pterygoid muscle.

Palato-Glossus.—The palato-glossus **arises** as a thin sheet of muscle, in continuity with its fellow, above the mucous membrane of the antero-inferior surface of the soft palate (Fig. 377). The fibres become roped together and pass downwards, forwards, and laterally in front of the tonsil, forming the substance of the palato-glossal arch to be **inserted** into the dorsum and side of the tongue by scattered fibres that blend with the stylo-glossus and the transversus linguæ.

Nerve-Supply.—All the muscles of the pharynx and soft palate, except the tensor palati and the stylo-pharyngeus, are innervated by the **vagus (tenth cranial) nerve**, through the pharyngeal plexus, but the principal motor fibres of the pharynx are derived mainly from the cranial root of the **accessory nerve**. The tensor palati receives its supply from the mandibular division of the **trigeminal** by a branch from the nerve to the medial pterygoid muscle through the otic ganglion. The stylo-pharyngeus is supplied by the **glosso-pharyngeal** nerve. The inferior constrictor receives additional supply from the external and recurrent laryngeal nerves.

Actions of the Muscles of the Pharynx and Soft Palate.—The muscles of the pharynx and soft palate are concerned in **the act of swallowing**. This act is divided into a *voluntary stage*, in which the bolus lies in front of the oro-pharyngeal isthmus,[1] and an *involuntary stage*, during which the food passes from the mouth through the pharynx. The movements that occur during the passage of food through the mouth are as follows: the cheeks are compressed by the action of the buccinator muscles; the tongue, hyoid bone, and thyroid cartilage are successively raised by the action of the muscles which close the mouth and elevate the hyoid bone. By these means the food is pushed backwards between the palatine arches.

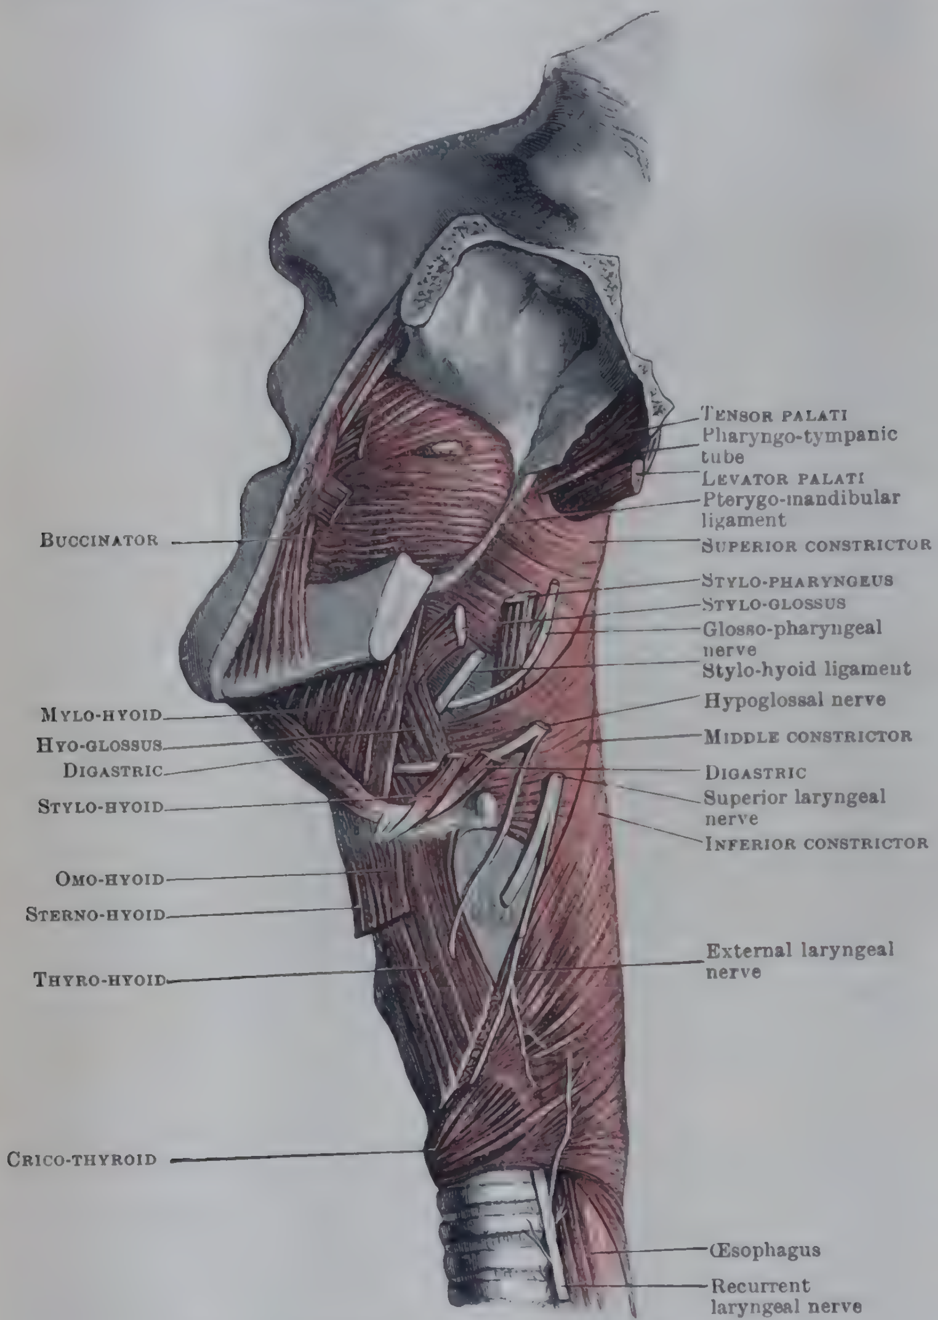

Fig. 379.—Lateral View of Wall of Pharynx.

At this time, by the contraction of the palato-glossus and palato-pharyngeus, the oro-pharyngeal isthmus is narrowed, while the levators raise the soft palate, and by bringing it into contact with the posterior wall of the pharynx, shut off the nasal portion of the cavity, thereby preventing regurgitation of food into the naso-pharynx—seen in paralysis of the palate. It should be noted that the levators, in raising the palate against the flange formed by Passavant's ridge (p. 445) to shut off the naso-pharynx, are assisted in this occlusion by their antagonists—the tensors—which keep the soft palate tense. The elevation of the tongue, hyoid bone (p. 438), and larynx causes the elevation of the epiglottis and the inlet of the larynx, which is closed by the approximation of the arytenoid cartilages to the tubercle of the epiglottis by the combined sphincteric action of the laryngeal muscles (arytenoid, thyro-arytenoid, and

[1] The term *oro-pharyngeal isthmus* (p. 566) is applied to the opening between the cavity of the mouth and the oral part of the pharynx, while the term *pharyngeal isthmus* (p. 587) is applied to the communication between the nasal and oral parts of the pharynx.

thyro-epiglottic). The food thus slips over the posterior surface of the epiglottis and the closed inlet of the larynx into the pharynx (see also Respiratory System, p. 700).

When the bolus of food enters the pharynx, it is clasped by the constrictor muscles, which, by their contractions, force it down into the œsophagus—their constriction at one level being accompanied by their relaxation at the level immediately below. The contraction of the constrictor muscles results in a flattening of the pharynx and elevation of its anterior attachments; and, as the larynx ascends, the pharynx also is pulled up by the palato-pharyngeus and stylo-pharyngeus.

During the act of swallowing, it is generally thought that the pharyngo-tympanic tube is opened by the contraction of the tensor palati muscle, which arises from it. On the other hand, it has been held that the tube is closed during swallowing by contraction of the levator palati compressing its wall.

Throughout the **production of speech** (Wardill, 1928; cf. Browne, 1935) the upper part of the superior constrictor (chiefly by means of its palatine bundle, p. 441) forms a ridge (Passavant, 1869) to or from which the soft palate moves in occluding or opening the pharyngeal isthmus. Occlusion is complete for most consonants, but not complete for vowels. (Occlusion, as by a "cold in the head", is therefore not such a serious defect for speech as is the patency in cleft palate.) The muscles which pull the palate away from the ridge are the palato-pharyngeus, the palato-glossus, and the tensor palati, while the levators close the isthmus—as may be seen by the dimples that appear at their insertion in the soft palate when they contract during the saying of "Ah".

FASCIÆ OF HEAD AND NECK

The **superficial fascia** of the head and neck possesses certain features of special interest. In the scalp, it is closely adherent to the skin and the epicranial aponeurosis, and it contains the superficial vessels and nerves. In the eyelids it is loose and thin and contains no fat. In the face and in the side of the neck, it is separated from the deep fascia by the facial muscles and the platysma. Between the buccinator and the masseter, it is continuous with the *buccal pad of fat*, which lies in the interval between those muscles.

The **deep fascia** of the head and neck presents remarkable characters in certain areas, but in studying the various planes described, it is well to remember in general that the fascia is a packing material that ensheaths more highly differentiated structures and fills the spaces between them (cf. p. 410).

In the scalp, it is replaced by the **epicranial aponeurosis.** *In the temple*, the **temporal fascia** is a stout layer that extends from the superior temporal line to the zygomatic arch and covers the temporal muscle. Near the zygomatic arch, it separates into two layers to enclose a quantity of fat and some small vessels. *On the face*, the deep fascia is practically non-existent anteriorly in relation to the facial muscles. Posteriorly it forms the **parotid fascia**; this fascia is thin where it covers the masseter, but it thickens to cover and ensheath the parotid gland.

In the neck, the deep fascia invests the muscles, and forms fascial coverings for the pharynx, trachea, œsophagus, glands, and large vessels, making, in brief, a superficial collar or tube connected with various intermuscular septa; but most of the deep septa are condensations of areolar tissue rather than definite membranes (Fig. 380). The **investing** layer is usually less dense where it is covered by the platysma; it encloses the sterno-mastoid muscle, and forms the roof of the posterior triangle as it extends backwards to enclose the trapezius; in this region a fascial sling keeps the posterior belly of the omo-hyoid approximately parallel to the clavicle. The fascia can be traced forwards over the anterior triangle to the median plane, where it is continuous with the fascia of the other side.

In the upper part of the neck, this layer is bound down to the body and greater horn of the hyoid bone, and then extends upwards over the digastric muscle and splits to enclose the submandibular gland, the superficial layer passing to the lower border of the mandible and the deep layer to the mylo-hyoid line. At the angle of the mandible it blends with the fascial sheath of the parotid gland. Through this intermediary the investing layer gains attachment to the zygoma, the posterior boundary of the squamo-tympanic fissure, the styloid process, and the lower border of the tympanic plate. Behind the parotid gland, the line of attachment of this layer follows the line of attachment to the skull of the sterno-mastoid and trapezius

muscles—so reaching the external occipital protuberance. A specially thickened portion of the parotid sheath extends between the styloid process and the posterior border of the mandible, separating the lower part of the parotid gland from the submandibular gland. This is termed the **stylo-mandibular ligament.**

Below the cricoid cartilage, the investing layer separates into anterior and posterior lamellæ which are continuous on each side with the layers that invest the sterno-mastoid muscle. At the suprasternal notch, the lamellæ are attached to the anterior and posterior surfaces of the manubrium sterni; the posterior lamella, which covers the infra-hyoid muscles, is attached also to the interclavicular ligament. The **suprasternal space** is enclosed between these two lamellæ, and contains the *jugular arch*, which connects the right and left anterior jugular veins.

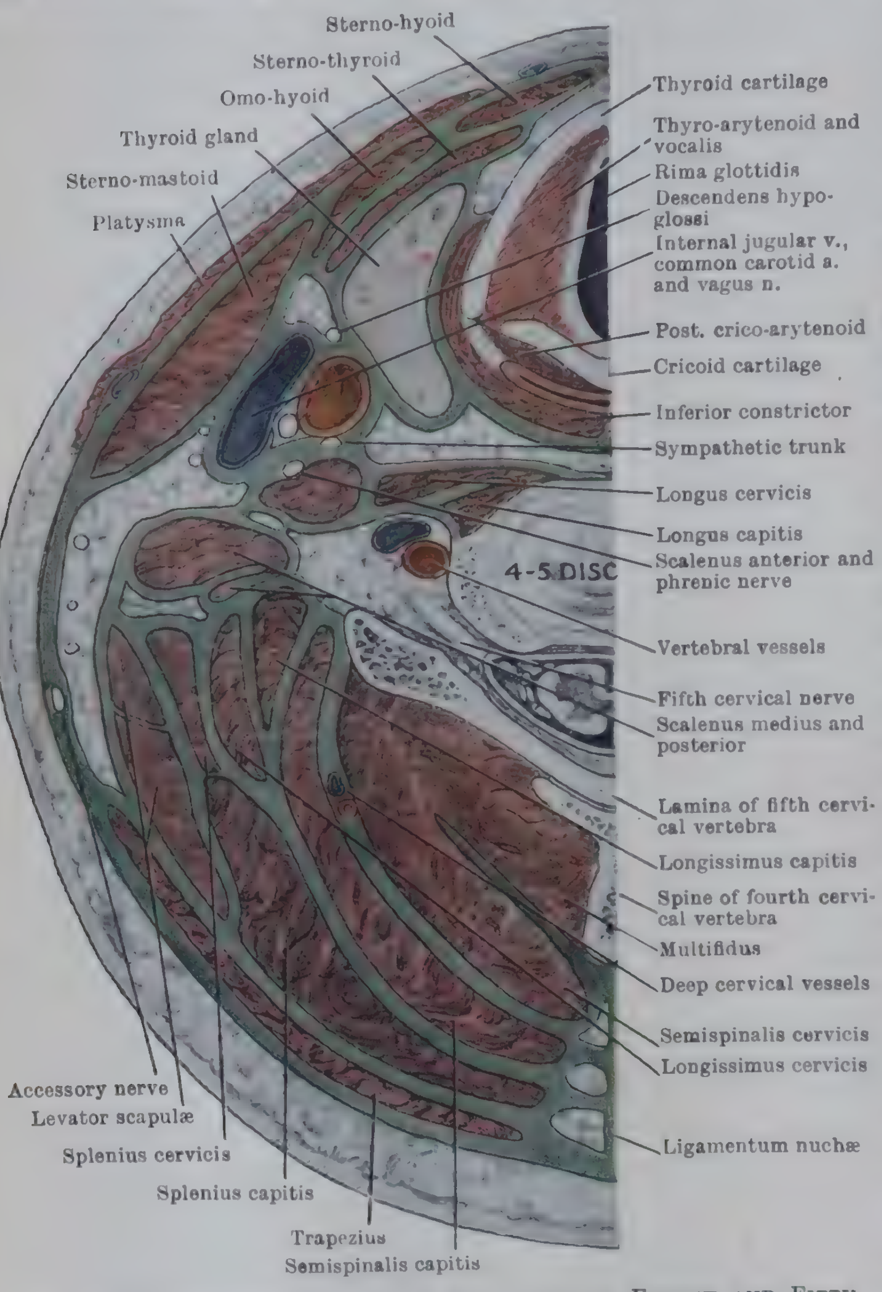

Fig. 380.—Transverse Section of Neck between Fourth and Fifth Cervical Vertebræ.

The **prevertebral fascia** extends from the basilar part of the occipital bone into the thorax, where it blends with the anterior longitudinal ligament. It covers the prevertebral muscles, and from their lateral borders extends over the scalene muscles on to the levator scapulæ and the splenius—covering the cervical plexus and constituting a fascial floor for the posterior triangle of the neck. The subclavian artery and the trunks of the brachial plexus, as they emerge from behind the scalenus anterior, carry a prolongation of this fascia downwards behind the clavicle into the axilla, where it forms the *axillary sheath.*

In the median plane, above, the prevertebral fascia is connected to the bucco-pharyngeal fascia by some loose areolar tissue which occupies the *retropharyngeal space*, and in which the retropharyngeal lymph-glands are imbedded.

As the phrenic nerve descends on the front of the scalenus anterior, it is situated between the muscle and the fascia. The nerves to the rhomboids and serratus anterior also, as they lie in the floor of the posterior triangle of the neck, are retro-fascial.

The **carotid sheath** is formed by a condensation of fibro-areolar tissue around and between the common carotid artery, the internal jugular vein and the vagus nerve, and is usually regarded as a derivative of the deep fascia of the neck. Around the artery the sheath is thick and the ansa hypoglossi and its constituent

nerves are embedded in it; but over the anterior, lateral, and posterior aspects of the vein it is reduced to a very thin layer. Antero-medially the carotid sheath blends with the sheath of the thyroid gland (pretracheal fascia), and, antero-laterally, it is intimately connected to the fascia on the deep surface of the sterno-mastoid and the infra-hyoid muscles. Posteriorly, it is connected to the prevertebral fascia by some loose areolar tissue in which the sympathetic trunk is embedded.

The **pretracheal fascia** is a very ill-defined layer; its most definite part forms a sheath for the thyroid gland. Placed deep to the sterno-thyroid muscle, it is attached to the oblique line of the thyroid cartilage, where it blends with the fascial covering of the inferior constrictor muscle. It is also bound down to the cricoid cartilage anteriorly; and, on the postero-lateral aspect of the lobe of the thyroid gland, it blends with the carotid sheath. From the isthmus of the thyroid gland it is carried downwards in front of the trachea, and blends with the fascial sheaths of the great vessels in the thorax.

MUSCLES OF THE THORAX

MUSCLES OF RESPIRATION

The muscles which complete the boundaries of the thorax are: (1) The external and internal intercostal muscles (Figs. 381-383); (2) the transversus thoracis;

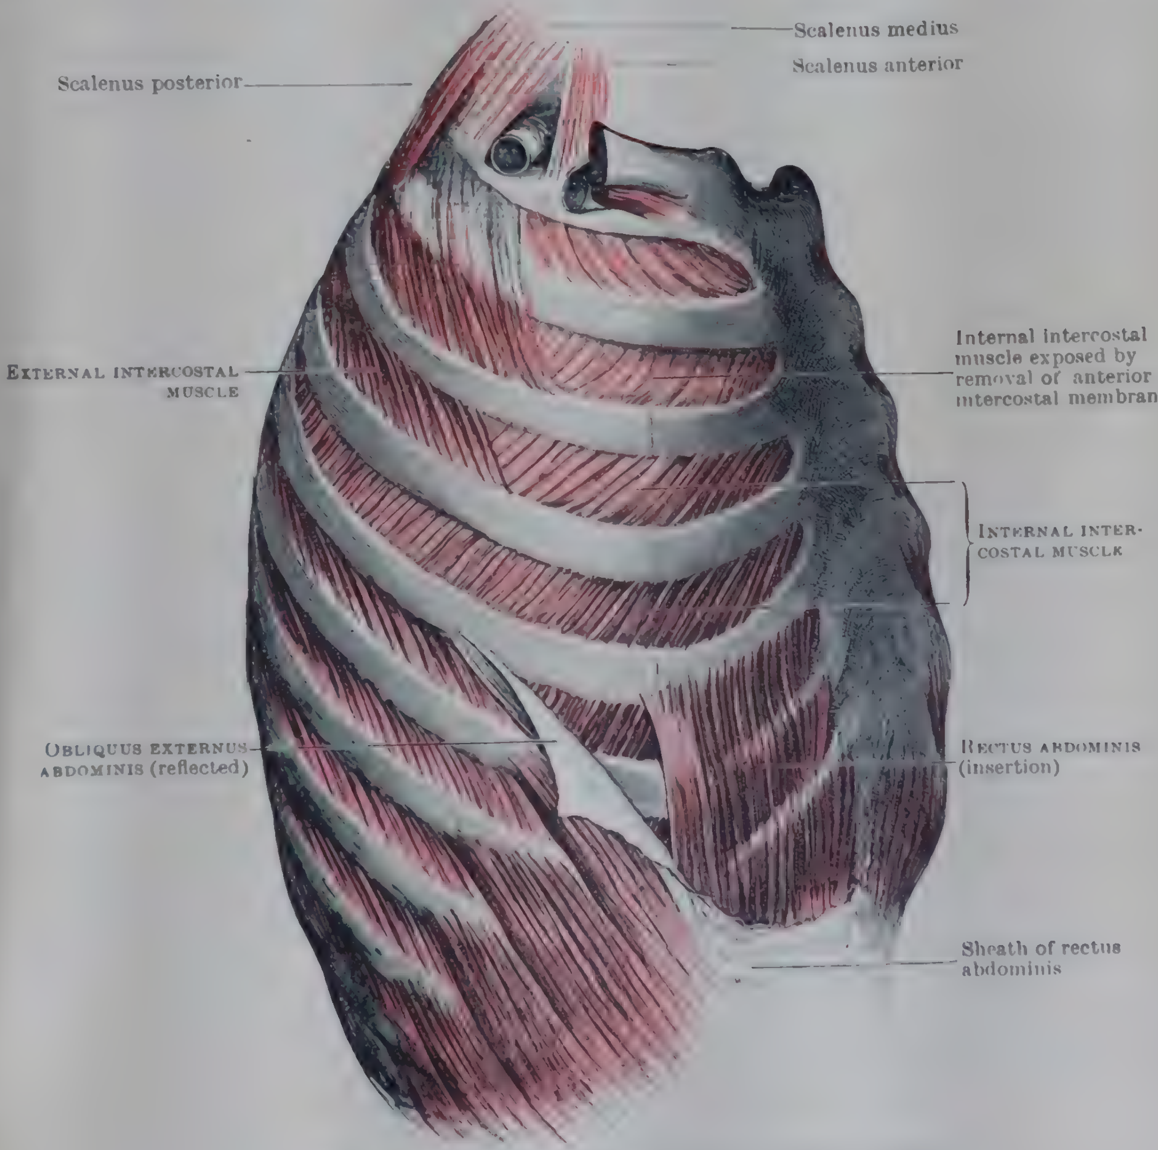

FIG. 381.—MUSCLES OF THE RIGHT SIDE OF THORACIC WALL.

(3) the levatores costarum; (4) the serrati posteriores: and (5) the diaphragm.

Intercostal Muscles.—In each intercostal space there are two intercostal

muscles—an external and an internal. Deep to the middle part of the internal intercostal there is a thin and variable layer called the innermost intercostal muscle (intercostalis intimus), which is part of the transversus thoracis.

Each **external intercostal muscle arises** from the lower border of a rib, and its fibres are directed downwards and forwards to be **inserted** into the upper border

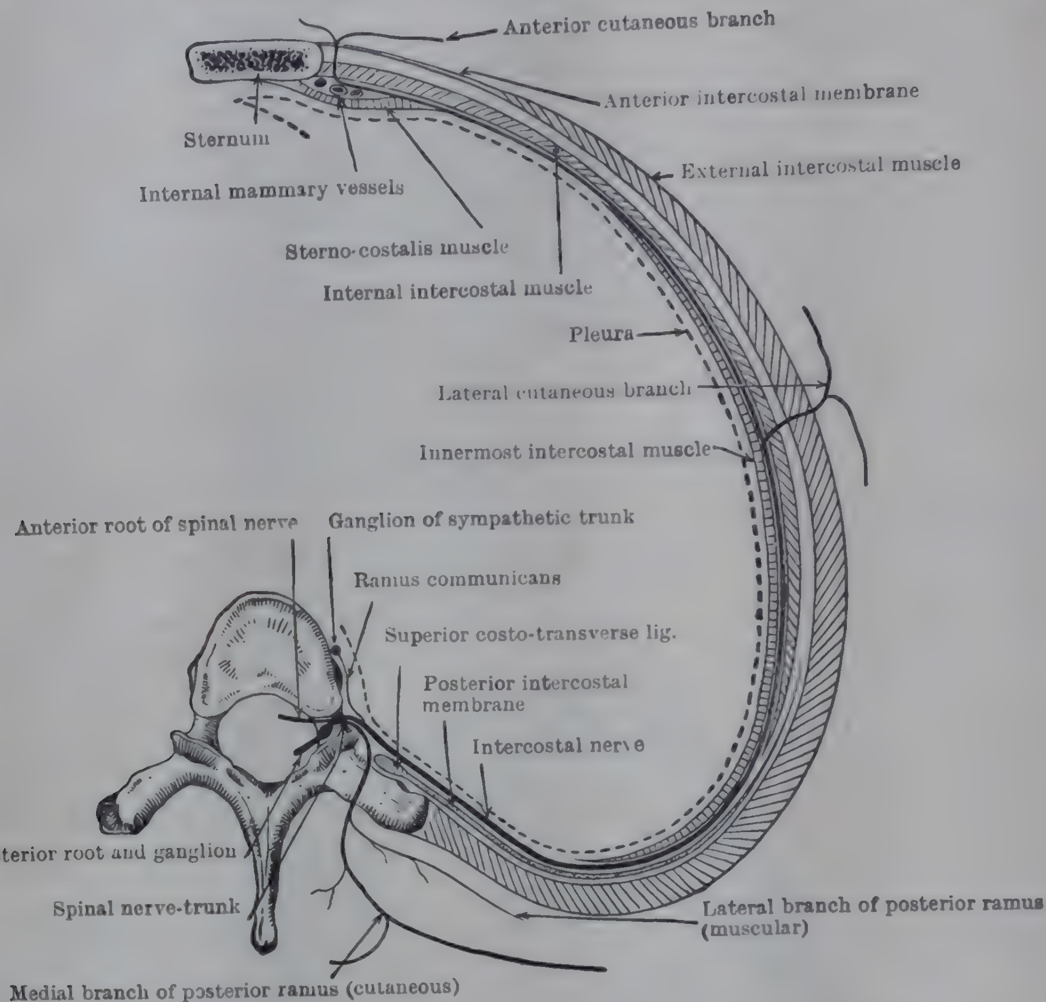

Fig. 382.—Diagram of Intercostal Space to show relations of Intercostal Muscles, Membranes, and Nerve.

of the rib below. It extends from the tubercle of the rib almost to the costal cartilages, gradually thinning to become continuous with the *anterior intercostal membrane*. This membrane extends onwards to the ventral end of the interspace and is attached above and below to the costal cartilages. In the lower spaces, the muscular fibres may merge into the external oblique muscle, which is the abdominal representative of this sheet.

Each **internal intercostal arises** from the upper border of the costal cartilage and rib and is directed upwards and forwards to be **inserted** into the costal cartilage and the upper edge of the costal groove of the rib above. It is thicker anteriorly than posteriorly and extends from the side of the sternum to the angle of the rib, where it is replaced by the *posterior intercostal membrane*, which extends to the tubercle of the rib and there becomes continuous with the superior costo-transverse ligament. The internal intercostal lies external to the intercostal vessels and nerves, and in the lower two spaces is continuous with the internal oblique muscle of the abdominal wall.

Transversus Thoracis.—This muscular sheet is divided into three parts, named the sterno-costalis, the innermost intercostals and the subcostals.

The **sterno-costalis** is the most constant part of the muscle, and lies on the back of the anterior wall of the thorax. It **arises** from the back of the xiphoid process and the body of the sternum as high as the level of the third costal cartilage, and is **inserted** into the costal cartilages from the sixth to the second. The lowest fibres are horizontal, and are continuous with the uppermost part of the transversus

abdominis; the other fibres pass obliquely upwards and laterally to their insertion. The internal mammary artery descends in front of the muscle; the pleura is behind it.

The **innermost intercostal** muscles are incomplete and variable layers that pass from rib to rib, deep to the internal intercostal. The fibres have the same direction as those of the internal muscle, and often cannot be distinguished from it except where they are separated by the intercostal nerve and vessels. Occasionally some of the bundles pass over a rib to the next below. They are connected by their fascia with the sternocostalis. Posteriorly they may be continuous with the subcostal muscles, or may be connected only by fascia with them also. (T. Walmsley, 1916; Davies, Gladstone & Stibbe, 1932.)

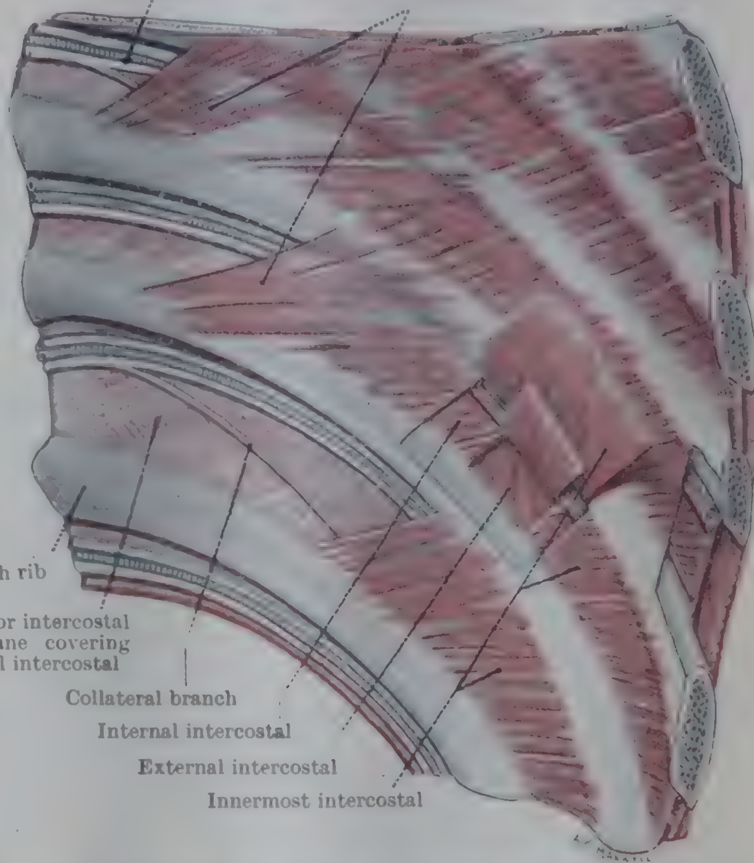

FIG. 383.—DISSECTION OF INNER SURFACE OF CHEST-WALL to show intercostal muscles, vessels, and nerves.

The **subcostal muscles** are slips that vary greatly in number, width, and length. They lie on the internal surface of the lower ribs near their angles. They are in the same plane as the innermost intercostals, and pass over one or two spaces.

Levatores Costarum.—These muscles are twelve small slips that **arise** from the transverse processes of the seventh cervical and upper eleven thoracic vertebræ. Each spreads out in a fan-like manner as it descends to the external surface of the rib immediately below, into which it is **inserted** medial to the angle.

Serrati Posteriores.—These are two thin and fairly wide muscles that lie on the outer aspect of the ribs between the superficial and deep muscles of the back. The **serratus posterior superior** has a membranous **origin** from the lower part of the ligamentum nuchæ and the spines of the last cervical and upper three or four thoracic vertebræ. It is directed obliquely downwards and laterally to be **inserted** by separate slips into the second, third, fourth, and fifth ribs. The muscle is concealed by the vertebro-scapular muscles, and crosses obliquely over the splenius, sacro-spinalis, and semispinalis capitis. Its aponeurosis is blended with the deep fascia that extends upwards from the lumbar fascia.

The **serratus posterior inferior** has a membranous **origin**, through the medium of the lumbar fascia, from the last two thoracic and first two lumbar spines. It forms four muscular bands which pass almost horizontally to an **insertion** into the last four ribs. The muscular slips overlap one another from below upwards. The muscle is concealed by the latissimus dorsi.

Diaphragm

The **diaphragm** is the great muscular and membranous partition that separates the cavities of the thorax and abdomen. A peripheral muscular portion completely surrounds a central aponeurotic membrane, and together

they form a thin but strong lamella which arches over the abdominal cavity, and is clothed on that surface, for the most part, with peritoneum. It is related, on its inferior, concave surface to the liver, stomach, and spleen, the kidneys and suprarenal glands, and the inferior vena cava. Its superior, convex surface bulges into the thoracic cavity, rising higher on the right side than on the left, and is related to the pericardium and pleuræ, and, along its margin, to the chest-wall. The œsophagus and thoracic aorta are in contact with this surface posteriorly.

The diaphragm as a whole has an extensive peripheral attachment to the inner surface of the lower margin of the thorax and to the lumbar vertebræ. Its muscular fibres, springing from sternum, ribs, and vertebræ, arch upwards and inwards, with varying degrees of curvature, to end in tendinous fibres which by their interlacement constitute the central tendon.

The **central tendon** is a dense felted aponeurosis, resembling a trefoil, since it

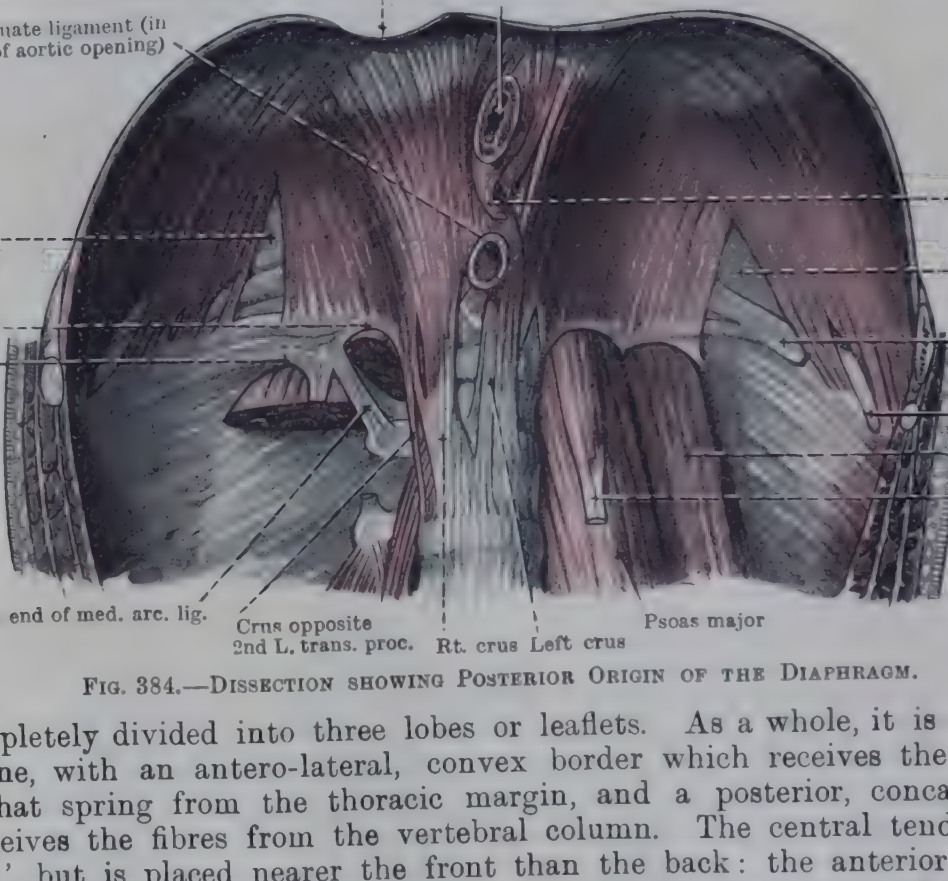

Fig. 384.—Dissection showing Posterior Origin of the Diaphragm.

is incompletely divided into three lobes or leaflets. As a whole, it is crescentic in outline, with an antero-lateral, convex border which receives the muscular fibres that spring from the thoracic margin, and a posterior, concave border that receives the fibres from the vertebral column. The central tendon is not 'central', but is placed nearer the front than the back: the anterior muscular fibres (from the xiphoid process) are consequently the shortest; and the crural fibres (from the vertebral column) are the longest. The middle or anterior lobe of the central tendon is rounded, and projects forwards from the convex border towards the sternum; by contrast, the lateral or posterior lobes appear to be narrowed from side to side. Nor is the central tendon symmetrical; the right lobe is the largest, the middle is intermediate in size, and the left is a little narrower.

The central tendon is made up of interlacing tendinous bundles which are continuous at each end with portions of the muscular sheet. The main bundles are related to the margins of the large opening for the inferior vena cava at the posterior part of the junction between the middle and right lobes; and the most obvious interlacement is found, in the densest part of the central tendon, in the median plane to the left of that opening. In that situation the interlacing tendinous bundles are arranged more or less regularly in the form of a St. Andrew's cross; in the right concavity of this X-shaped figure the vena caval opening is situated, and it has been shown that there is frequently a small venous foramen in the corresponding situation on the left side, so that the whole arrangement is in reality symmetrical (Blair, 1923).

The fleshy portion of the diaphragm is naturally divided into two portions—

a sterno-costal and a vertebral (distinguished in the classical descriptions as the *greater* and the *lesser* muscles of the diaphragm)—which are not only distinct developmentally but are separated on one or both sides of most bodies by a hiatus in the muscular sheet termed the *vertebro-costal trigone*. The sterno-costal portion

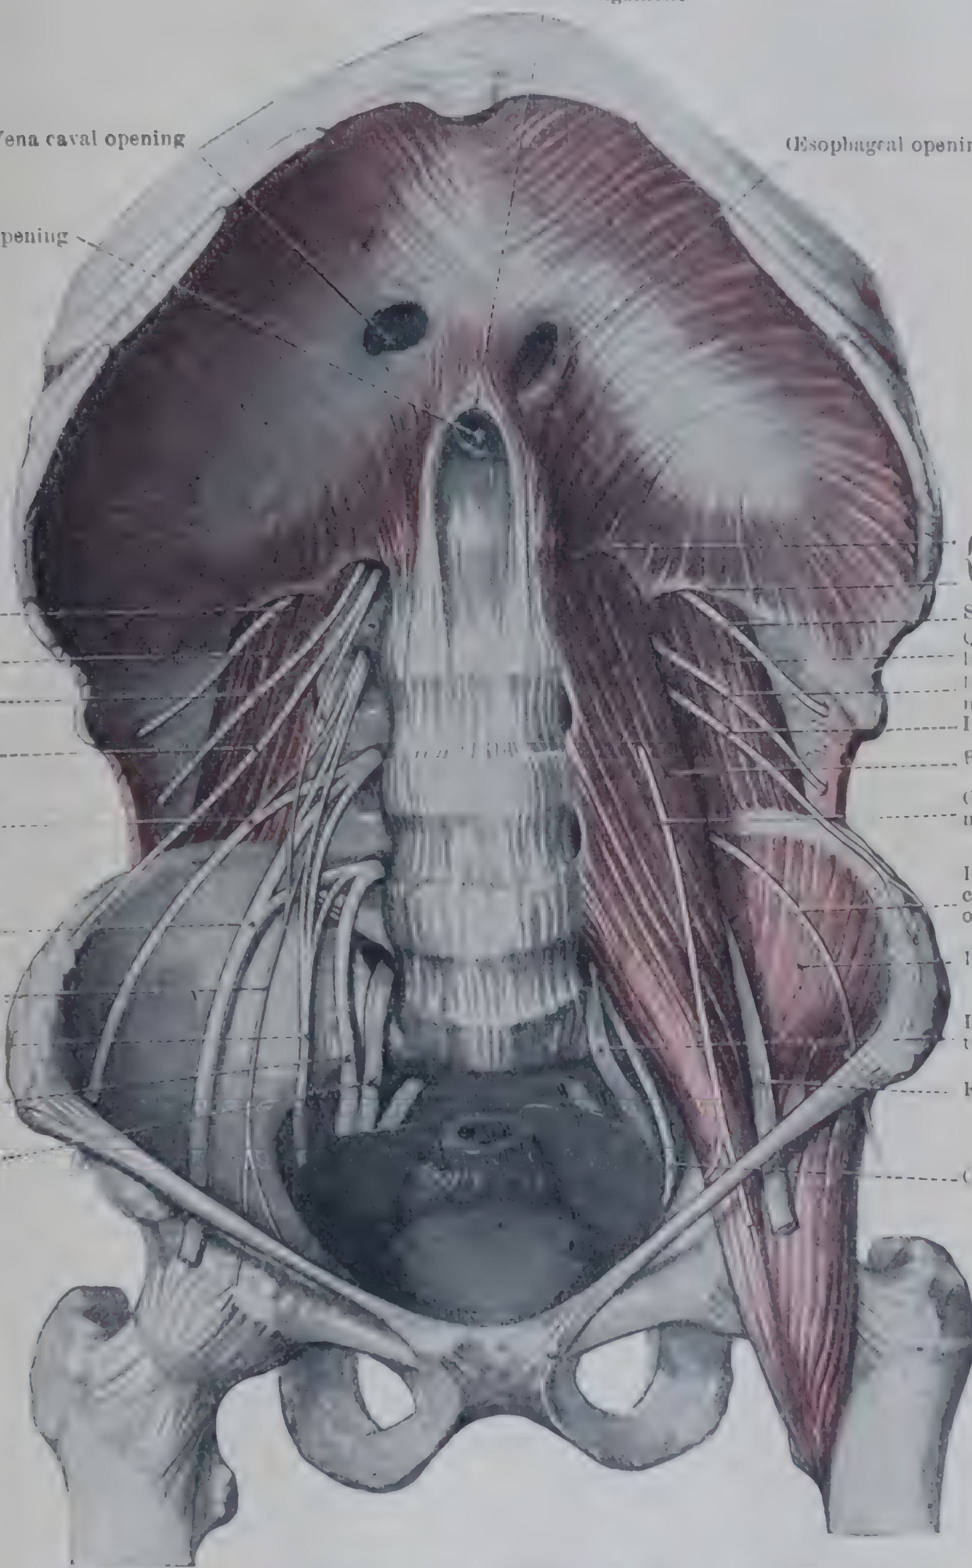

FIG. 385.—DIAPHRAGM AND POSTERIOR WALL OF ABDOMEN.

is subdivided, according to the attachment of its fibres, into sternal and costal parts.

The **sternal part** consists of a pair of short narrow slips that **arise** from the back of the xiphoid process and pass backwards and slightly upwards to be **inserted** into the central tendon.

The **costal part arises** from the deep surfaces of the lower six costal cartilages on each side by fleshy bands which interdigitate with those of the transversus abdominis. It is **inserted** into the whole length of the antero-lateral border of the central tendon.

The **vertebral part arises** from the lumbar vertebræ—directly from the bodies of the first three by the crura, and indirectly from the transverse processes of the first or second (or both) by means of the medial and lateral arcuate ligaments. It is **inserted** into the posterior border of the central tendon.

The **crura** are a pair of elongated musculo-tendinous bundles which arise, at the sides of the aorta, from the anterior surfaces of the bodies of the lumbar vertebræ—the right crus from the first three, the left crus from the first two. They are partly separated from the vertebral bodies by the upper lumbar arteries, but are firmly attached, with the anterior longitudinal ligament, to their margins and to the intervertebral discs.

The **right crus** is, as a rule, much the larger. It spreads out to form a thick triangular sheet which is directed upwards to its insertion into the middle part of the concave border of the central tendon on both sides of the median plane. Its left margin is directed obliquely upwards and to the left in front of the aorta, and splits as it approaches the central tendon to form an elliptical opening for the passage of the œsophagus (Figs. 384 and 385 show slight variations); the muscular fibres usually meet again and decussate to form the anterior margin of that opening, which is thus separated from the central tendon and surrounded by a sphincter-like arrangement of the muscle. From the right crus, below the œsophageal opening (from both sides of which it may spring), a narrow, detached band of muscle passes forwards and downwards to the left of the cœliac artery; this is the upper portion of the **suspensory muscle of the duodenum** (Low, 1907). (See also Digestive System, p. 633.)

The **left crus** is very variable in its size and attachments, but usually it is much smaller and arises higher up and farther from the median plane than the right crus. The main part of its muscular fibres is directed upwards to the left of the œsophageal opening, from which it is separated by the left margin of the right crus. Frequently a separate bundle passes to the right, between the aortic and œsophageal openings behind the fibres of the right crus (Fig. 384), to be inserted into the central tendon in the neighbourhood of the vena caval opening; but as a general rule this bundle takes no part in the formation of the œsophageal opening.

The medial part of each crus forms at its origin a tendinous funnel; the mouth of each funnel is limited above by a spiral edge that runs downwards and laterally from the aortic opening, and from it the muscular bundle emerges. Each crus is connected with its fellow of the opposite side by a tendinous band, called the **median arcuate ligament**, which arches between them, in front of the aorta, and gives origin to fibres which join the right crus as it splits to encircle the gullet. The most lateral part of the crus is continuous with the medial end of the medial arcuate ligament. Each crus is frequently divided into two or three distinct portions in relation to the passage of the splanchnic nerves and the sympathetic trunk. The splanchnic nerves pierce the crus between the medial and intermediate parts. The sympathetic trunk sometimes pierces the crus between the intermediate and lateral parts.

Between the crus and the medial edge of the costal portion of the diaphragm the origin of the lateral part of its vertebral portion is associated with the tendinous structures known as the medial and lateral arcuate ligaments; by means of these the origin of the diaphragm is carried across the upper parts of the psoas major and quadratus lumborum muscles. Both of these arches have frequently been described as mere thickenings of the fascial covering of those two muscles, but one of them is in reality an independent structure with which the fascia is fused. The medial arch is an essential tendinous origin of the diaphragm itself, while the lateral is a thickened portion of the anterior lamella of the lumbar fascia from which muscular fibres of the diaphragm may secondarily arise. It may be compared with the *arcuate line* formed by the aponeurosis of the internal oblique muscle in the lower part of the posterior wall of the sheath of the rectus abdominis.

The **medial arcuate ligament** springs from the side of the body of the second (or first) lumbar vertebra, where it is continuous with the lateral part of the crus, and arches obliquely over the upper part of the psoas muscle, behind the lateral border of which it passes downwards and medially to be attached to the transverse process of the first (or second) lumbar vertebra near the tip. The lateral end of the ligament furnishes a direct tendinous origin of the diaphragm from the transverse process to which it is attached, and the part of the arch which lies in front of the psoas gives rise to a thin sheet of muscle which fills the interval between that origin and the crus.

The **lateral arcuate ligament** stretches from the transverse process of the first (or second) lumbar vertebra across the upper part of the quadratus lumborum to be attached laterally to the twelfth (or eleventh) rib. Between the lateral margin of the quadratus and the costal attachment the ligament is continuous below with the posterior aponeurosis of the transversus abdominis, and it corresponds to similar, smaller arches which exist between the ends of the twelfth and eleventh, and of the eleventh and tenth ribs. A broad band of muscular fibres sweeps upwards from this ligament to be inserted into the medial and posterior border of the lateral portion of the central tendon. This band is overlapped towards its insertion by the edge of the costal portion of the diaphragm, and it may or may not completely fill the interval between the edge of the psoas and the last rib.

The **vertebro-costal trigone** may be defined as the interval between the posterior margin of the costal part and the lateral margin of the vertebral portion of the diaphragm. A

muscular hiatus is present in this situation on one or both sides in at least 80 per cent. of bodies, disclosing to a considerable extent the lower limit of the pleura, with which the kidney may thus be intimately related; it is more frequent, and (when bilateral) usually larger, on the left side. It varies in size from a slight separation of the muscular fibres just medial to the twelfth rib (or the eleventh when the twelfth is short and does not give origin to the diaphragm) to a large, triangular gap with a base extending from the lateral border of the psoas to the twelfth (or eleventh) rib, and an apex reaching the central tendon. Its size depends upon the degree of lateral migration of the vertebral part of the diaphragm. The gap is occasionally filled by a sheet of muscle whose fibres arch *transversely* between the margins of the two portions of the diaphragm; this sheet is sometimes in continuity with the subcostal sheet of muscle, of which it appears to be a portion displaced in *front* of the lower limit of the pleura. The vertebro-costal hiatus in the muscular continuity of the diaphragm is situated in the position of the pleuro-peritoneal opening of the embryo, and is the site of congenital diaphragmatic hernia (more common on the left side), in which the pleural and peritoneal cavities are continuous.

The diaphragm is pierced by numerous structures. The superior epigastric artery enters the sheath of the rectus abdominis between its sternal and costal origins; the musculo-phrenic artery passes between its attachments to the seventh and eighth costal cartilages. The splanchnic nerves pierce the crus, and the sympathetic trunk descends behind the medial end of the medial arcuate ligament. The subcostal nerve and vessels pass behind the lateral arcuate ligament; and the aorta and thoracic duct pass between the crura, behind the median arcuate ligament (*aortic opening*). The azygos vein is usually described as passing through the aortic opening, but it is placed postero-lateral to the thoracic duct and completely under cover of the right crus. The special openings are two in number. The *vena caval opening* in the right half of the central tendon transmits the inferior vena cava and small branches of the right phrenic nerve. The *œsophageal opening* is in the muscular substance of the diaphragm, behind the central tendon, and is surrounded by a sphincter-like arrangement of the fibres of the right crus (Low, 1907; Whillis, 1931). Besides the œsophagus, this opening transmits the two gastric nerves, each containing fibres from both the right and the left vagus, and œsophageal branches of the left gastric artery.

The comparative morphology of the diaphragm and its derivation from the fourth cervical myotome are summarized on p. 555.

Nerve-Supply.—The intercostal muscles, the transversus thoracis, the levatores costarum, and the serrati posteriores (superior, Th. 1-4; inferior, Th. 9-11) are all supplied by the **anterior primary rami** of the **thoracic nerves**.

The diaphragm receives its motor supply from the **phrenic nerve** (C. 3. 4. 5.), mainly on its inferior surface after the nerves have pierced it. The phrenic nerves contain afferent fibres also, and the branches to the diaphragm from the lower intercostal nerves (9th, 10th, and 11th), which have been described, may be of this nature, or they may supply motor fibres to a portion of the subcostal sheet if that is incorporated in the diaphragm, between its lumbar and sterno-costal portions, in the closure of the vertebro-costal trigone. The sympathetic nerve-supply to the diaphragm is conveyed to it from the cœliac ganglion through the phrenic plexus, with which the phrenic nerve communicates.

Actions.—The opposite respiratory movements of expiration and inspiration, essentially associated with the rise and fall of the diaphragm, are effected by antagonistic forces and are supported by an array of accessory and fixation muscles; and the greater the respiratory excursions, the more reserves are enlisted. The delicate, yet intensive, control exercised by the diaphragm in regulating the outflow of air through the larynx is remarkably evident in singing, when it opposes its abdominal antagonists, while the quadratus lumborum acts as a fixation muscle.

Before considering the details of these movements, points of clinical value regarding the position of the diaphragm as affected by posture in the living subject during expiration and inspiration may be considered with reference to the radiographs on Plates XXXVIII and XXXIX, pp. 456-457. With the subject standing (Fig. **1**) the diaphragm occupies a lower level than in the supine position (Fig. **3**), in which the abdominal weight presses against the diaphragm instead of pulling it downwards. Breathless patients breathe more easily, therefore, when propped up in bed. When the subject lies prone the diaphragm rises markedly on the right side. The diaphragm occupies the same level in sitting as in standing (Pls. XXXVIII and XXXIX, Figs. **1** and **2**).

When the subject lies on one side (Figs. **4** and **5**), apart from the fact that the corresponding side of the diaphragm, owing to the pressure of the abdominal viscera, reaches a higher level than in other positions, the costo-diaphragmatic recess (p. 711)

are separate to the mid line. It gains attachments, below to the pubic tubercle and the front of the symphysis (Fig. 391), above to the xiphoid process, and by its intermediate decussating fibres to the **linea alba.**

The muscle is superficial in almost its whole extent. It is overlapped posteriorly by the latissimus dorsi, but is often separated from it immediately above the iliac

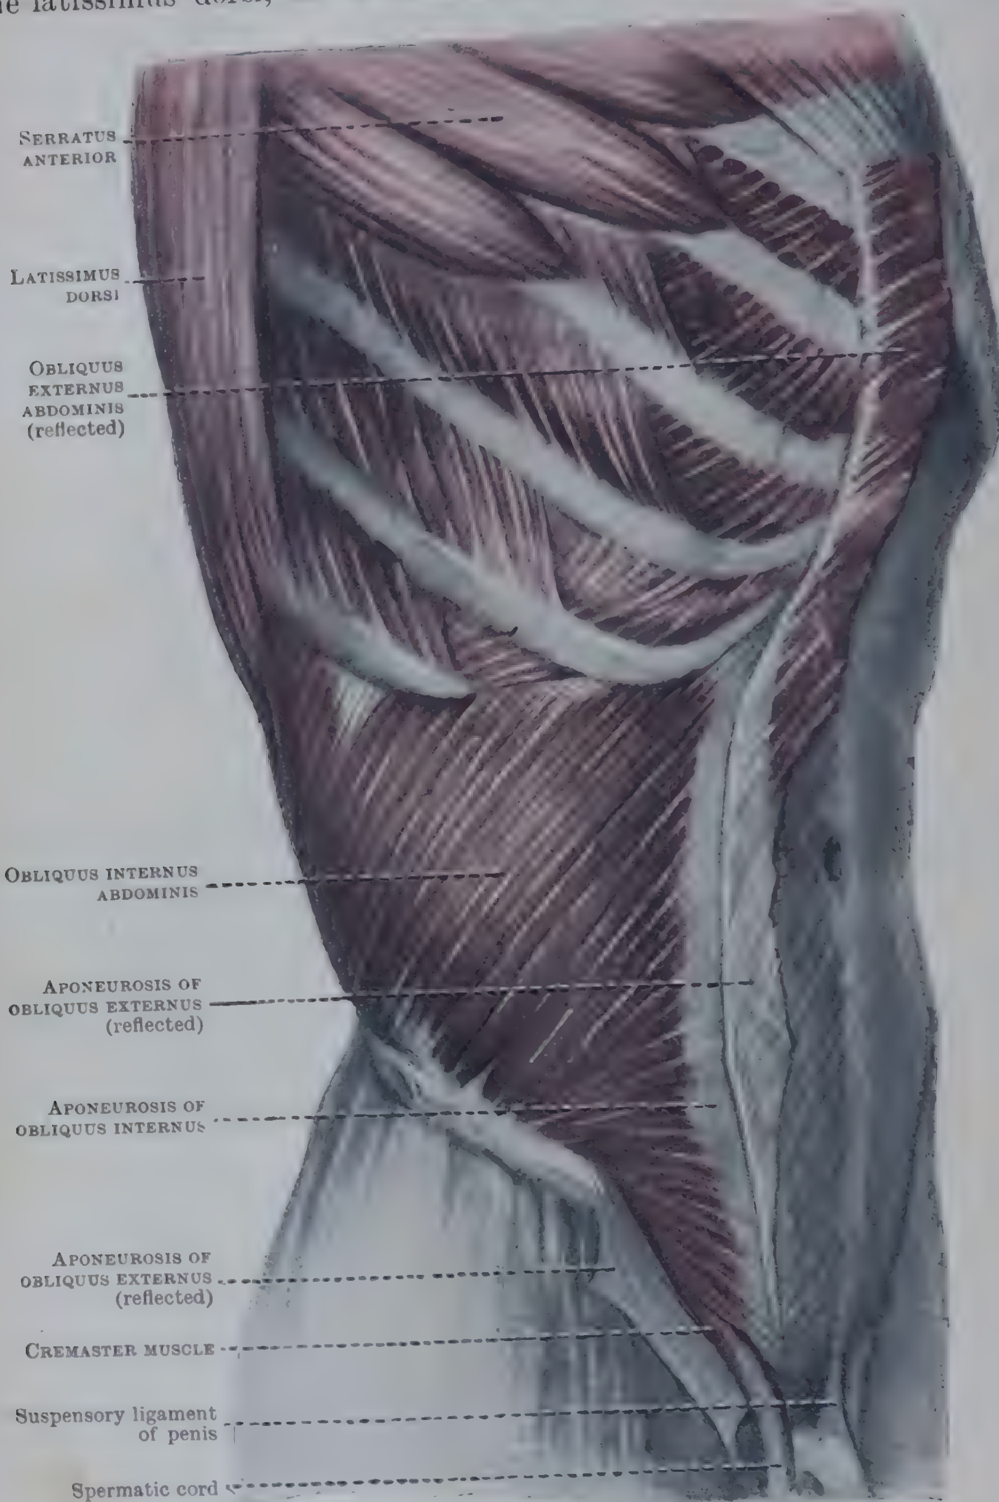

FIG. 387.—RIGHT OBLIQUUS INTERNUS ABDOMINIS.

crest by an angular interval called the **lumbar triangle.** The uppermost part of the aponeurosis covers the insertion of the rectus abdominis on the chest-wall, and gives origin to fibres of the pectoralis major; its lower border is folded slightly backwards upon itself, between the anterior superior iliac spine and the pubic tubercle, to form the inguinal ligament; and immediately above the pubic tubercle there is a cleft in the aponeurosis, called the superficial inguinal ring, which transmits the spermatic cord or the round ligament of the uterus.

The **linea alba** is a band of interlacing fibres, narrow below the umbilicus but increasing to about half an inch in width in its upper part. It occupies the median

[Facing

plane of the anterior abdominal wall in its whole extent, is pierced by the umbilicus and forms the greater part of the ultimate insertion of all the lateral abdominal muscles.

The **umbilicus** or navel is a little below the middle of the linea alba, usually opposite the disc between the third and fourth lumbar vertebrae. It is a puckered scar in the skin and the linea alba, and it results from the closure of the *umbilical orifice* of the fœtus. The orifice transmits the umbilical vein and arteries and the connexion between the allantois and the urachus. After birth the derivatives of those structures remain attached to the umbilicus—the round ligament of the liver derived from the vein, the lateral umbilical ligaments from the arteries, and the

Fig. 388.—Left Inguinal Canal. Structures seen on reflexion of Obliquus Externus.

median umbilical ligament from the urachus. The deep surface of the umbilicus is related also to the extraperitoneal tissue; and a fibrous band may connect it with the diverticulum ilei when the diverticulum is present.

The **inguinal ligament** is a tendinous band curving with a downward convexity from the anterior superior iliac spine to the pubic tubercle across the iliacus, psoas major and pectineus. The convexity gives attachment to the fascia lata. The ligament is the lower margin of the external oblique aponeurosis folded back on itself, and its upper surface is therefore grooved. In its lateral part, this surface gives partial origin to the internal oblique and the transversus, and receives the attachments of the fascia transversalis and fascia iliaca; in its medial part it forms the gutter-like floor of the inguinal canal. This portion includes the **pectineal part** of the ligament, which is a triangular expansion that spreads *backwards* from the most medial part of the ligament to the pectineal line (Fig. 391). Some of these

fibres are reflected from the pectineal line obliquely through the linea alba to mingle with the aponeurosis of the other side; this **reflected part** of the inguinal ligament, sometimes described as an additional insertion of the opposite external oblique aponeurosis, is seldom well marked. A lateral extension along the pectineal line from the pectineal part of the inguinal ligament is termed the *pectineal ligament* (Astley Cooper). The inguinal ligament is related posteriorly to the femoral nerve and to the femoral vessels enclosed in the femoral sheath: the nerve is between the iliacus and the psoas major; the artery is on the psoas; the vein is partly on the psoas and partly on the pectineus. The lateral margin of the pectineal part of the ligament is the medial boundary of the *femoral ring* (p. 532 and Fig. 393).

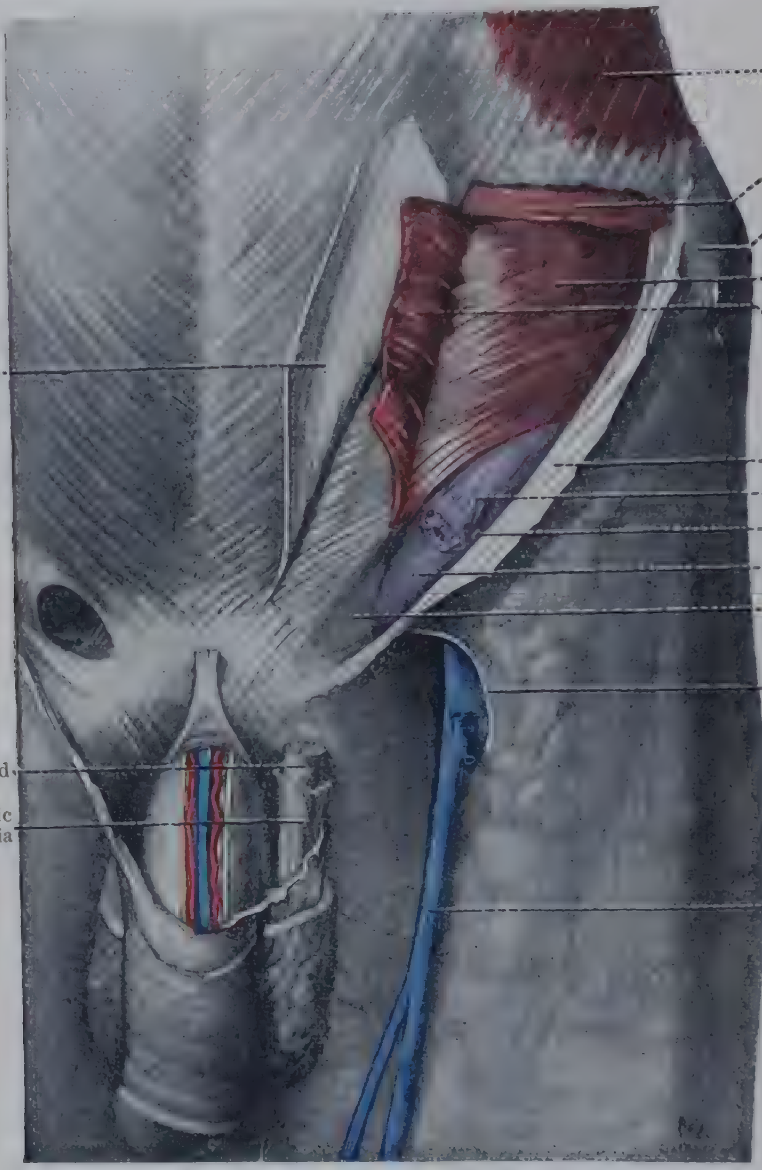

FIG. 389.—DISSECTION OF INGUINAL CANAL.

The **superficial inguinal ring**, important as the place of exit of an inguinal hernia, is a triangular cleft in the external oblique aponeurosis with its base at the pubic crest and its apex directed upwards and laterally.

The margins of the cleft are called its crura. The **inferior crus** is narrow, and is formed from that part of the aponeurosis which is fixed to the pubic tubercle, and constitutes the medial end of the inguinal ligament. The **superior crus**, flat and broad, is the part of the aponeurosis which is attached to the pubic crest and symphysis. In the male it transmits the spermatic cord, enclosed in the internal spermatic fascia and the cremaster muscle and fascia; in the female the cleft is much smaller and transmits the round ligament of the uterus. The opening is variable in width and is triangular in outline; its edges are drawn together by a thin fascia, strengthened superficially by a number of arched and horizontal fibres, called the **intercrural fibres** (Fig. 394), which arise from the inguinal ligament and

sweep medially across the cleft in the aponeurosis; but the margins of the opening are readily felt in the living subject if the finger is passed upwards over the spermatic cord, invaginating the overlying skin, till it is opposite the ring, and is then pressed backwards.

The intercrural fibres and the crura of the ring are continuous with a thin tubular

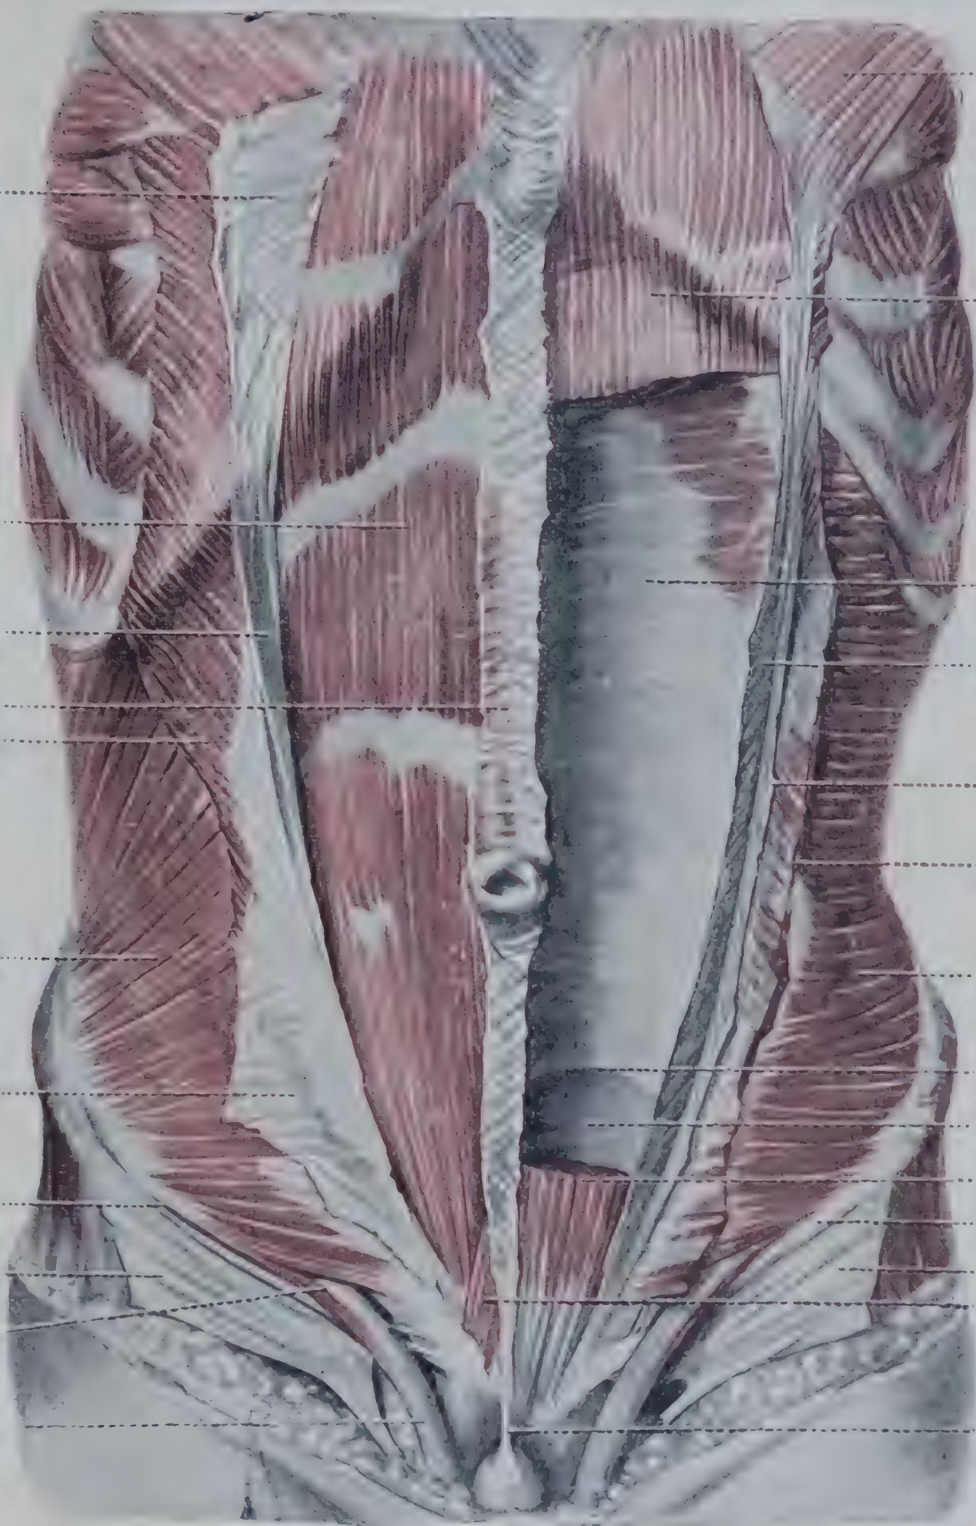

FIG. 390.—DEEP DISSECTION OF ABDOMINAL WALL. RECTUS MUSCLE AND ITS SHEATH.

sheath, called the **external spermatic fascia**, which forms an envelope for the spermatic cord (or for the round ligament) after it has passed beyond the abdominal wall; and it must be noted that the ring is not apparent until the external spermatic fascia has been removed from its edges.

Obliquus Internus Abdominis.—The internal oblique muscle is a broad, thin sheet situated between the external oblique and the transversus. It arises from (1) the lumbar fascia, (2) the anterior half or two-thirds of the intermediate area of the iliac crest, and (3) the lateral two-thirds of the inguinal ligament.

It runs, for the most part, upwards and forwards, and its highest and most posterior fibres are inserted directly into the cartilages of the last three ribs in line with the internal intercostals. The rest of the muscular fibres spread like a fan and become an aponeurosis, the change taking place along a line that extends downwards and medially from the tenth costal cartilage to the pubic bone. The principal insertion of the aponeurosis is the whole length of the linea alba, but it does not reach its insertion as an undivided sheet. The lower fourth passes in front of the rectus abdominis, and, spreading downwards and medially, reaches the pubic bone as well as the linea alba. The upper three-fourths splits at once into

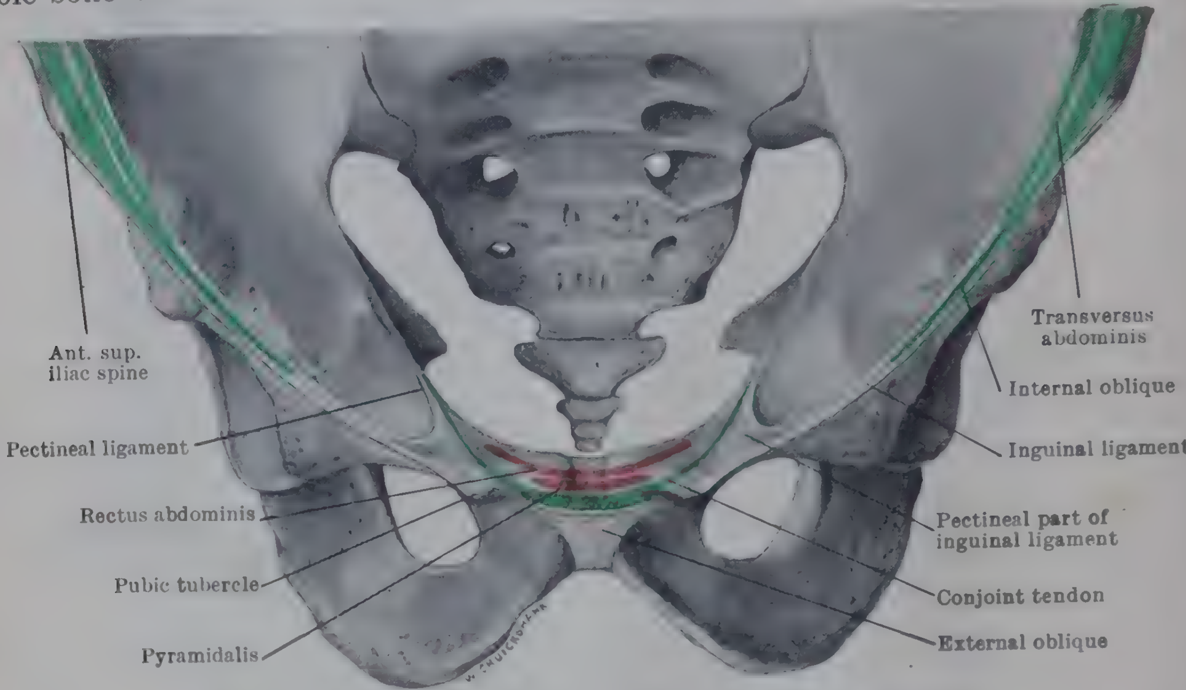

Fig. 391.—Muscle-Attachments to Inguinal Ligament and Pubis.

two layers which enclose the rectus as they pass to their insertion into the linea alba and the xiphoid process; the posterior layer is attached also to the margins of the ninth, eighth, and seventh costal cartilages, and above that level the rectus abdominis muscle is therefore in direct contact with the chest-wall. The part which passes undivided in front of the rectus is derived from the fleshy fibres that arise from the inguinal ligament. It fuses with the part of the transversus aponeurosis that has a like origin to form a sheet called the conjoint tendon. The **conjoint tendon** meets its fellow at the linea alba, and also extends downwards to be attached to the pubic crest and the pectineal line (Fig. 391).

The internal oblique is limited above by the inferior margin of the thorax. Its lower fibres, arching over the spermatic cord, assist in forming, laterally, the anterior wall of the inguinal canal; medially, by means of the conjoint tendon, they help to form the posterior wall.

Its lowest fibres are continued into the **cremaster muscle**, which is prolonged along the spermatic cord through the inguinal canal.

Cremaster—The cremaster muscle, a series of delicate muscle-fibre festoons connected by fascia—the *cremasteric fascia*—**arises** from the inferior edge of the internal oblique and the adjacent part of the inguinal ligament, and loops over the spermatic cord and testis, the highest fibres getting an **insertion** into the pubic tubercle. In the female it is more largely represented by fascia than by muscle-fibres. The name 'cremaster' refers to the suspensory function of the muscle [κρεμαστός=suspended].

Transversus Abdominis.—The transversus abdominis muscle **arises** (1) from the deep surfaces of the costal cartilages of the lower six ribs, interdigitating with the origins of the diaphragm; (2) from the transverse processes of the lumbar vertebræ through the middle layer of the lumbar fascia; (3) from the anterior half or two-thirds of the inner lip of the iliac crest; and (4) from the lateral third of the inguinal ligament.

The muscular fibres run, for the most part, horizontally forwards, and they end

in an aponeurosis which has a twofold **insertion.** (1) After taking part in the formation of the sheath of the rectus, the aponeurosis is attached to the xiphoid process, the whole length of the linea alba, and the pubic symphysis. (2) The fibres that arise from the inguinal ligament form the larger part of the conjoint tendon, to which the lower part of the internal oblique also contributes.

The aponeurosis of the transversus abdominis is widest opposite the interval between the last rib and the iliac crest, and gradually becomes narrower above and below. Near the xiphoid process it is barely 3 cm. wide, and in this situation fleshy fibres of the muscle are separated from the rectus abdominis only by the posterior lamella of the aponeurosis of the internal oblique (Fig. 390).

The lower intercostal nerves lie between the internal oblique muscle and the transversus muscle, which is lined on its deep surface by the fascia transversalis. Its inferior border forms a concave edge, separated from the inguinal ligament by a semilunar interval in which the fascia transversalis appears, and through which the spermatic cord emerges at the deep inguinal ring, under cover of the internal oblique muscle and the aponeurosis of the external oblique.

Pyramidalis.—The pyramidalis is a small triangular muscle that lies on the front of the lower part of the rectus abdominis. It **arises** from the pubic crest lower down than the origin of the rectus (Fig. 391). It is directed obliquely upwards, for a variable distance, to be **inserted** into the linea alba (Fig. 390). The muscle is often absent.

Rectus Abdominis.—The rectus abdominis muscle is long and strap-like; and it **arises** by a medial head from the ligaments in front of the pubic symphysis, many of the fibres coming from the opposite side, and by a lateral head from the pubic crest (Figs. 390, 391).

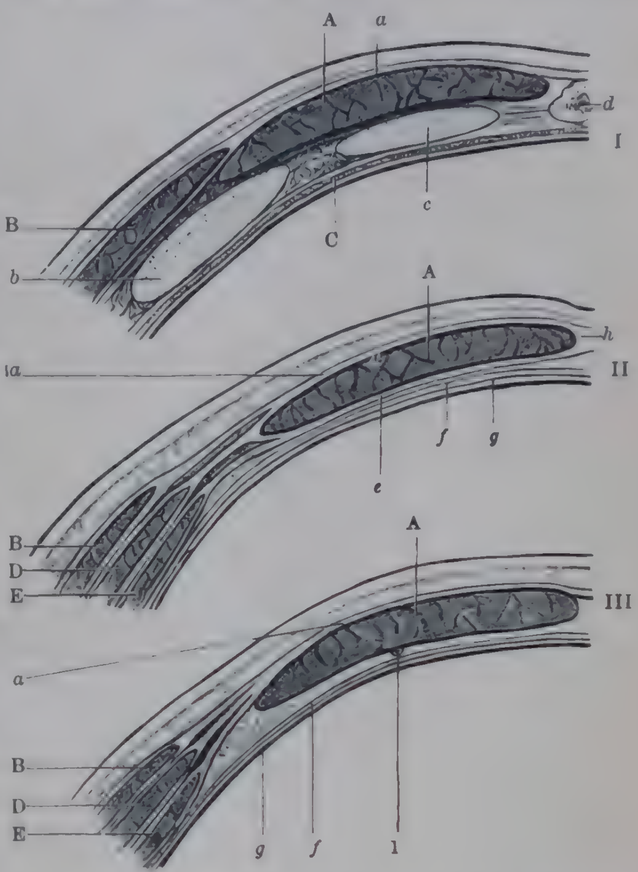

Fig. 392.—Sheath of Rectus Abdominis Muscle.

I. In the thoracic wall; II. In the upper three-quarters of the abdominal wall, cf. Fig. 390; III. In the lower fourth of the abdominal wall. (Below the umbilicus, the fusion of the aponeuroses of external and internal oblique muscles in front of the rectus is incomplete, p. 455).

The muscle widens as it passes upwards, and is **inserted** into the anterior surface of the xiphoid process, and into the superficial surfaces of the seventh, sixth, and fifth costal cartilages. On its anterior surface, but not extending through the entire substance of the muscle, are three or more transverse **tendinous intersections**, firmly adherent to the anterior wall of the sheath of the muscle; the lowest is at the side of the umbilicus, and the highest is near the xiphoid process. These may be evident in the well-developed living subject (Pl. XXXVII, p. 456, Fig. 3). The medial border of the muscle lies alongside the linea alba; its lateral border is convex, and corresponds to a shallow groove on the skin called the **linea semilunaris.** The muscle is pierced by the terminal branches of the lower thoracic nerves after they have passed between the muscle and the posterior wall of its sheath.

The **sheath of the rectus abdominis** is derived from the aponeuroses of the lateral muscles of the abdominal wall, which, after enclosing the rectus, give rise, in the median plane, to the linea alba. At the linea semilunaris, the aponeurosis of the internal oblique splits into anterior and posterior layers. The anterior layer, joined by the aponeurosis of the external oblique, passes in front of the rectus and

constitutes the anterior wall of the sheath. The posterior layer, joined by the aponeurosis of the transversus muscle, passes behind the rectus and constitutes the posterior wall of its sheath. (In the uppermost part of the posterior wall there are muscular fibres of the transversus as well as aponeurotic fibres.) This arrangement obtains in the upper three-fourths of the abdominal wall. Below the level of the anterior superior iliac spine the sheath of the muscle is deficient posteriorly, and a crescentic border, called the **arcuate line,** marks the lower limit of the posterior wall. In consequence, the rectus in the lower fourth of the abdominal wall rests directly on the fascia transversalis. Close examination, however, usually reveals a thin layer behind the muscle in continuity with the arcuate line, and merging below with the fascia transversalis. In this region (see p. 455) the rectus is covered anteriorly by the aponeuroses of the external oblique, internal oblique, and transversus (Fig. 392). The upper part of the rectus, lying directly on the chest-wall, (because the posterior wall of the sheath ascends no higher than the costal margin) is covered anteriorly by only a single layer of aponeurosis derived from the external oblique, which in that situation is giving origin to the pectoralis major muscle. In addition to the rectus the sheath contains the pyramidalis, the superior and inferior epigastric vessels, the terminal portions of the lower five intercostal vessels and nerves and the subcostal vessels and nerve.

Inguinal Canal.—The spermatic cord in the male (or the round ligament in the female) traverses the **inguinal canal**, which is an oblique passage through the muscular layers of the lowest part of the abdominal wall. The canal, about $1\frac{1}{2}$ inches long, begins at the *deep inguinal ring*, which is an area of evagination in the fascia transversalis, half an inch or less above the inguinal ligament, and midway between the anterior superior iliac spine and the pubic symphysis. It ends at the *superficial inguinal ring*, which is an area of evagination in the external oblique aponeurosis immediately above the pubic tubercle and the medial end of the inguinal ligament. The *anterior wall* of the canal is formed by the aponeurosis of the external oblique, and in its lateral part by the muscular fibres of the internal oblique; the *posterior wall* of the canal is formed by the fascia transversalis, and in its medial part by the conjoint tendon and by the reflected part of the inguinal ligament when that structure is well developed. Thus, the anterior wall is strongest opposite the deep inguinal ring, and the posterior wall opposite the superficial ring. The *floor* of the canal is formed by the inguinal ligament, and, medially, by its pectineal part; the *roof* is formed by the arching fibres of the internal oblique and transversus. The spermatic cord, evaginating the transversalis fascia, enters the inguinal canal at the deep inguinal ring, and is there invested by its *first coat*—the **internal spermatic fascia**—a sheath of fascia derived from the margins of the ring and continuous with the fascia transversalis. The cord then passes obliquely medially, downwards, and forwards, and escapes below the lower border of the internal oblique muscle, from which it carries off a *second coat*, partly fascial, partly muscular—the **cremaster muscle** and **fascia**. Continuing its course, in front of the conjoint tendon, it emerges through the superficial inguinal ring, from the edges of which the **external spermatic fascia** is derived, *i.e.*, the *third* or *external coat* of the cord.

The **inguinal triangle** is the site of one form of inguinal hernia. It is bounded below by the inguinal ligament, medially by the rectus abdominis muscle, and laterally by the inferior epigastric artery coursing upwards and medially behind the fascia transversalis. The spermatic cord passes over the base of the triangle, covered over by the aponeurosis of the external oblique. Behind the cord, and forming the floor of the triangle, is the fascia transversalis, partially covered, in the medial portion of the triangle, by the conjoint tendon. The floor is divided into medial and lateral parts by the lateral umbilical ligament.

Quadratus Lumborum.—The quadratus lumborum extends between the iliac crest and the last rib, and lies alongside the tips of the lumbar transverse processes. It **arises** from the posterior part of the iliac crest, from the ilio-lumbar ligament, and from the transverse processes of the lower lumbar vertebræ. It is **inserted** into the medial part of the lower border of the last rib and the transverse processes of the lumbar vertebræ. Its lateral border is directed obliquely upwards and medially.

It is enclosed between the anterior and middle layers of the lumbar fascia, and is overlapped, medially, by the psoas major in front and the sacro-spinalis behind.

Nerve-Supply.—The nerve-supply of the foregoing muscles is derived from the anterior primary rami of the **lower six thoracic** and **upper four lumbar nerves.** The external oblique and the rectus are supplied by the lower five intercostal nerves (T. 7-11), the internal oblique and the **transversus** by the lower **five** intercostal, the subcostal (T. 12), and the ilio-hypogastric and ilio-inguinal (L. 1). The pyramidalis muscle is innervated by the **subcostal nerve** (T. 12). The cremaster muscle receives its supply from the **genital branch of the genito-femoral nerve** (L. 1, 2). The quadratus lumborum is supplied by the subcostal nerve and the first three or four lumbar nerves.

Actions.—(1) By virtue of their normal tone, the anterior and lateral muscles of the abdominal wall support the abdominal viscera and help to retain them in position.

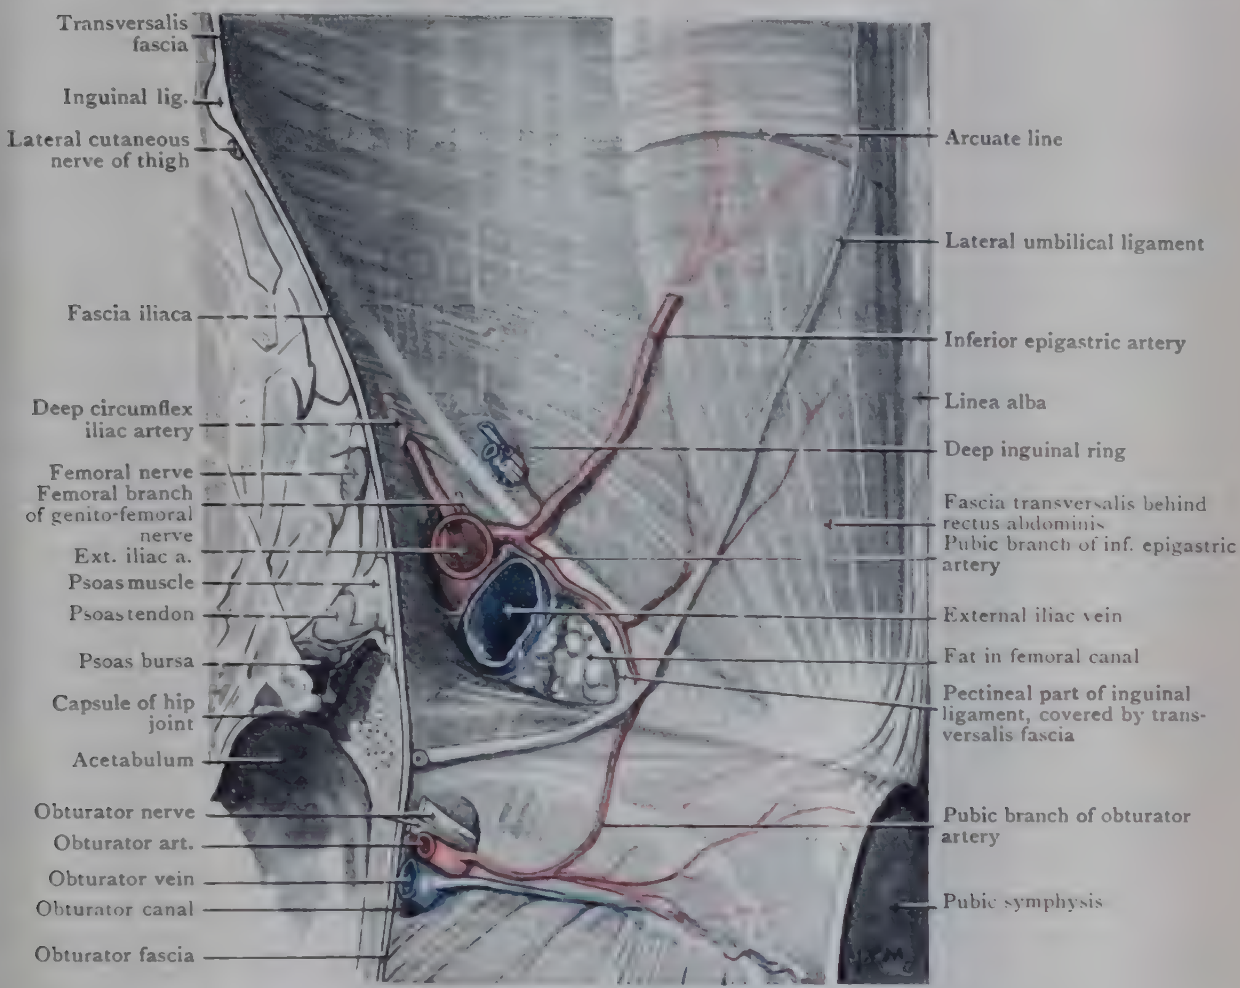

FIG. 393.—DEEP INGUINAL RING, FEMORAL RING, AND OBTURATOR CANAL SEEN FROM INSIDE THE ABDOMEN.

(2) Acting in concert with but against the diaphragm, they can compress the contents of the abdomen (Pl. XXXVII, p. 456, Fig. 4), and are powerful agents in vomiting, defæcation, micturition, and parturition. (3) They take part in forced expiration. (4) Contraction of the abdominal muscles increases the pressure in that cavity, and automatically compresses the walls of the inguinal canal; if, however, the closure of the canal is imperfect, the same forces may produce hernia through the canal. (5) In bending the body forwards, the important factor is relaxation of the post-vertebral muscles; but, when the movement is resisted, the anterior muscles come into play as flexors of the vertebral column. They flex the pelvis in jumping and climbing and act powerfully in the exercise of raising both lower limbs when the body is supine because of their rôle (an exhausting one) of fixation of the pelvis and vertebral column. The vertebral column and pelvis are laterally flexed when one set of muscles acts alone. The oblique muscles produce a certain amount of rotation of the vertebral column, the internal oblique of one side acting in association with the external oblique of the other side. The quadratus lumborum is a lateral flexor of the vertebral column, and assists in inspiration by fixing the twelfth rib and so facilitating the action of the diaphragm. For the postural action of the flexors of the trunk, see p. 409.

FASCIÆ OF ABDOMINAL WALL

The fasciæ of the abdominal wall are—*externally*, the superficial and deep fasciæ, *internally*, the fascia transversalis. The fascia transversalis clothes the deep surface of the anterior and lateral walls of the abdominal cavity, is continuous with the diaphragmatic, lumbar, psoas, iliac, and pelvic fasciæ, and is lined with **extraperitoneal tissue**. In this way a fascial envelope is formed which encloses the abdominal and pelvic cavities, the viscera, and the great vessels.

The **superficial fascia** of the abdomen is liable to contain a large quantity

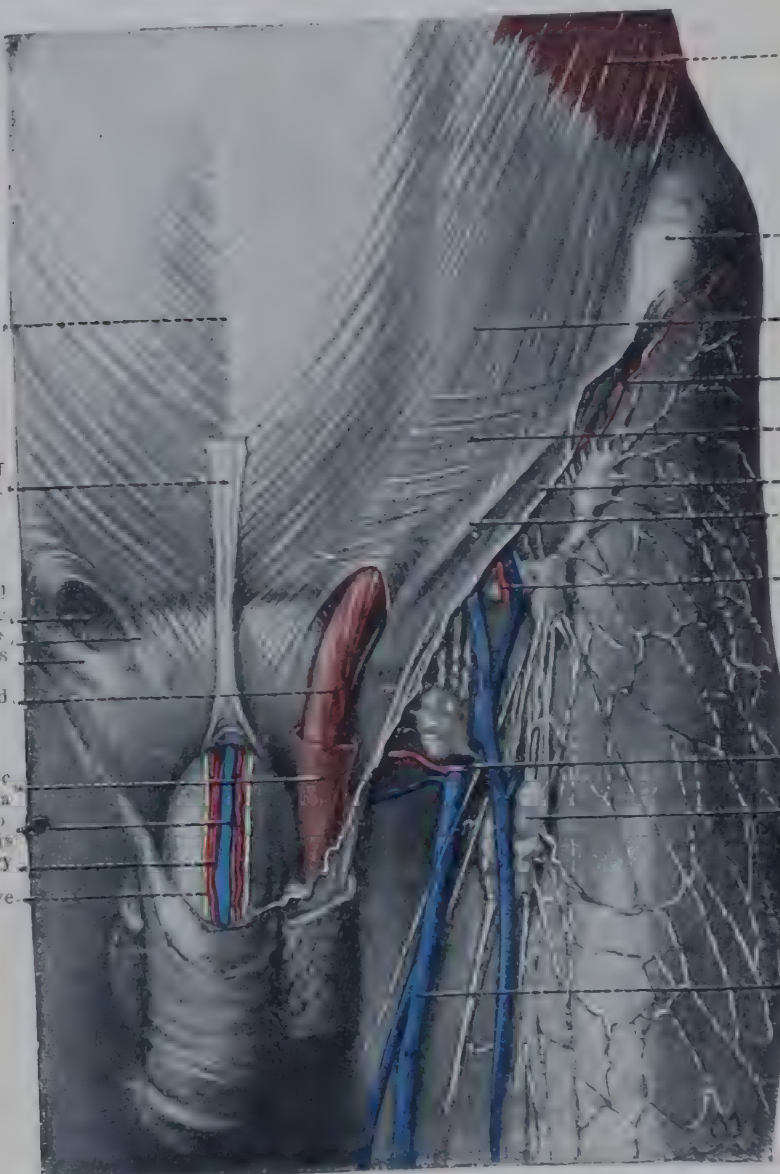

Fig. 394.—Superficial Anatomy of the Groin.

of fat. In the groin it is separated into *two layers*: a superficial, **fatty layer** continuous over the inguinal ligament with the fascia of the anterior surface of the thigh, and a deeper, **membranous layer** attached to the fascia lata of the thigh just distal to the inguinal ligament (Fig. 398). The two layers are separated by the lymph-glands and the superficial vessels of the groin. Higher up in the abdominal wall the two layers blend together. In the median plane the membranous layer, adherent to the linea alba except just above the pubis, descends as the *fundiform ligament* to the dorsum of the penis and makes a sling continuous with the superficial fascia of the penis. The fundiform ligament is separated by an areolar space from the suspensory ligament of the penis, which is formed by the deep fascia (Fig. 402). As the layers pass downwards over the spermatic cord, they are replaced by the fascia and *dartos muscle* of the scrotum [δαρτός = flayed]. The attachment of the fascia to the groin prevents the passage into the thigh of fluid extravasated beneath the membranous layer of the abdominal wall (p. 469 and

Fig. 398). The membranous layer represents the elastic tunic which supports the abdominal wall and inguinal mammary glands in such animals as the cow.

The **deep fascia** of the abdominal wall resembles similar fasciæ in other situations. It forms an investment for the external oblique muscle, and becomes thin and almost imperceptible in relation to the aponeurosis of that muscle.

From the front of the symphysis the fascia descends as a triangular band—the *suspensory ligament*—to be attached to the deep fascia of the penis.

The **fascial lining** of the abdominal cavity is a continuous layer of membrane which receives different names in different parts of its extent. The **transversalis fascia** covers the deep surface of the transversus muscle, and is continuous medially with the fasciæ of the quadratus lumborum and the psoas muscles. It is continuous above with the fascia of the diaphragm, and below with the **fascia iliaca** at the iliac crest and the inguinal ligament (see p. 531). Along with the fascia iliaca it forms the **femoral sheath**. It is evaginated by the spermatic cord, or by the round ligament of the uterus, at the deep inguinal ring, and its prolongation into the inguinal canal around the cord forms the **internal spermatic fascia**. Internally, it is lined with the peritoneum, from which it is separated by a layer of extraperitoneal tissue.

The **extraperitoneal tissue** is usually loaded with fat; it envelops the kidneys, ureters, suprarenal glands, abdominal aorta, and inferior vena cava and their branches, and forms sheaths for the vessels and ducts (ureter, vas deferens, etc.). It is continued upwards into the posterior mediastinum of the thorax through the aortic opening in the diaphragm, and is in continuity with the extraperitoneal tissue in the pelvis. It not only completely invests the kidneys and suprarenal glands, but also becomes insinuated between the layers of peritoneum that uphold and envelop the intestines. On the anterior wall, below the level of the umbilicus, it contains the inferior epigastric vessels, the lateral and median umbilical ligaments, and the upper part of the bladder when it is distended. This tissue is absent in relation to the diaphragm, on the under surface of which there is no fat.

MUSCLES AND FASCIÆ OF PERINEUM AND PELVIS

MUSCLES OF PERINEUM

The perineum is the lowest part of the trunk, and is a diamond-shaped space whose boundaries are those of the outlet of the pelvis. It is divided by an imaginary line into an *anal triangle* behind and a *urogenital triangle* in front. In the anal triangle there is only one perineal muscle—the external sphincter ani. A fibrous sheet called the *perineal membrane* stretches across the pubic arch and divides the urogenital triangle into upper and lower pouches (p. 467). The lower or superficial pouch contains three pairs of muscles—ischio-cavernosus, bulbo-spongiosus, and the superficial transversus perinei. The upper or deep pouch contains the sphincter urethræ and a pair of deep transverse perineal muscles.

Sphincter Ani Externus.—This muscle is fusiform in outline, flattened, and obliquely placed around the anus and anal canal. It can be separated into three layers—subcutaneous, superficial, and deep. (1) The most superficial lamina consists of subcutaneous fibres decussating posterior and anterior to the anus, but without bony attachments. (2) The main portion of the muscle is attached posteriorly to the coccyx, and anteriorly to the perineal body. (3) The deepest fibres form, for the most part, a complete sphincter for the anal canal—encircling its lower two-thirds, blending anteriorly with the perineal body and the superficial transversus perinei muscle, and closely associated behind with the fibres of the pubo-rectales.

Superficial Transversus Perinei.—The superficial transversus perinei, not always present, is a feeble bundle of fibres that **arises** from the fore part of the

medial side of the ischial tuberosity and passes medially below the posterior border of the perineal membrane to be **inserted** into the perineal body.

Bulbo-Spongiosus.—*In the male*, the right and left bulbo-spongiosus muscles are united together by a fibrous median raphe, and they cover the bulb of the penis and the adjoining part of the corpus spongiosum. They **arise** from the raphe and the perineal body, and their fibres, curving upwards and forwards round the sides of the bulb, have a triple **insertion**: from behind forwards, (1) into the lower surface of the perineal membrane; (2) into the dorsal surface of the corpus spongiosum penis; and (3), after encircling the corpora cavernosa penis, into the deep fascia on the dorsum of the penis.

In the female, the bulbo-spongiosus muscles are separate. Each is a thin layer

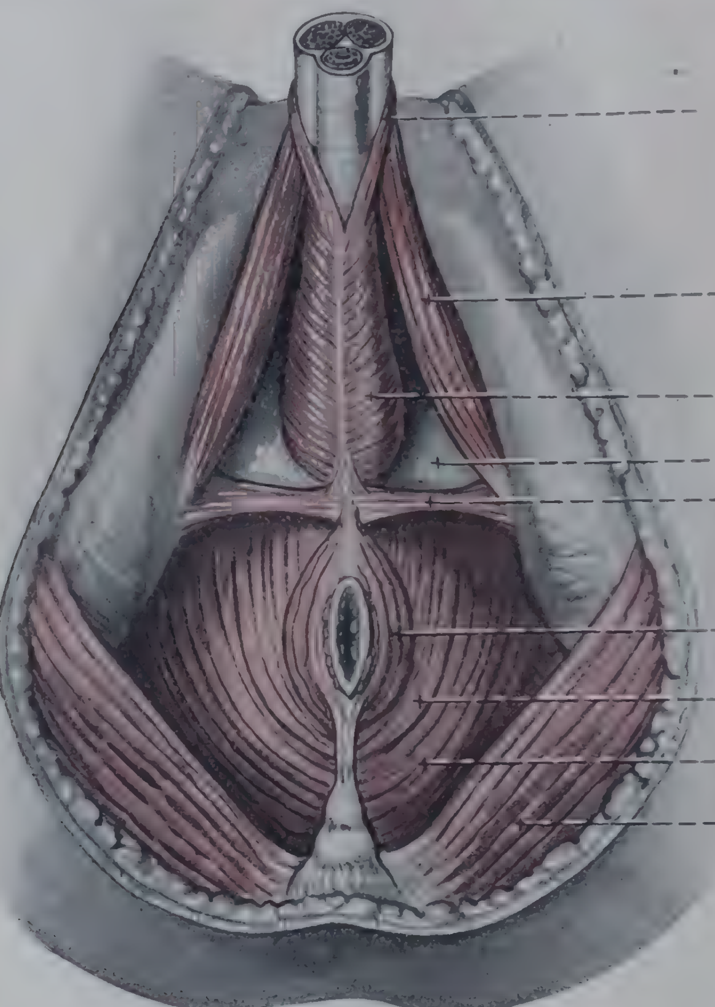

Fig. 395.—Muscles of the Male Perineum.

that lies at the side of the lower part of the vagina and covers the bulb of the vestibule. It **arises** from the perineal body, and, passing forwards, its fibres separate to be **inserted** into the side of the pubic arch and into the root and dorsum of the clitoris.

Ischio-Cavernosus.—The ischio-cavernosus, partly fleshy, partly tendinous, covers the crus of the penis or of the clitoris. It **arises** from the medial side of the ischial tuberosity, and passes forwards over the crus to be **inserted** into the margin of the pubic arch on each side of the crus and into the corpus cavernosum (Figs. 395, 396, and 403).

Perineal Body.—The perineal body is a fibro-muscular node of considerable importance in the anatomy of the perineum, especially in the female, for it may be torn during child-birth. It is placed between the anal canal and the perineal membrane: it is inseparably blended with the membrane (and, in the male, with the fascial sheath of the prostate), and both striated and plain muscle-fibres enter into its constitution. The superficial and deep transverse perineal muscles, the bulbo-spongiosus, the external sphincter ani and the levator ani all contribute to it;

and, in addition, prolongations of the longitudinal fibres of the gut (superior and inferior recto-urethralis muscles) are continued into it.

Perineal Membrane.—This membrane stretches across the pubic arch. In the male it almost completely fills the archway, but in the female it is defective in the middle to give passage to the vagina and the urethra. Its posterior border is fused with the posterior borders of (1) the membranous layer of the superficial fascia of the perineum, and (2) the layer of fascia that covers the upper surface of the sphincter urethræ and deep transversus perinei. In the median plane this border is thickened, and is united with the perineal body. Its anterior border is thickened to form a band called the *transverse perineal ligament*; this ligament is separated from the inferior pubic ligament by an oval gap that transmits the dorsal vein of the clitoris or the deep dorsal vein of the penis; and this border also is fused with the fascia that covers the sphincter urethræ. The space between the membrane and that fascia is therefore closed; it is called the **deep perineal pouch**, and contains the sphincter urethræ and the deep transversus perinei, the internal pudendal vessels and the dorsal nerve of the penis or of the clitoris, the terminal branches of the perineal nerve and the vessels of the bulb; in the male, it contains, also, the membranous part of the urethra and the bulbo-urethral glands; and, in the female, it is divided into two parts by the vagina and urethra. The **superficial perineal pouch** is the space between the perineal membrane and the membranous layer of the superficial fascia; a slight median septum divides it posteriorly into right and left pockets. In the male it is occupied by the root of the penis, the three pairs of muscles already described, and superficial vessels and nerves. In the female, the vagina divides it into halves; each half contains the corresponding muscles, vessels, and nerves, the crus of the clitoris, the bulb of the vestibule and the greater vestibular gland. The perineal membrane is pierced, in the male, by the urethra, the arteries to the bulb, the internal pudendal vessels, the dorsal nerves of the penis, and the ducts of the bulbo-urethral glands, and, in the female, by corresponding vessels and nerves and the vagina and urethra.

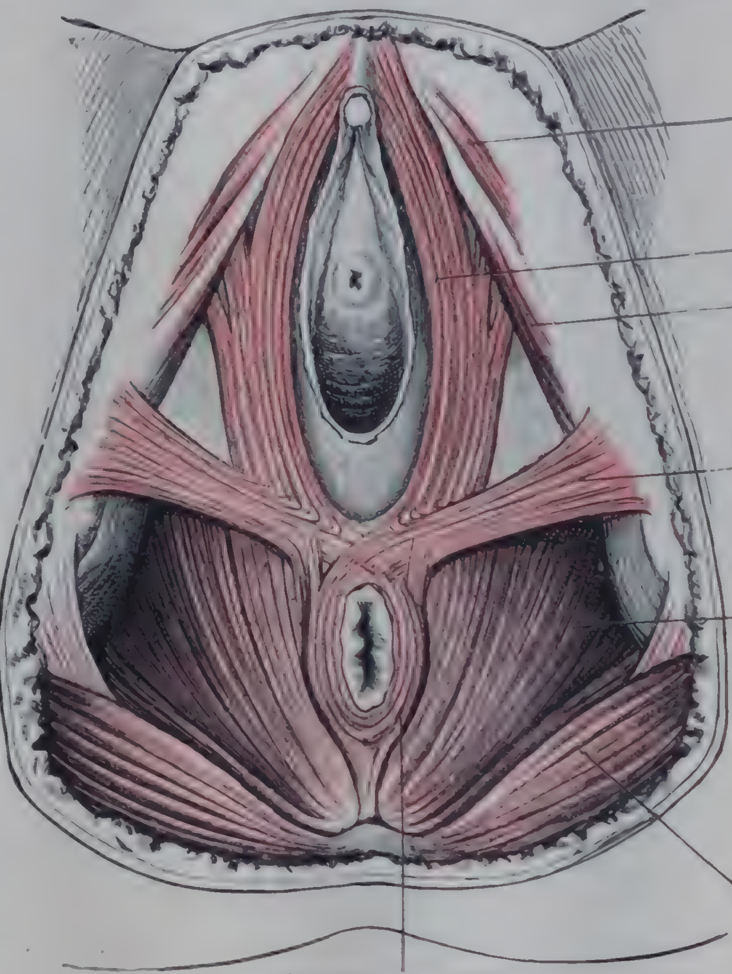

Fig. 396.—Muscles of Female Perineum.
(After Peter Thompson, 1899.)

Sphincter Urethræ.—The sphincter of the urethra **arises** from the inferior pubic ramus, and is directed medially—its fibres radiating towards the urethra.

In the male it is **inserted** into a median raphe, partly in front of the urethra, but for the most part behind it. The fibres most intimately related to the urethra form a muscular sheath for the canal, and have no bony attachments. This is the sphincter proper of the urethra, a striated muscle, and the most important voluntary control of micturition. *In the female* it encloses the urethra, but, together

with the deep transversus perinei, it is also attached to the side of the vagina. The **deep transversus perinei** is a small muscular slip closely connected with the posterior fibres of the sphincter; *in the male* it is inserted into the perineal body.

Nerve-Supply.—All the muscles of the perineum are supplied from the **anterior primary rami** of the **third** and **fourth sacral nerves**. The external sphincter of the anus has three nerves of supply — from the perineal and inferior hæmorrhoidal nerves (branches of the pudendal nerve S. 3. 4.), and the perineal branch of the fourth sacral nerve. All the other muscles are supplied by the **perineal nerve**.

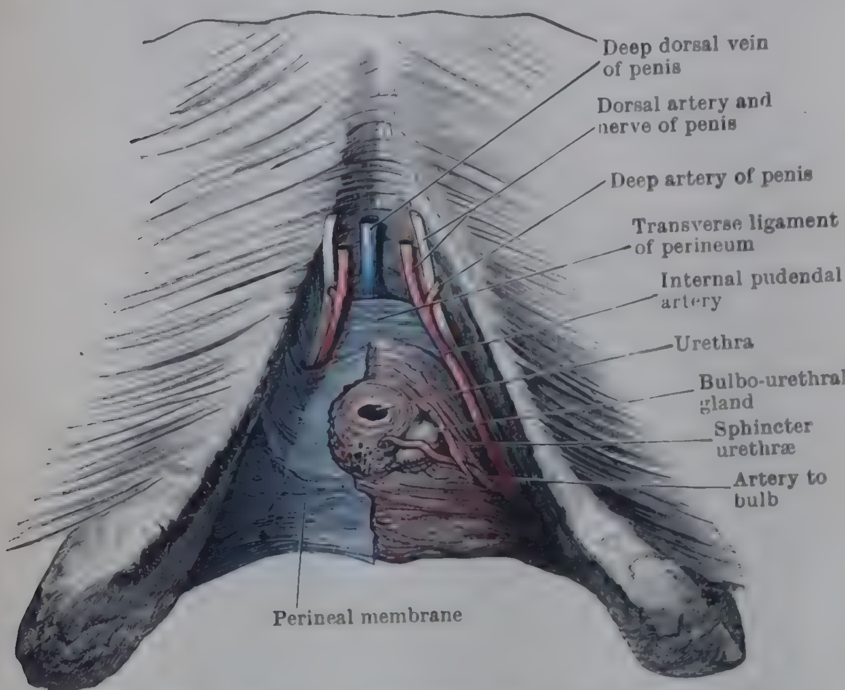

Fig. 397.—Perineal Membrane and Sphincter Urethræ.

Action of the Perineal Muscles. — The sphincter ani externus keeps the anal orifice firmly closed by its tonic contraction—which may be voluntarily increased. The bulbo-spongiosus in the male, relaxed during the course of micturition, contracts to expel the last drops of urine; it acts also as an accessory muscle in erection of the penis by compressing the bulb and impeding the venous return; in the female it compresses the bulb of the vestibule and constricts the vaginal orifice—forming with the pubo-coccygeus a kind of sphincter. The ischio-cavernosus, by compressing the crus and impeding venous return, is the chief muscular agent in erection of the penis or the clitoris. The sphincter urethræ compresses the urethra at the end of micturition. The deep transversus perinei assists other muscles attached to the perineal body in fixing that body and in supporting the prostate.

FASCIÆ OF PERINEUM

The **superficial fascia** of the perineum possesses certain special features (Figs. 398, 402, 403). It is continuous with the superficial fascia of the abdominal wall, thigh, and buttock, and is prolonged on to the penis and scrotum. In the penis, it is devoid of fat and consists only of areolar tissue. In the scrotum, it is intermingled with involuntary muscular fibres, and constitutes the **dartos muscle**, which assists in suspending the testes and corrugates the skin of the scrotum. This fascia also forms the **septum of the scrotum**, which, extending upwards, incompletely separates the two testes and their coverings. In the female, the superficial fascia, in which there is a considerable quantity of fat, takes a large share in the formation of the mons pubis and the labia majora.

The superficial fascia over the posterior part of the perineum fills up the ischio-rectal fossæ, in the form of a pair of **ischio-rectal pads of fat**, at the sides of the rectum and anal canal. Over the ischial tuberosities the fat is intermingled with bands of fibrous tissue closely adherent to the subjacent deep fascia.

The fascia in the anterior part of the perineum closely resembles the same fascia in the groin. It is divisible into a superficial, **fatty layer** and a deep, **membranous layer**. The **fatty layer** is continuous with the same layer in the thigh, and with the fat of the ischio-rectal fossa. The **membranous layer** is attached on each side to the deep fascia on the front of the pubis and to the side of the pubic arch, posteriorly to the posterior border of the perineal membrane, and in the median plane to the median raphe of the bulbo-spongiosus muscles and to the septum of the scrotum. Anteriorly the fascia invests the scrotum and gives a

tubular covering to the penis. Finally it is continued over the spermatic cords to the anterior abdominal wall. The importance of this fascia lies in relation to the extravasation of urine from a rupture of the urethra in the perineum. By the fascial attachments the fluid is prevented from passing backwards into the ischio-rectal fossa, or sidewards into the thigh. It is directed forwards—invading the subcutaneous tissues of the scrotum (the septum of the scrotum being incomplete, the fluid can pass across the median plane to the opposite half of the perineum and scrotum) and gravitating into the fascial covering of the penis as far as the glans, and lastly mounting upwards around the spermatic cord to the anterior abdominal wall, where it is kept from entering the front of the thigh

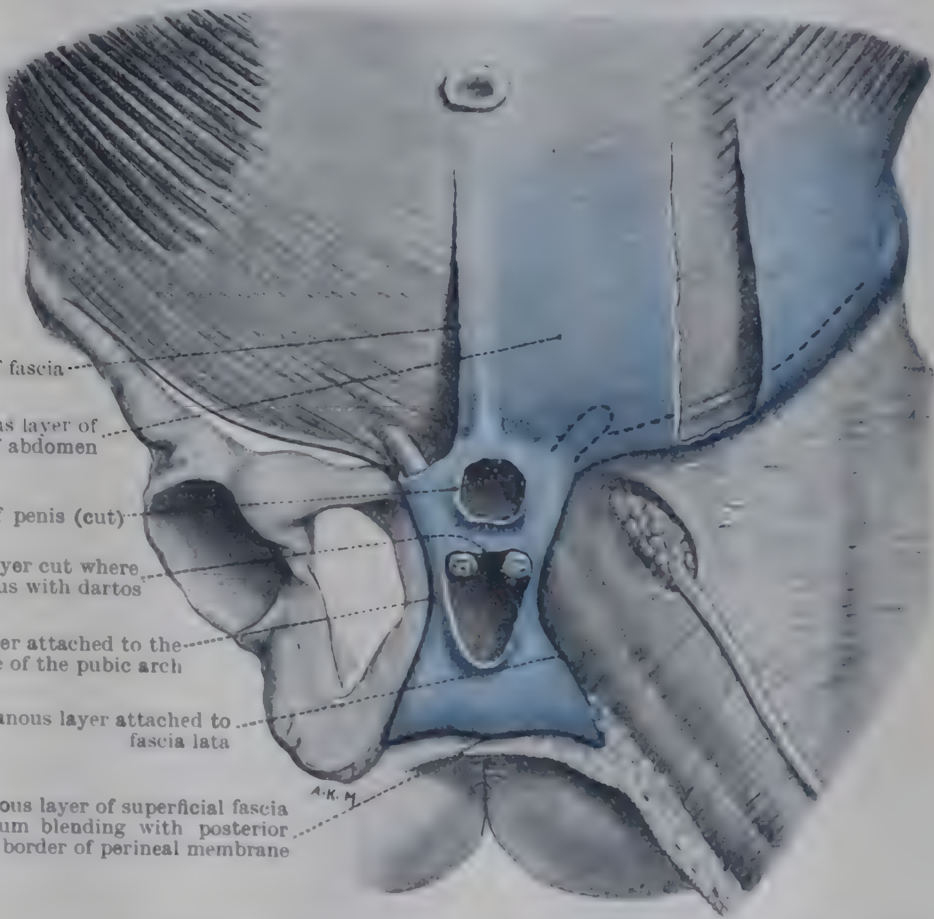

FIG. 398.—DIAGRAM SHOWING CONTINUITY OF MEMBRANOUS LAYER OF THE SUPERFICIAL FASCIA OF ABDOMINAL WALL AND PERINEUM.

by the fusion of the membranous layer of the superficial fascia with the fascia lata (p. 464).

The **deep fascia** of the perineum exists only in the form of the delicate fasciæ of the muscles.

MUSCLES OF PELVIS

Pelvic Diaphragm.—The pelvic diaphragm is formed by the levator ani and coccygeus muscles, which serve to uphold the pelvic floor and are related to the rectum and to the prostate or the vagina.

Levator Ani.—The levatores ani muscles form a thin sheet which stretches across the pelvic cavity and separates it from the posterior part of the perineum. Anteriorly, the two muscles are separated by a narrow interval which is occupied, in the male, by the lower part of the prostate and the anal canal, and, in the female, by the urethra, the vagina, and the anal canal. Posteriorly, they meet each other in the **ano-coccygeal body**—a fibro-muscular body mingled with fat placed between the anal canal and the tip of the coccyx. The postero-lateral border is free, and is separated from the coccygeus muscle by areolar tissue. The *superior* (pelvic) surface of the levator ani is separated by fascia from the peritoneum, rectum, and bladder in both sexes; from the prostate and seminal vesicle in the male;

and from the vagina in the female. Its *inferior* (perineal) surface is separated by fascia from the ischio-rectal pad of fat.

The muscle **arises** anteriorly from the pelvic surface of the pubic bone, and posteriorly from the pelvic surface of the ischial spine; between those two bony attachments it takes origin from the *obturator fascia—i.e.*, the thick fascia which covers the obturator internus muscle.

Its fibres run backwards and medially and very slightly downwards, with

FIG. 399.—LEFT LEVATOR ANI MUSCLE.

varying degrees of obliquity, and are **inserted** (1) into the perineal body, (2) into the ano-coccygeal body, and (3) into the front and sides of the coccyx. In addition, some of the fibres form a sling around the upper end of the anal canal.

The levator ani is divisible into two distinct portions, namely, the **ilio-coccygeus** and the **pubo-coccygeus**, and the latter can be subdivided into three parts, imperfectly separated from one another, viz.—the *pubo-coccygeus proper*, the *pubo-rectalis*, and the *levator prostatæ*.

The **ilio-coccygeus** is the posterior part of the levator ani, and its origin extends as far forwards as the obturator canal. It is usually a thin sheet in which the muscular fibres are

feebly developed and often separated by membranous intervals. The strong fascia from which it arises represents the upward continuation of the muscle to reach the arcuate line of the pelvis, and has, secondarily, become blended with the obturator fascia. This attachment to the arcuate line is the primitive origin of the ilio-coccygeus and is the normal condition

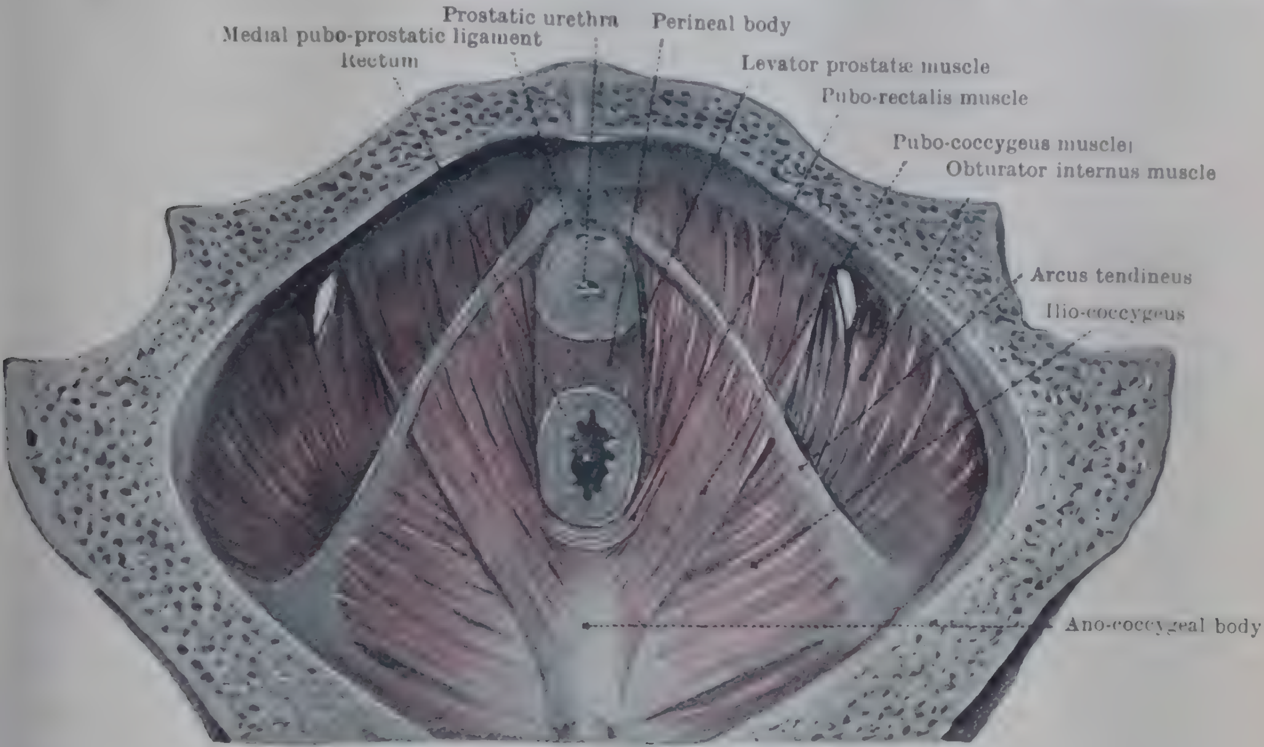

FIG. 400.—LEVATOR ANI MUSCLE VIEWED FROM ABOVE.

in many mammals. The fibres run medially to be inserted into the side of the coccyx and the ano-coccygeal body, but, at their insertion, they are covered on their pelvic aspect by the backward-running fibres of the pubo-coccygeus (Figs. 399, 400).

The **pubo-coccygeus** is composed of those fibres of the levator ani which arise in front of the obturator canal. The most anterior (medial) fibres pass backwards in contact with the side

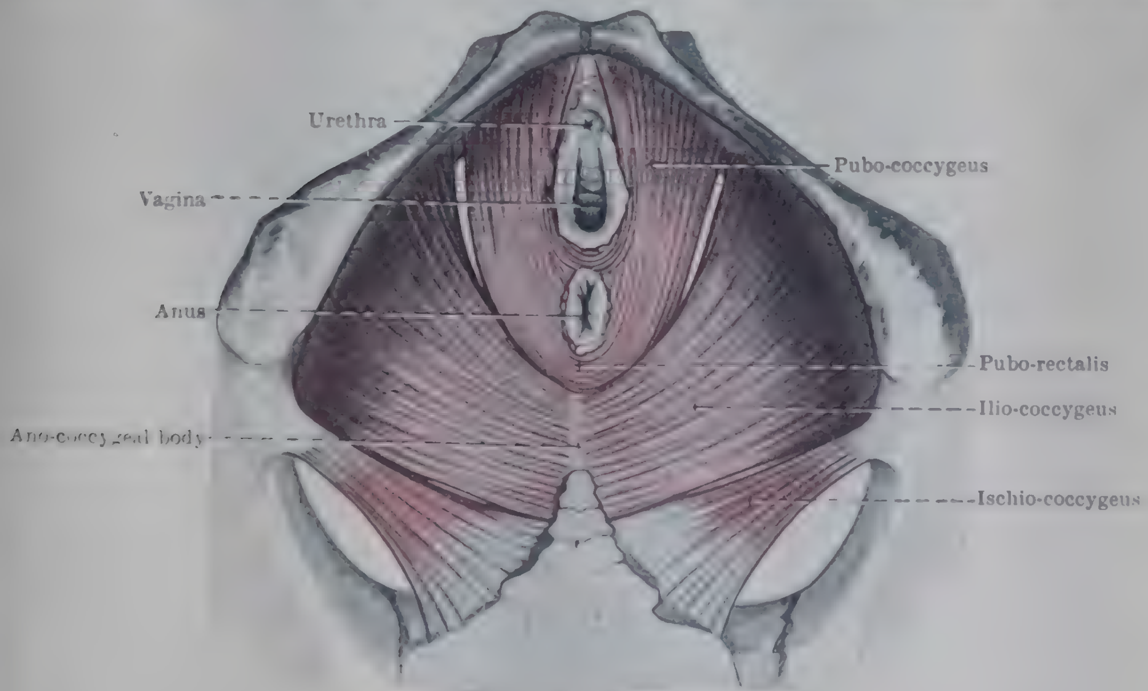

FIG. 401.—DISSECTION OF FEMALE PELVIC DIAPHRAGM FROM BELOW. (After Peter Thompson, 1899.)

of the prostate (*levator prostatæ*) or of the vagina (*sphincter vaginæ*), and are inserted into the perineal body, where they mingle with the deeper fibres of the sphincter ani externus.

The fibres which have a more lateral origin from the pubic bone form the *pubo-rectalis*. This muscle sweeps backwards over the side of the prostate (or vagina) and the upper part of the anal canal, behind which it becomes directly continuous with the corresponding muscle of the opposite side. The pubo-rectales form therefore a U-shaped sling for the ano-rectal junction (Figs. 400,

401), and, associated with deep fibres of the external sphincter, they can constrict the anal canal in the male, and the vagina and anal canal in the female. Together, they constitute the most highly developed part of the pelvic diaphragm.

The *pubo-coccygeus proper* is the remainder of this part of the levator ani muscle. Its fibres run backwards and medially, above the fibres of the ilio-coccygeus, and are inserted (1) into the ano-coccygeal body, where they meet the fibres of the opposite side, and (2) into the sides and front of the coccyx.

The **coccygeus** (ischio-coccygeus), which lies on the same plane as the

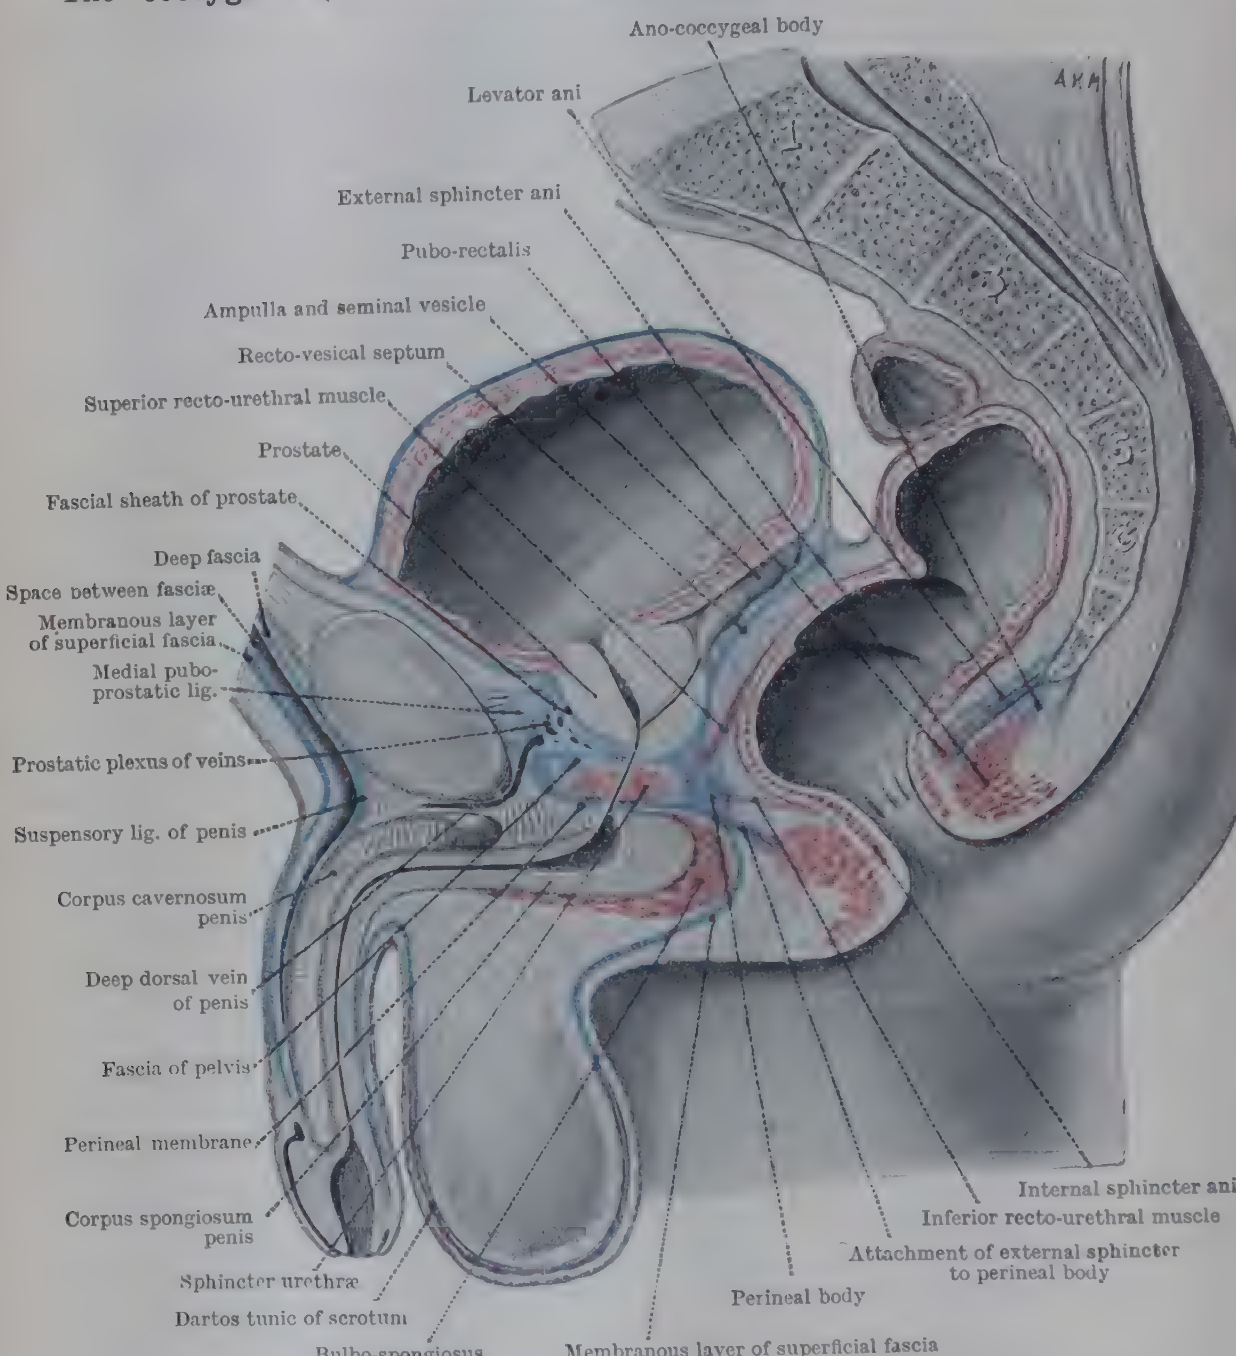

FIG. 402.—SAGITTAL SECTION OF MALE PELVIS SHOWING FASCIÆ IN BLUE (SEMIDIAGRAMMATIC).

ilio-coccygeus, is a fan-shaped muscle. It **arises** from the pelvic surface of the ischial spine and is **inserted** into the margin of the lower two pieces of the sacrum and the upper two pieces of the coccyx.

Nerve-Supply.—The pelvic diaphragm, like the perineal muscles, is supplied from the anterior primary rami of the **third** and **fourth sacral nerves**. Direct branches enter the levator ani and the coccygeus on their pelvic surfaces, and in addition the anterior part of the levator ani is supplied on its perineal surface by the perineal branch of the pudendal nerve.

Actions.—Both these muscles play a very important part in retaining the pelvic viscera in position, especially in the female. In addition, the pubo-rectales reinforce the sphincters of the vagina and anal canal, and the fibres which are inserted into the perineal

body draw it upwards and forwards. This latter action assists in the later stages of expulsion during defæcation and parturition.

Comparative Morphology.—In pronograde mammals the ilio-coccygei and pubo-coccygei are inserted into the caudal vertebræ and act, respectively, as abductors and flexors of the tail. The ischial origin of the ilio-coccygeus in Man is secondary; the true ischio-coccygeus is the 'abductor caudæ' of tailed mammals. Although the pubo-coccygei may have a compressing effect on the vagina and rectum, such action is purely secondary. In pronograde animals there is not the same need for a muscular pelvic diaphragm, and, consequently, the two muscles are separated from each other both dorsal and ventral to the rectum.

The adoption of the erect attitude necessitates the provision of a strong, but elastic, pelvic floor, to maintain the pelvic viscera in position and to permit the downward passage of the fœtus. This function is assumed by the ilio- and the ischio-coccygei, which are no longer needed to act on a tail; and the pubo-coccygei become specialized in relation to the anal and vaginal canals. For further information the student should consult Thompson (1899).

Ischio-Rectal Fossæ.—The ischio-rectal fossæ are the pair of wedge-shaped spaces that occupy the lateral parts of the anal triangle of the perineum. The lateral wall of each fossa is the obturator fascia; the medial wall is the fascia that covers the perineal surface of the levator ani; the edge of the wedge is at the junction of these fasciæ; and the base is the skin of the perineum. The fossa is filled with the plug of fat known as the ischio-rectal pad. It is crossed transversely by the inferior hæmorrhoidal nerve and the inferior rectal vessels; the perineal branch of the fourth sacral nerve and the perforating cutaneous nerve appear in its posterior part, and the posterior scrotal (or labial) nerves and vessels in its anterior part; the internal pudendal vessels, the perineal nerve, and the dorsal nerve of the penis (or clitoris) traverse the pudendal canal in its lateral wall. Posteriorly, it extends backwards for a little distance above the sacro-tuberous ligament and the gluteus maximus. Anteriorly, it sends forward a 'diverticulum' (Fig. 403) above the deep perineal pouch as far as the pubis; this extension retains the lateral and medial boundaries of the fossa—the fascia of the obturator internus and levator ani—and is occupied by loose, vascular fatty tissue.

FASCIÆ OF PELVIS

The extraperitoneal tissue in the pelvic cavity is of great importance. The internal iliac vessels and their branches, the visceral nerves and plexuses, the ureters, and vasa deferentia lie in this tissue. It forms in relation to **the rectum** a thick sheath, for the most part devoid of fat, which completely encloses the lower part of the rectum. It forms a kind of packing for the parts of **the bladder** that are not covered with peritoneum, and it surrounds the prostate with a strong sheath. In the female it forms, in addition, the fibrous basis of the **broad ligament**, and also occurs as a layer, devoid of fat, which loosely connects the anterior surface of the **cervix uteri** with the base of the bladder.

The **fascia of the pelvis** covers the free surfaces of the muscles—*fascia of pelvic muscles*—and is condensed around the viscera, vessels, and nerves to ensheath them—*visceral fascia*; and between the pubis and the neck of the bladder it is thickened to form a pair of strong bands called the **medial pubo-vesical ligaments** in the female, and **medial pubo-prostatic ligaments** in the male.

The muscles which line the walls (obturator internus, piriformis, coccygeus, sphincter urethræ, and deep transversus perinei) and those which form the floor of the pelvis (levatores ani) are covered on their 'visceral' surfaces by a layer of fascia which is thicker over the obturator internus than it is elsewhere. This thickened part is, in reality, the aponeurosis of origin of the ilio-coccygeus muscle (p. 471), and it is continued upwards to reach the arcuate line of the pelvis. The surface of this aponeurosis is crossed by a linear thickening (*arcus tendineus*) which extends from the ischial spine to the body of the pubis, where it blends with the medial pubo-prostatic ligament. In its posterior part this arc marks the origin of the fleshy fibres of the ilio-coccygeus, but its anterior part crosses the pelvic surface of the pubo-coccygeus at least 1·5 cm. below its origin from the bone. The anterior portion of the arcus tendineus may represent an additional tendon of origin for the ilio-coccygeus (Thompson, 1901).

A strong fascial sheath is provided for the prostate. The **fascial sheath of the prostate** is largely derived from the fibrous tissue which is condensed around the prostatic venous plexus. It is continuous inferiorly with the roof of the deep perineal pouch (Fig. 403), on each side with the fascia of the levator ani, and superiorly with the fascia condensed around the vesical plexus of veins on the infero-lateral surfaces of the bladder. Anteriorly it is attached to the pelvic surface of the pubic bones near the symphysis by the **medial pubo-prostatic ligaments**. These two strong bands and the fascia which connects them to each other and to that covering the levatores ani contain a number of plain muscle-fibres. The term *lateral pubo-prostatic ligament* is applied to the fascia on the anterior part of the levator ani muscle.

The posterior part of the sheath of the prostate differs from the rest of the sheath in its mode of formation, and is a definite layer easily demonstrated by dissection. In a four months' fœtus the recto-vesical peritoneal pouch is very much deeper than it is in the adult, and the subsequent

alteration in level is brought about by the occlusion of the lower part of the pouch. The fused walls of the occluded portion persist as a fairly strong sheet, called the **recto-vesical septum**, which extends from the perineal body to the floor of the recto-vesical pouch—thus retaining its primitive connexion with the peritoneum. It is separated by areolar tissue from the prostate, seminal vesicles, and vasa deferentia anteriorly and from the ampulla of the rectum posteriorly.

In enucleating the prostate, the surgeon endeavours to leave the fascial sheath of the prostate (and also the capsule of the gland) *in situ*.

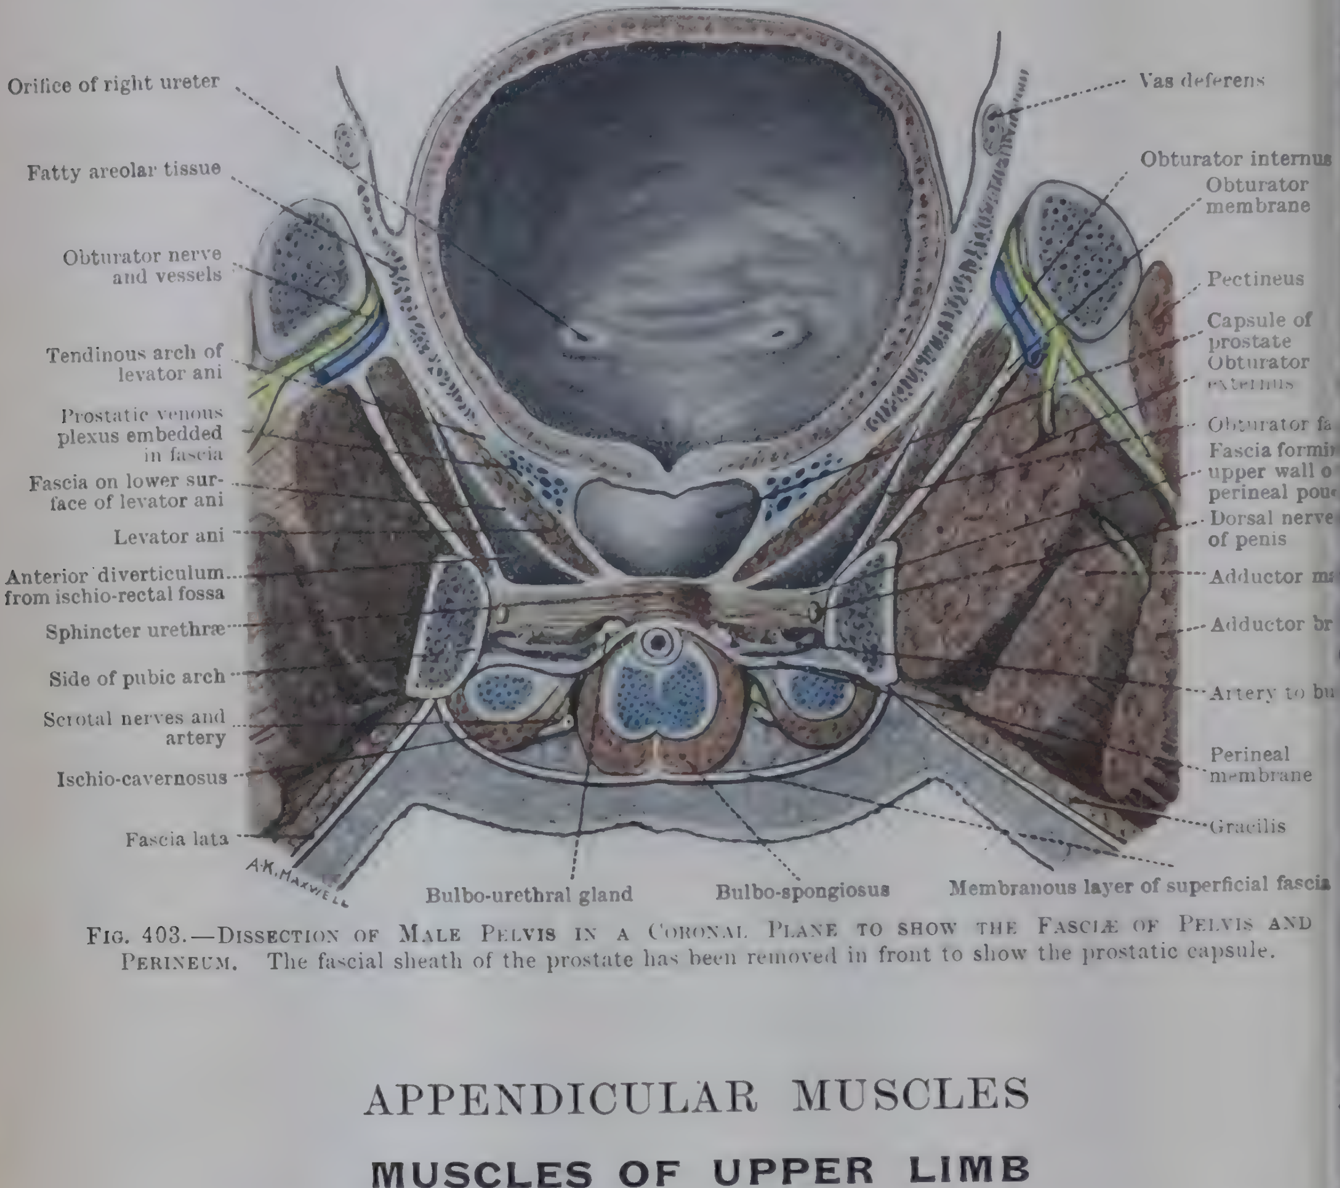

FIG. 403.—DISSECTION OF MALE PELVIS IN A CORONAL PLANE TO SHOW THE FASCIÆ OF PELVIS AND PERINEUM. The fascial sheath of the prostate has been removed in front to show the prostatic capsule.

APPENDICULAR MUSCLES

MUSCLES OF UPPER LIMB

The muscles of the upper limb are divisible into the following series and groups, according to their regional arrangement and their functions. 1. Muscles connecting the limb to the trunk—Dorsal Group (superficial muscles of the back), and Ventral Group (Muscles of the Pectoral Region). 2. Muscles of the Shoulder. 3. Muscles of the Upper Arm (flexor and extensor groups). 4. Muscles of the Forearm (flexor and extensor groups). 5. Short muscles of the Hand.

MUSCLES CONNECTING UPPER LIMB TO TRUNK

Two groups of muscles connect the upper limb to the trunk—a dorsal group arising primarily from the vertebral column, and a ventral group arising mainly from the thoracic skeleton. With two exceptions (one in each group), all the muscles are inserted into the shoulder girdle (clavicle and scapula). The exceptions are the latissimus dorsi and the pectoralis major, which are inserted into the humerus; and each of them has an additional origin from the shoulder girdle itself—the pectoralis major from the clavicle and the latissimus dorsi from the scapula.

I. Superficial Muscles of the Back

The dorsal group comprises the first two layers of the muscles of the back—(1) trapezius and latissimus dorsi; (2) levator scapulæ and rhomboidei (major and minor).

Trapezius.—The trapezius is a large, triangular muscle situated in the upper part of the back and the back of the neck. It **arises** from the medial third of the superior nuchal line of the occipital bone, from the external occipital protuberance (Fig. 405), from the ligamentum nuchæ, from the spines of the seventh cervical and all the thoracic vertebræ, and the intervening supraspinous ligaments. The origin is by tendinous fibres which are mainly short, but in the lower part of the neck the tendinous fibres extend towards the shoulder to afford a larger area of origin for the thickest part of the muscle; between the two muscles there is thus formed

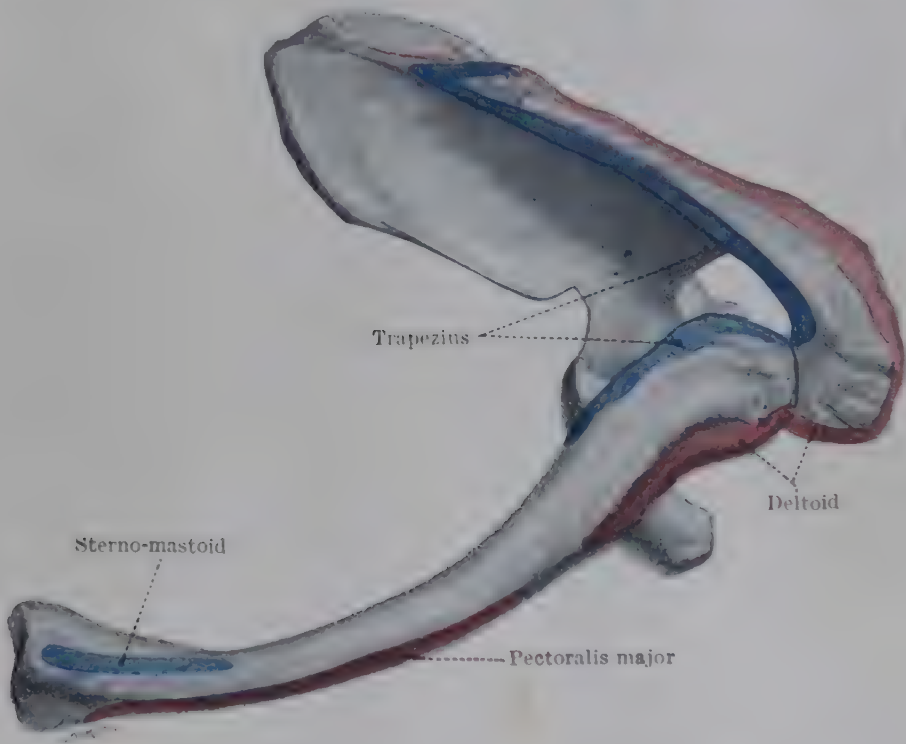

FIG. 404.—SHOULDER GIRDLE FROM ABOVE SHOWING MUSCLE-ATTACHMENTS.

a characteristic, irregular, diamond-shaped tendinous area which surrounds the seventh cervical spine, and forms the floor of a shallow depression seen in the living subject (Pl. XXXVII, p. 456, Fig. 2).

The muscular fibres converge towards the bones of the shoulder to be **inserted** continuously from before backwards as follows: (1) The occipital and upper cervical fibres—into the posterior border of the lateral third of the clavicle (Figs. 404, 405); (2) the lower cervical and upper thoracic fibres—into the medial border of the acromion, and the upper border of the crest of the spine of the scapula; and (3) the lower thoracic fibres, by a triangular, flat tendon, separated by a small *bursa* from the smooth area at the root of the spine—into the tubercle of the crest of the scapula. The fibres inserted into the clavicle, acromion, and the upper border of the spine of the scapula spread over the adjacent subcutaneous surfaces of these bones for a variable distance. The occipital portion of the muscle may be in the form of a separate slip, or it may be absent.

The trapezius is superficial in its whole extent. Its upper lateral border forms the posterior limit of the posterior triangle of the neck. The lower lateral border, passing over the upper edge of the latissimus dorsi and the medial margin of the scapula, forms a boundary of the so-called *triangle of auscultation*, which is completed below by the latissimus dorsi, and laterally by the rhomboideus major; that space is increased when the arms are folded to pull the scapulæ forwards. The trapezius overlaps the upper margin of the latissimus dorsi, and covers the rhomboidei,

levator scapulæ, splenius capitis, semispinalis capitis, and the deeper axial muscles of the back, along with the superficial and the deep branches of the transverse

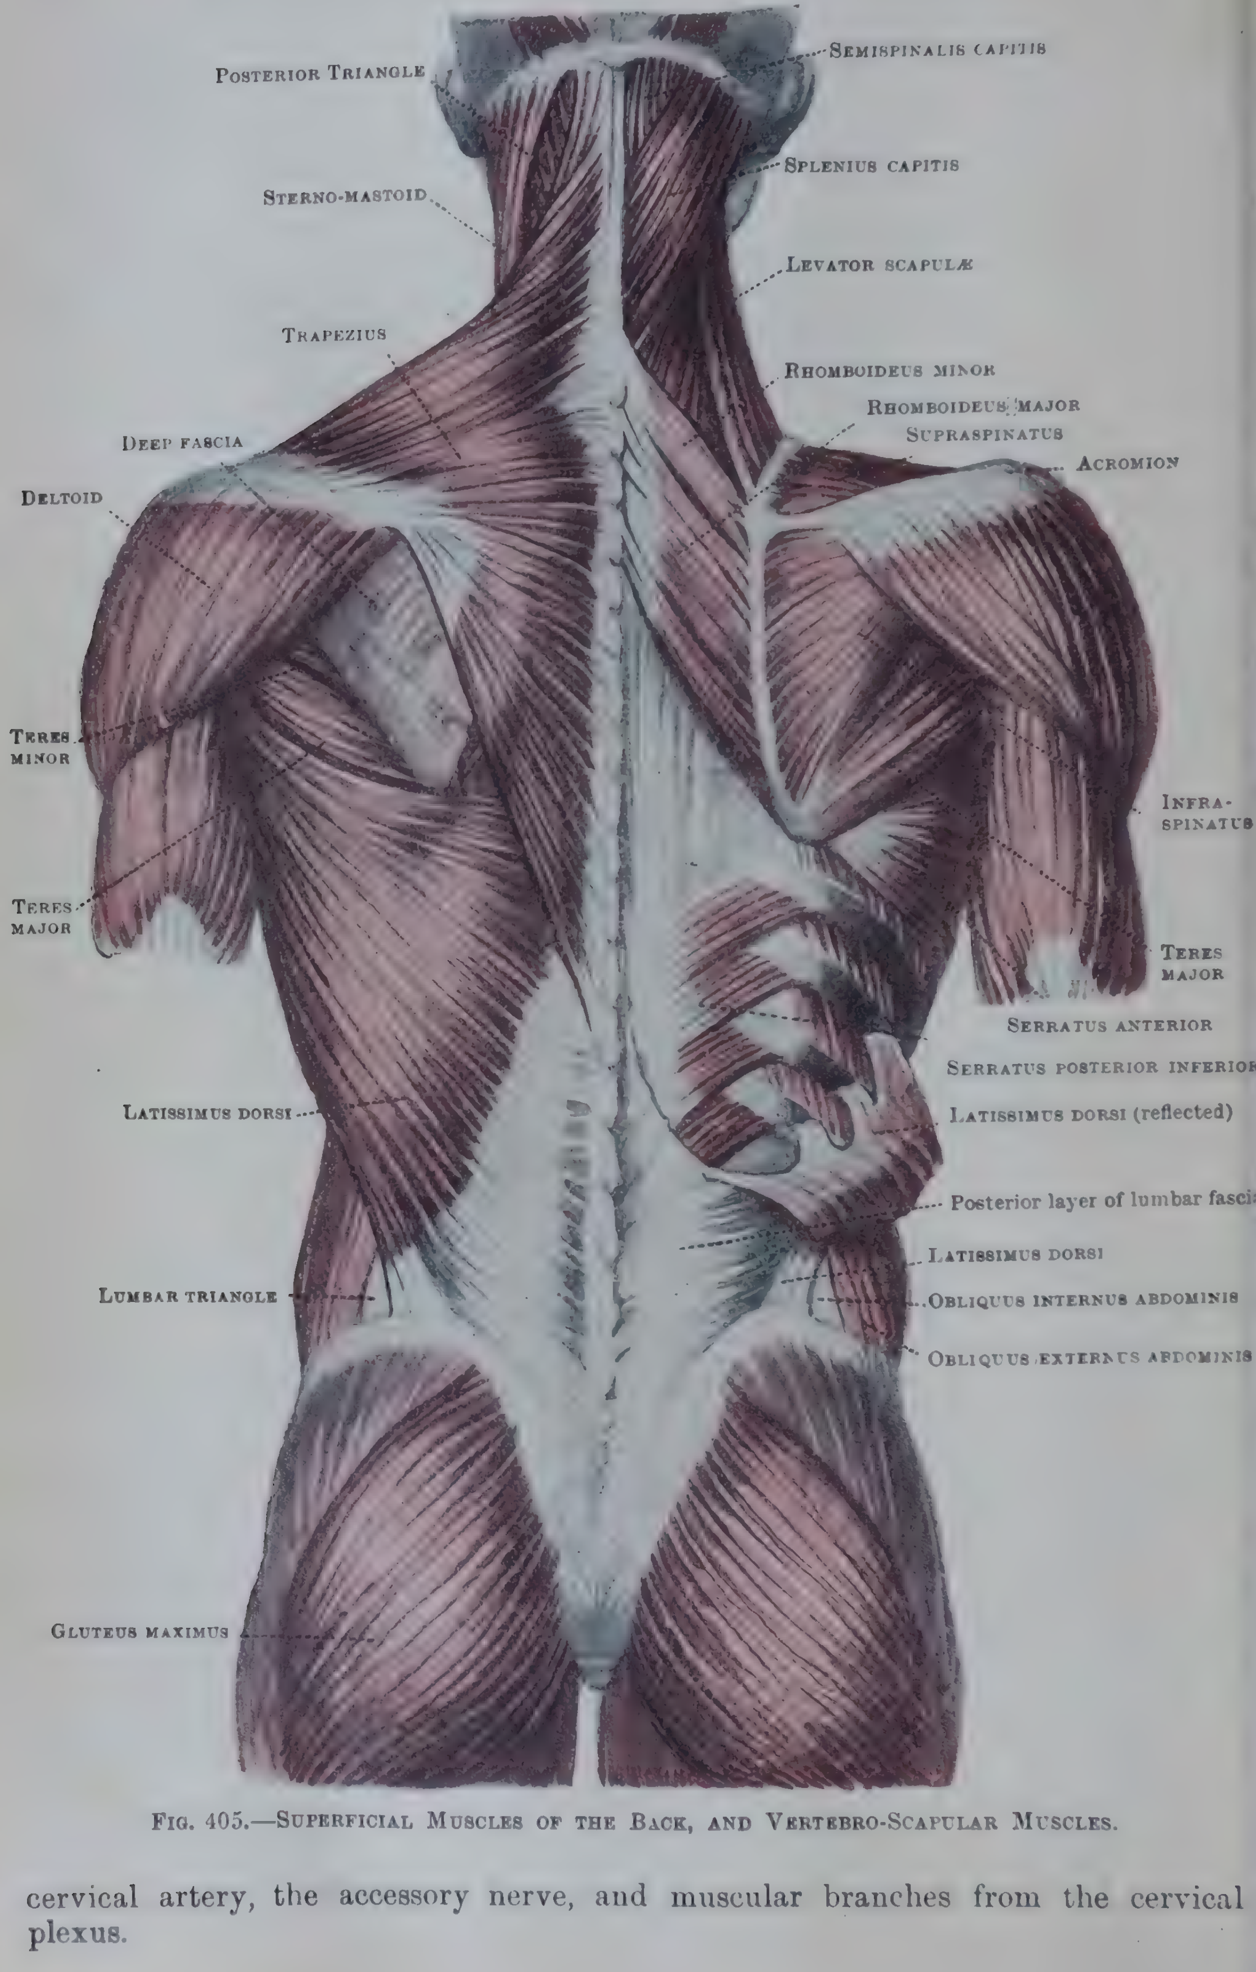

Fig. 405.—Superficial Muscles of the Back, and Vertebro-Scapular Muscles.

cervical artery, the accessory nerve, and muscular branches from the cervical plexus.

Latissimus Dorsi.—The latissimus dorsi is a wide triangular muscle which lies in the lower part of the back. The greater part of the muscle **arises**—(1) from the spines of the lower six thoracic vertebræ, and, through the posterior layer of the lumbar fascia, from the spines of the lumbar and sacral vertebræ and the iliac crest. Its lateral border also arises directly by tendinous fibres from the posterior part of the outer lip of the iliac crest. From this main origin the muscle is directed upwards and laterally, its fibres converging towards the lower border of the axilla. In relation to its lateral and upper borders additional fibres arise. (2) *Along the lateral border* muscular slips arise from the lower three or four ribs, interdigitating with the slips of origin of the obliquus externus abdominis. (Fig. 405 and Pl. XL, p. 457, Figs. 1, 2.) (3) As *the superior border* of the muscle passes horizontally over the inferior angle of the scapula, an additional fleshy slip usually takes origin from that part of the bone and joins the muscle on its deep surface (Fig. 406).

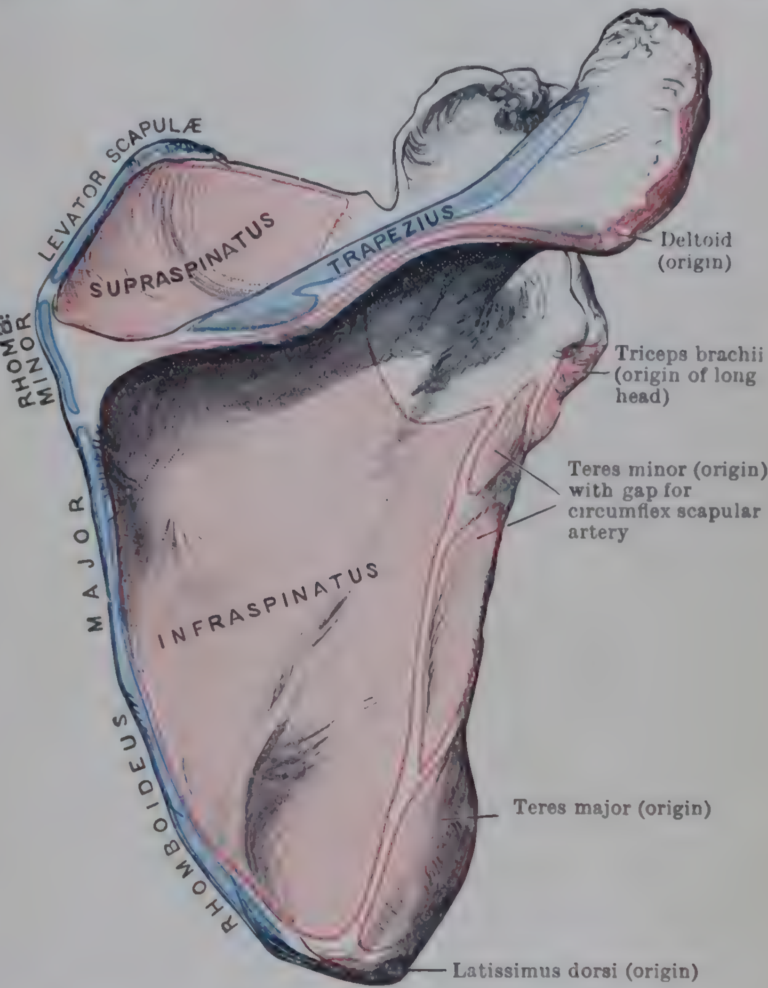

FIG. 406.—MUSCLE-ATTACHMENTS TO DORSAL SURFACE OF RIGHT SCAPULA.

Beyond the inferior angle of the scapula the latissimus dorsi, greatly narrowed, curves spirally round the teres major muscle in the lower edge of the posterior axillary fold. It ends in a ribbon-like tendon which is closely adherent at first to the teres major and is **inserted** into the floor of the bicipital groove of the humerus (Fig. 415). It is placed behind the axillary vessels and nerves, and in front of the insertion of the teres major—a *bursa* intervening. Because of the spiral turn, the anterior surface of the tendon of insertion is continuous with the posterior surface of the rest of the muscle.

In the back the latissimus dorsi is superficial, except that its upper part is concealed by the trapezius. It covers part of the lumbar fascia, the serratus posterior inferior, the lower ribs, and the inferior angle of the scapula. At its upper border is the *triangle of auscultation*; at its lateral border is the *lumbar triangle*—a small space bounded by the iliac crest, the latissimus dorsi, and the obliquus externus abdominis. That space is sometimes the site of a lumbar hernia.

Levator Scapulæ.—This strap-like muscle **arises** by tendinous slips from the posterior tubercles of the transverse processes of the first three or four cervical vertebræ, between the attachments of the scalenus medius in front and the splenius cervicis behind. It is directed downwards to be **inserted** into the medial margin of the scapula, from the upper angle to the spine (Figs. 405, 406).

It is concealed in its upper third by the sterno-mastoid muscle. Its middle third forms part of the floor of the posterior triangle of the neck. Its lower third is hidden by the trapezius, and conceals the nerve to the rhomboids and the deep branch of the transverse cervical artery.

Rhomboidei.—The **rhomboideus minor** may be regarded as a separated slip of the rhomboideus major, with which it is often continuous. It **arises** from the

lower part of the *ligamentum nuchæ,* the spines of the seventh cervical and first thoracic vertebræ, and the supraspinous ligament between them. Passing obliquely downwards and laterally, it is **inserted** into the medial border of the scapula opposite the root of the spine (Figs. 405, 406). The **rhomboideus major arises** from the spines of the thoracic vertebræ from the second to the fifth inclusive, and from the corresponding supraspinous ligaments. It also passes downwards and laterally to be **inserted** into the medial border of the scapula, between the spine and the inferior angle (Figs. 405, 406). The muscle is inserted directly into the scapula by means of its lower fibres only. Its upper part is attached to a membranous band which is connected to the medial border of the scapula, for the most part by loose areolar tissue, but is fixed to the bone near the spine and at the inferior angle.

The rhomboid muscles are concealed to a large extent by the trapezius; they cover the serratus posterior superior and the sacro-spinalis.

Nerve-Supply.—Associated in the movements of the upper limb on the trunk, the superficial muscles of the back are all supplied by nerves that are derived from the cervical region of the spinal cord but reach the muscles by various routes. The trapezius has a double nerve-supply, similar to that of the sterno-mastoid: (1) from the terminal fibres of the **spinal portion** of the **accessory** nerve and (2) from the **cervical plexus** (anterior primary rami, C. **3** and **4**). The cervical nerves communicate with the accessory nerve in the posterior triangle of the neck and beneath the trapezius; and it is probable that they are mainly concerned in conveying afferent impulses from the muscle.

The latissimus dorsi has a single nerve—the **nerve to the latissimus dorsi**—which supplies it on its deep surface; it is a branch from the posterior cord of the brachial plexus (C. (6), 7, 8). The levator scapulæ and the rhomboid muscles are associated together in their nerve-supply, which is derived in succession from the anterior primary rami of the **third, fourth,** and **fifth cervical** nerves. The **nerve to the rhomboids** from the brachial plexus (C. (4) 5), passing beneath the levator scapulæ and the rhomboids, supplies all three muscles on their deep surfaces. The upper part of the levator scapulæ is supplied in addition by small branches from the anterior primary rami of the third and fourth cervical nerves which enter the muscle on its superficial surface near its origin.

It should be noted that the cervical nerves which supply this group of muscles, in spite of the fact that it is situated mainly in the back, are derived through the cervical and brachial plexuses from the *anterior* primary rami of the spinal nerves concerned; the explanation is to be found in the developmental origin of the muscles from the ventro-lateral sheet of musculature and their subsequent migration to obtain secondary attachment to the vertebral column (pp. 553, 555).

MUSCLES AND FASCIÆ OF PECTORAL REGION

2. Muscles of Pectoral Region

The ventral group of muscles connecting the upper limb to the trunk comprises the pectoralis major, pectoralis minor, subclavius, and the serratus anterior. The sterno-mastoid, by virtue of its attachment to the clavicle, may be considered a member of this group; it has already been described (p. 434).

Pectoralis Major.—The pectoralis major is a large fan-shaped muscle **arising** in two main portions—a small clavicular and a large sterno-costal—separated by a distinct interval. (1) The *clavicular part* arises from the front of the clavicle in its medial half or two-thirds (Figs. 404, 408, 409). (2) The *sterno-costal part* is larger, and arises from the anterior surface of the manubrium and body of the sternum by tendinous fibres that decussate with those of the opposite muscle (Figs. 407, 408); more deeply, from the cartilages of the first six ribs; and by a small slip, sometimes separate (*abdominal part*), from the aponeurosis of the external oblique muscle of the abdominal wall.

The fibres converge towards the proximal part of the arm, and are inseparably blended at a point half an inch from their **insertion** into the lateral lip of the bicipital groove of the humerus.

The arrangement of the fibres of the muscle at its insertion is peculiar. The clavicular part is attached to the humerus in front of the sterno-costal part and blends, inferiorly, with the tendinous insertion of the deltoid, the lateral fibres

of origin being inserted proximal to the medial fibres. The upper sterno-costal fibres disappear under cover of the clavicular part near its insertion and are blended with the deep surface of its tendon. The lower sterno-costal fibres and the abdominal part curve upwards behind the upper sterno-costal fibres; the abdominal part has the highest attachment to the shaft of the humerus, and helps to form a fascial expansion which extends upwards over the biceps tendon to the capsule of the shoulder joint. In this way a bilaminar tendon is produced, united along its inferior border. The superficial lamina is formed by the upper sterno-costal fibres blended for the most part with the tendon of the clavicular part and the deep lamina, by the twisted, lower sterno-costal and abdominal fibres.

Placed superficially, the pectoralis major lies in the anterior wall and anterior fold of the axilla (Pl. XL, p. 457, Fig. 3, and Fig. 412, p. 483). Its upper border is separated from the edge of the deltoid muscle by an interval called the *infra-clavicular fossa* (Pl. XLI, p. 512, Fig. 3), in which lie the cephalic vein and the deltoid branches of the acromio-thoracic artery. Its deep surface is in relation with the ribs and intercostal muscles, the clavi-pectoral fascia and the structures piercing it, the pectoralis minor, the biceps and coraco-brachialis, the axillary vessels, and the nerves of the brachial plexus.

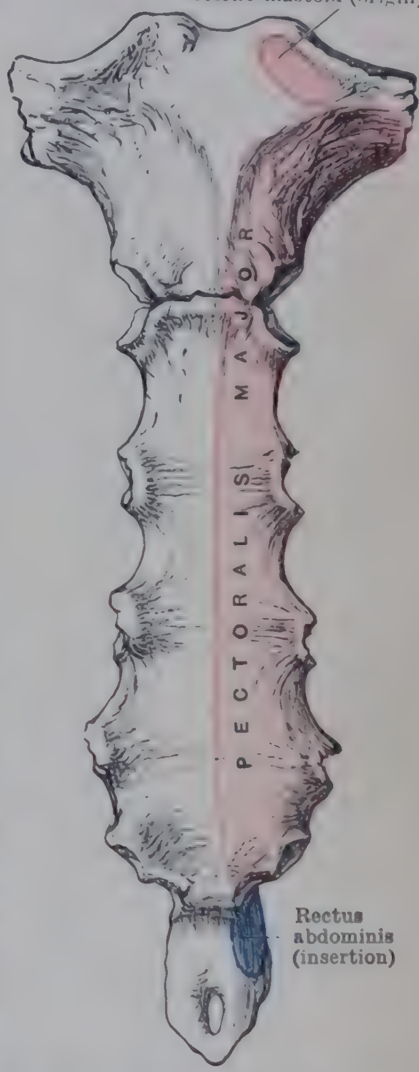

FIG. 407.—MUSCLE-ATTACHMENTS TO FRONT OF STERNUM.

Sternalis Muscle.—The sternalis is an occasional muscle (4·4%) that lies parallel to the sternum on the origin of the pectoralis major. It has variable attachments to the costal cartilages, sternum, rectus sheath, sterno-mastoid, and pectoralis major. Its **nerve-supply** is from one or both of the pectoral nerves. In certain rare cases it has been said to be innervated by intercostal nerves.

Chondro-Epitrochlearis, Dorso-Epitrochlearis, Axillary Arches, Costo-Coracoideus.—One or other of the above-named slips is occasionally present, crossing the floor of the axilla in the interval between the latissimus dorsi and the pectoralis major. They take **origin** from the costal cartilages, ribs, or borders of the pectoralis major (*chondro-epitrochlearis, axillary arches, costo-coracoideus*), or from the border of the latissimus dorsi (*dorso-epitrochlearis, axillary arches, costo-coracoideus*). Their **insertion** is variable. The *chondro-epitrochlearis* and *dorso-epitrochlearis* are inserted into the fascia of the arm, the medial intermuscular septum, or the medial epicondyle of the humerus. The *axillary arches* are inserted into the border of the pectoralis major, the fascia of the arm, or the coraco-brachialis or biceps muscle. The *costo-coracoideus*, arising from the ribs or the aponeurosis of the external oblique, or detaching itself from the border of the pectoralis major or latissimus dorsi, is inserted into the coracoid process, alone or along with one of the muscles attached to that bone. These variable slips of muscle are supplied by the medial pectoral nerve, the medial cutaneous nerve of the arm, or the intercosto-brachial nerve.

Pectoralis Minor.—The pectoralis minor (Fig. 408) is a narrow, flat, triangular muscle that lies in the anterior wall of the axilla behind the pectoralis major. It **arises**, under cover of the pectoralis major, from the third, fourth, and fifth ribs near their anterior ends, and from the fascia of the corresponding intercostal spaces. It may have an additional origin from the second rib (Fig. 359, p. 420); and that from the fifth rib is often absent. Directed upwards and laterally, it is **inserted** by a short, flat tendon into the anterior half of the medial border and upper surface of the coracoid process (Fig. 411), and usually also into the conjoint tendon of the biceps and coraco-brachialis.

It crosses the axillary vessels and the cords of the brachial plexus, and is pierced by the medial pectoral nerve. Its fascial sheath is continuous above with the clavi-pectoral fascia and below with the axillary fascia.

Either in part or wholly, the pectoralis minor may pass over the coracoid process (separated from it by a *bursa*) to pierce the coraco-acromial ligament and be attached to the capsule of the shoulder joint.

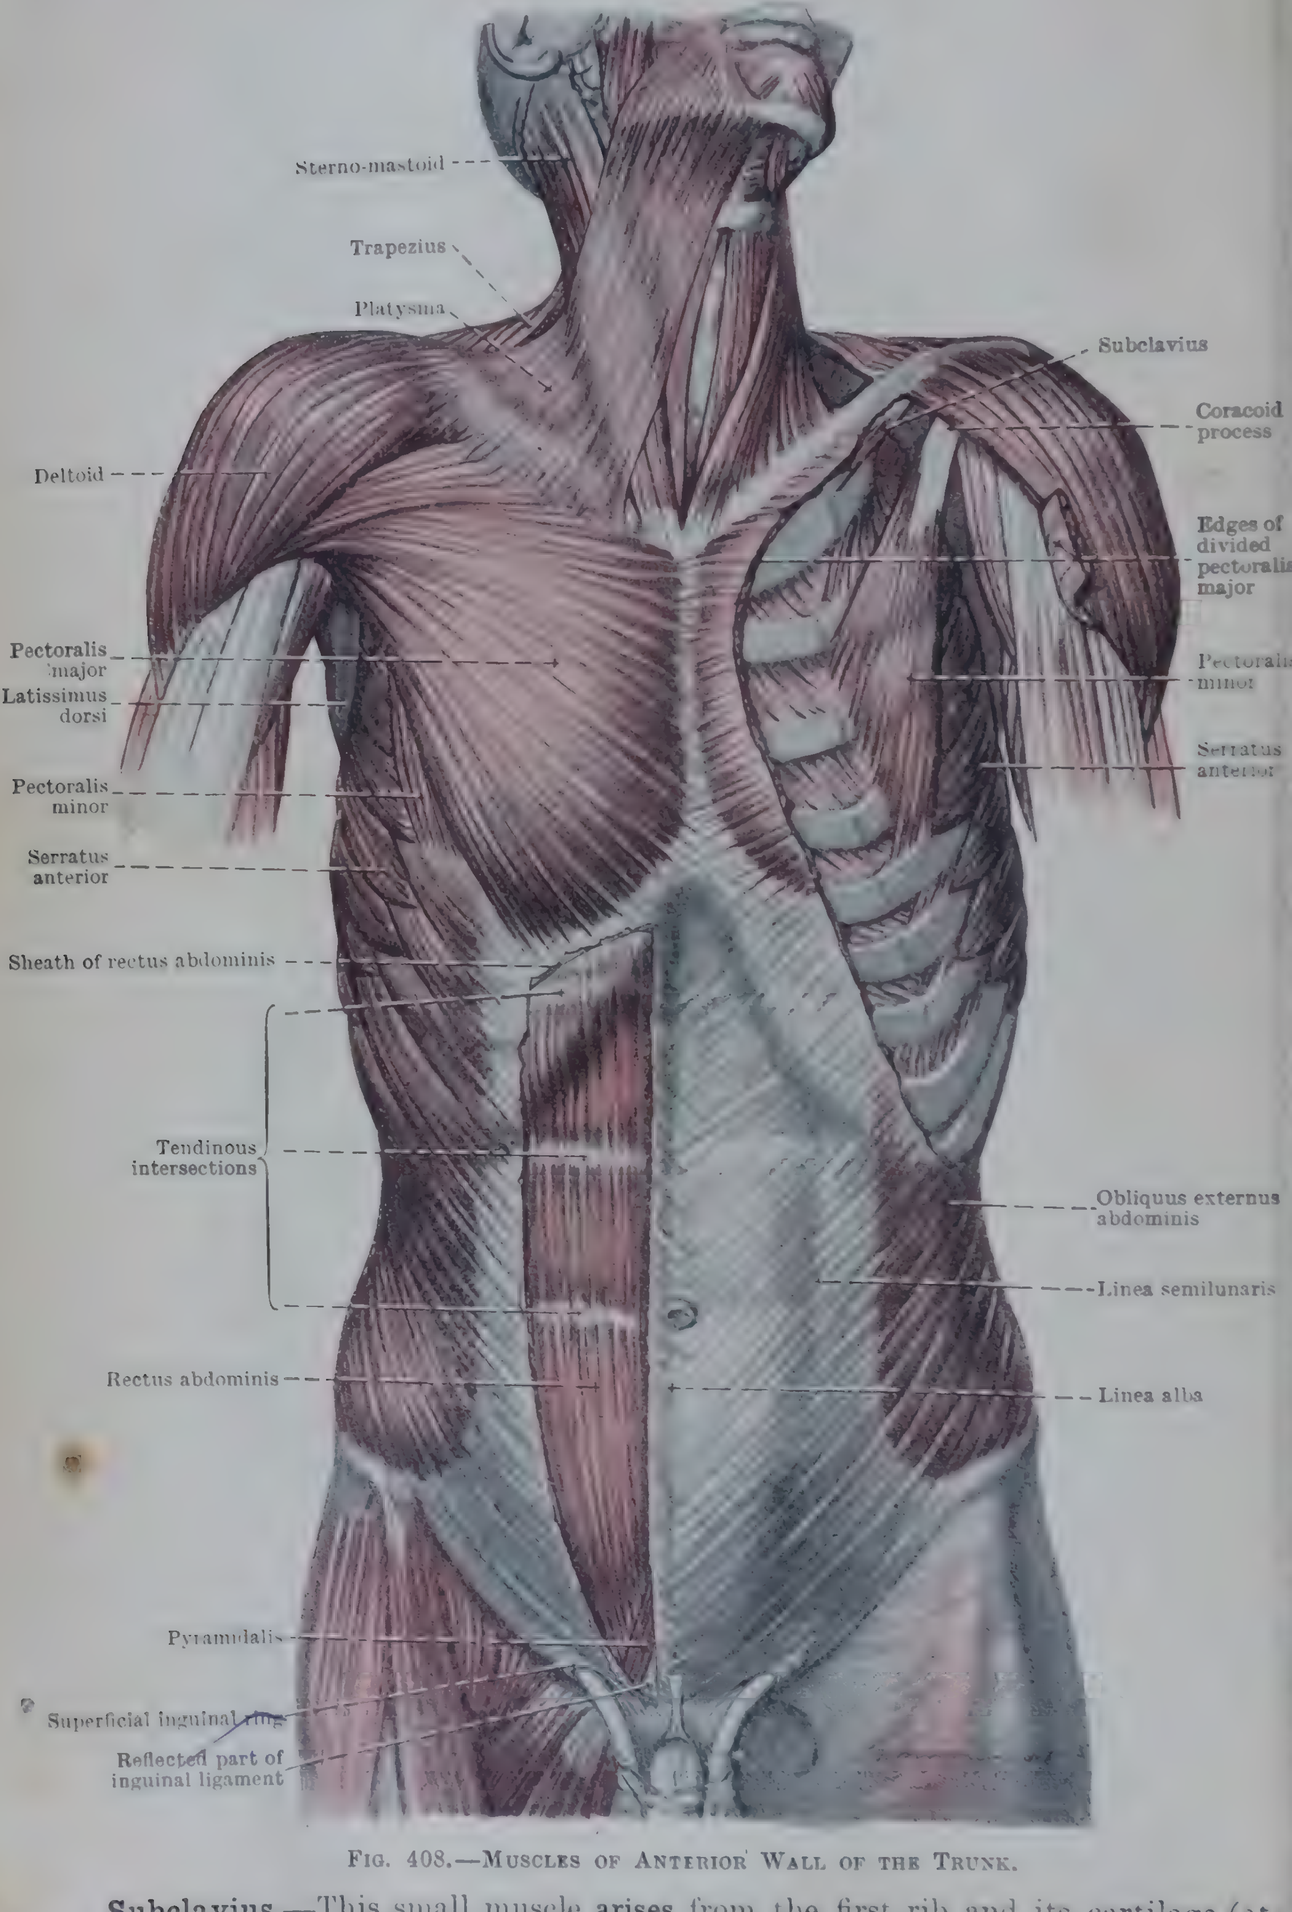

FIG. 408.—MUSCLES OF ANTERIOR WALL OF THE TRUNK.

Subclavius.—This small muscle **arises** from the first rib and its cartilage (at their junction) in front of the costo-clavicular ligament, and passes upwards and

laterally to be **inserted** into the floor of an elongated groove on the lower surface of the clavicle. It is concealed by the clavicle and the pectoralis major; and the clavi-pectoral fascia splits to enclose it.

Serratus Anterior.—The serratus anterior is a large, curved, quadrilateral

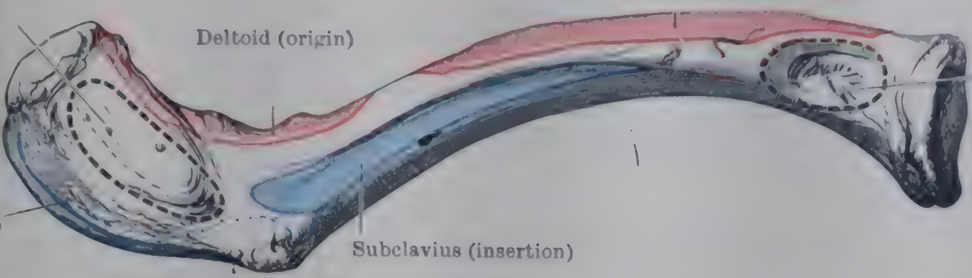

FIG. 409.—MUSCLE-ATTACHMENTS TO INFERIOR SURFACE OF RIGHT CLAVICLE.

muscle that lies on the side of the chest and in the medial wall of the axilla. It **arises** by fleshy slips from the outer surfaces of the upper eight (or nine) ribs. The first slip is a double one, arising from the first two ribs and the fascia of the intervening space (Fig. 410).

The **insertion** of the muscle is threefold. (1) The first slip is directed backwards to be inserted into the costal surface of the scapula at the superior angle. (2) The next three slips are inserted into the medial border of the scapula. (3) The last four slips are directed obliquely upwards and backwards to be inserted on the costal surface of the scapula at the inferior angle (Fig. 411).

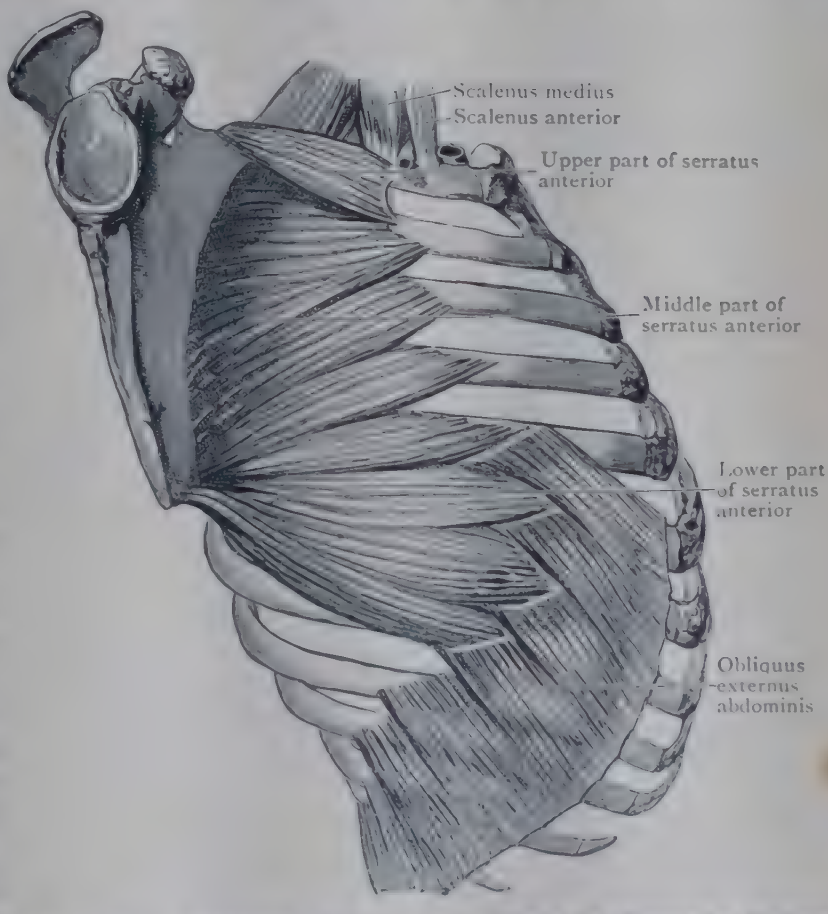

FIG. 410.—SERRATUS ANTERIOR AND ORIGIN OF EXTERNAL OBLIQUE. The Scapula is drawn away from the side of the chest.

The lateral surface of the muscle is partly superficial (Pl. XL, p. 457, Fig. 2) below the axilla, where its slips of origin interdigitate with those of the obliquus externus abdominis. Higher up, it forms the medial wall of the axilla and is partly covered by the infero-lateral part of the mammary gland. It is in contact with the pectoral muscles anteriorly and the subscapularis posteriorly. Its upper border appears in the floor of the posterior triangle of the neck, and over it the axillary artery and the cords of the brachial plexus enter the axilla. The lower border is oblique, and is in contact with the latissimus dorsi muscle. The muscle is sometimes continuous, in the neck, with the levator scapulæ.

Nerve-Supply.—The muscles of the pectoral region are all supplied by branches from the nerves of the brachial plexus (C. 5. 6. 7. 8. T. 1.). The **nerve to the subclavius** is a fine branch which arises above the clavicle from the upper trunk of the brachial plexus (C. 5. 6.), and descends in front of the subclavian artery to reach the muscle.

The pectoral muscles are each supplied by both pectoral nerves. The **lateral pectoral nerve**, derived from the lateral cord of the brachial plexus (C. 5. 6. 7.), divides into two branches, both of which pierce the clavi-pectoral fascia to supply respectively the clavicular and the upper portion of the sterno-costal part of the pectoralis major; the lower branch communicates over the axillary artery with the **medial pectoral nerve**. This nerve, a derivative of the medial cord (C. 8. T. 1.), likewise divides into two branches which supply the pectoralis minor and, piercing that muscle (the lower may wind round its inferior border), terminate in the lower part of the pectoralis major.

The serratus anterior is supplied, on its superficial aspect, by the **nerve to serratus anterior**, a branch from the anterior primary rami of the fifth, sixth, and seventh cervical nerves. The contributions from these nerves are distributed in order from above downwards—the highest fibres of the muscle being supplied by the fifth, the lowest by the seventh.

Actions of Muscles in Movements of the Shoulder Girdle.—The great range of action of the upper limb is due to a combination of free movements of the arm at the shoulder joint with movements of the shoulder girdle on the trunk. The action of the muscles which connect the limb to the trunk is most readily appreciated with reference to the movements of the scapula. From the position of rest, with the arm hanging by the side, the scapula is freely movable on the chest-wall in three directions by (1) elevation, (2) forward translation, and (3) lateral rotation (the inferior angle passing forwards and laterally). Those movements are normally combined and may be readily observed as the arm is raised above the head; they then occur as associated movements of the girdle as a whole at the sterno-clavicular joint, and as compensating or adapting movements between clavicle and scapula at the acromio-clavicular joint. All the muscles which act from the trunk upon the limb are so arranged that they tend to produce or to antagonize this combination of three movements of the scapula.

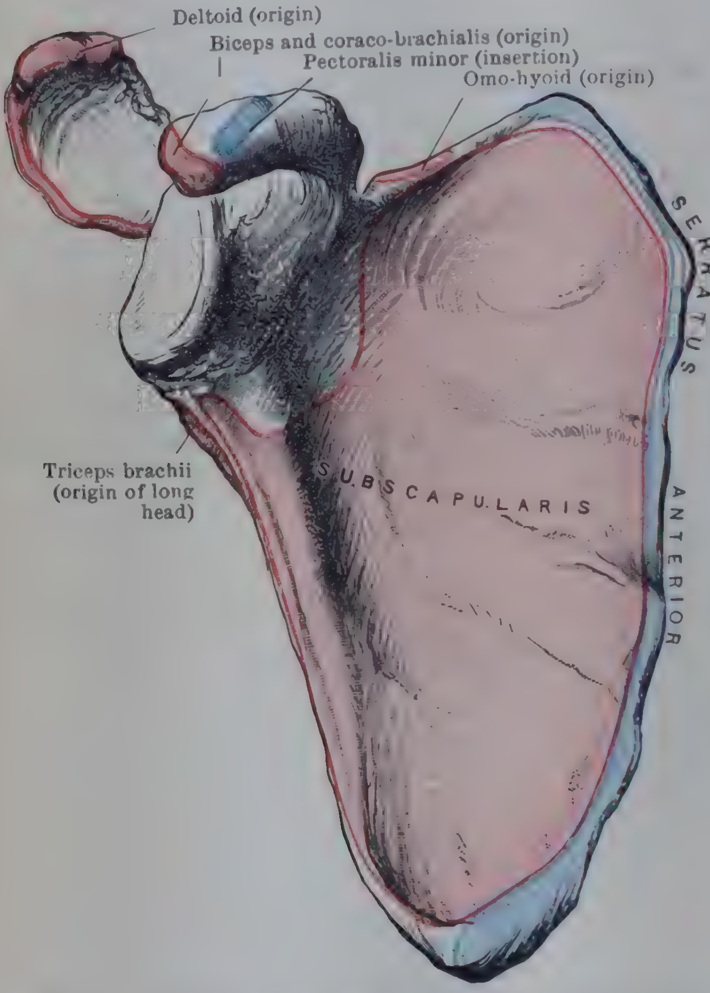

Fig. 411.—Muscle-Attachments to Costal Surface of Right Scapula.

The **trapezius** muscles, by their tonic or postural action alone, keep the shoulders braced and thus help to suspend the upper limbs—drooping shoulders are an outward sign of diminished nervous and muscular tone. When a weight is shouldered, the muscle has to work harder to maintain the position of the shoulder.

The lever afforded by the spine of the scapula is like a winged nut for the grip of this muscle in rotating the scapula during elevation of the upper limb (Fig. 209, p. 241; and Pl. XXXVII, p. 456, Fig. 2). The lateral angle is then raised, the superior angle lowered, and the inferior angle directed laterally; and the various fibres, converging on the spine, co-operate in producing this movement (cf. Pl. XXXII, p. 347, and Fig. 404, p. 475).

The **levator scapulæ** and the **rhomboids** act in concert with their antagonist (the trapezius) in pulling the shoulders backwards—the movement being the resultant of their opposed forces. In the rotatory movement of shrugging the shoulders, the trapezius and the serratus anterior, followed by the levator and the rhomboids, act in sequence, first one group predominating, then the other, with at times the opposed action of both groups securing a resultant movement—the approximation of the scapulæ. When the trapezius is paralysed the lateral angle of the scapula is lower than on the unaffected side, and the other angles are higher; this tilting is brought about by the levator and the rhomboids—assisted by the weight of the limb.

The **serratus anterior** is a powerful factor in steadying the scapula, in pulling it forwards, and, acting with the trapezius, in raising its inferior angle as the limb is elevated (Pl. XL, p. 457, Fig. 2). When the limb is raised forwards to the horizontal, the serratus gives the extra forward thrust as in fencing, and is brought into use in pushing movements. It acts from its insertion in forced inspiration, or in hand balance exercises ("standing on the hands")—in which most of the muscles of the arm reverse their actions. In paralysis of the serratus anterior, the medial border of the scapula stands farther away from the chest-wall ("winged scapula") than it does in paralysis of the trapezius, and the patient has difficulty in raising his arm much beyond the horizontal position, whereas the arm may be completely raised (though clumsily) in trapezius paralysis. As a rule, when abduction of the arm begins, its weight causes a slight medial movement of the inferior angle of the scapula, but in a few cases it moves immediately lateralwards. The muscles that rotate the scapula are active throughout elevation of the arm, and so also are the muscles that produce this movement at the shoulder joint (cf. Actions, p. 487).

The **pectoralis minor** assists in drawing the shoulder forwards, and is an opponent of the trapezius by depressing the shoulder and rotating the scapula medially. Its action

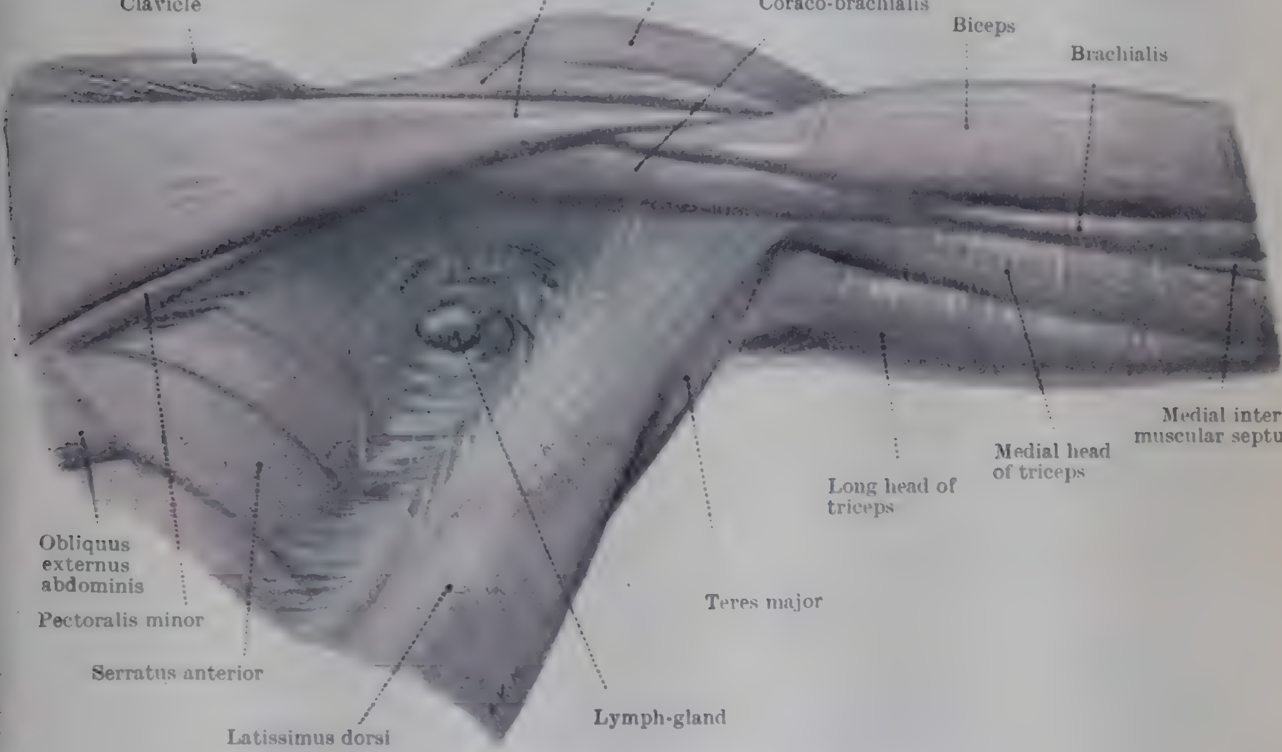

FIG. 412.—FASCIA AND MUSCLES OF LEFT AXILLA.

is very difficult to appreciate in the living subject, since it lies under cover of the pectoralis major and is never paralysed alone.

The **subclavius** is a depressor of the lateral end of the clavicle, and by drawing the bone medially towards the sternum it steadies it in movements of the shoulder girdle.

Two of the muscles that attach the upper limb to the trunk (**latissimus dorsi** and **pectoralis major**) act primarily at the shoulder joint, but also take part indirectly in the movements of the shoulder girdle. The latissimus dorsi (Pl. XL, p. 457, Fig. 1) assists in backward movements of the girdle, the pectoralis major in forward movement (Pl. XLI, p. 512, Fig. 3), and together they take part in the movement of depression of the shoulder (Pl. XLI, Fig. 2). Both these muscles can act, from their insertions, upon the trunk: (1) they are the chief climbing muscles—drawing the body upwards when the arms are fixed; (2) when the shoulders are elevated and fixed they act as accessory muscles of respiration (p. 454). The pectoralis major, with the minor, assists violent inspiratory efforts by raising the upper ribs, and the costal slips of the latissimus dorsi raise the lower ribs. The latissimus dorsi muscles appear also to assist the abdominal muscles in violent expiratory efforts by their general compressing effect on the thorax (p. 454).

It is a most interesting feature of the pectoralis major that the clavicular fibres assist in raising the arm forwards to the horizontal, while the sterno-costal fibres, acting against resistance, depress the arm. When the subject carries out both these opposite movements simultaneously, one with each arm, against resistance, the lop-sided effect

produced upon the great pectoral muscles is remarkable (Pl. XLII, p. 513, Fig. 1). (This exercise also produces marked asymmetry of the thoracic cage). It is noteworthy also that when the erect arm is being depressed against resistance, the clavicular fibres, though anatomically in a position to assist, are in fact inactive.

FASCIÆ OF PECTORAL REGION

The **superficial fascia** of the chest usually contains a quantity of fat in which the mammary gland is embedded. The fibres of the platysma muscle lie beneath the upper part of the fascia, and many of them pierce it to take origin from the skin.

The **deep fascia** is attached above to the clavicle, and medially to the sternum. It invests the pectoralis major, and is continuous below with the fascia of the abdominal wall. Beyond the lateral border of the great pectoral muscle it is thickened and forms the floor of the axillary space **(axillary fascia)**—continued posteriorly on to the posterior fold of the axilla and laterally into connexion with the deep fascia of the upper arm.

Clavi-Pectoral Fascia.—Beneath the pectoralis major a deeper stratum of fascia invests the pectoralis minor muscle. At the supero-medial border of that muscle it forms the clavi-pectoral fascia, which passes upwards to the inferior border of the subclavius muscle, where it splits into two layers, attached in front of and behind that muscle to the borders of the inferior surface of the clavicle. The membrane, traced medially along the subclavius muscle, is attached to the first costal cartilage; passing laterally along the pectoralis minor, it reaches the coracoid process and the coraco-clavicular ligament; and the part of the membrane that extends directly between the first costal cartilage and the coracoid process is thicker than the rest of it. The clavi-pectoral fascia is pierced by the cephalic vein, acromio-thoracic artery, and branches of the lateral pectoral nerve. Its deep surface is connected with the sheath of the axillary vessels.

At the infero-lateral border of the pectoralis minor there is a further extension of the deep fascia beneath the pectoralis major. It passes downwards to join the fascia of the floor of the axilla, and it is continued laterally into the fascia that covers the biceps and coraco-brachialis muscles.

MUSCLES AND FASCIÆ OF SHOULDER

Muscles of Shoulder

The **muscles** proper to the shoulder are the deltoid, supraspinatus, infraspinatus, teres minor, teres major, and subscapularis.

Deltoid Muscle.—The deltoid, a coarsely fasciculated, multipennate muscle, has an extensive **origin** from: (1) the front of the clavicle in its lateral third (Fig. 404); (2) the lateral border of the acromion; (3) the lower lip of the crest of the spine of the scapula and the fascia of the infraspinatus muscle. Its origin embraces the insertion of the trapezius.

The fibres of the muscle converge on the lateral surface of the shaft of the humerus to be **inserted** into the deltoid tuberosity. The insertion is partly united with the tendon of the pectoralis major (Fig. 418, p. 491).

The most anterior part of the deltoid muscle is formed of parallel fibres, not uncommonly separate from the rest of the muscle at their origin. Those fibres may be continuous across the clavicle with the trapezius. The most posterior fibres have a membranous origin, and converge on the main tendon. The middle fibres are multipennate, being attached above and below to three or four septal tendons which extend for a variable distance downwards and upwards from the origin and insertion of the muscle—an arrangement that increases the number of the fibres and consequently the power of the deltoid. The increased power is necessary owing to the obvious mechanical disadvantage at which the muscle acts, and the fact that its action is usually exerted against the force of gravity.

The deltoid is superficial in its whole extent. It is spread out over the greater tuberosity of the humerus and so forms the prominence of the shoulder. Its anterior border is separated from the pectoralis major by a narrow interval

occupied by the cephalic vein and deltoid branch of the acromio-thoracic artery. The deep surface of the muscle is related to—(1) the *coracoid process*, associated with which are the coraco-acromial ligament, and the attachments of the pectoralis minor, the coraco-brachialis, and the short head of the biceps muscle; (2) the subscapularis, supraspinatus, infraspinatus, and teres minor, which cover the capsule of the shoulder joint; and (3) the proximal part of the lateral surface of the *shaft of the humerus* and the posterior circumflex humeral vessels and the circumflex nerve. The *sub-acromial bursa* separates the middle fibres of the deltoid, the acromion and the coraco-acromial ligament from the supraspinatus, infraspinatus, and subscapularis tendons.

FIG. 413.—LEFT SCAPULAR MUSCLES AND TRICEPS.

Supraspinatus.—The supraspinatus **arises**, by fleshy fibres, from the walls of the supraspinous fossa (except near the neck of the bone) and from the deep fascia. It is directed forwards and laterally under the trapezius muscle, the acromion and coraco-acromial ligament, to be **inserted** by a broad, thick tendon into the anterior facet on the top of the greater tuberosity of the humerus and into the capsule of the shoulder joint.

Infraspinatus.—The infraspinatus **arises** from the walls of the infraspinous fossa (excepting near the neck of the bone and the flat surface along the lateral margin) and from the thick fascia over it. The fibres of the muscle converge on the neck of the scapula and are **inserted** by tendon into the middle facet on the greater tuberosity of the humerus and into the capsule of the shoulder joint. The *bursa of the infraspinatus muscle* separates the muscle from the neck of the scapula, and occasionally communicates with the cavity of the shoulder joint.

The supraspinatus and the upper part of the infraspinatus muscles are covered by the trapezius, acromion, and deltoid and, in turn, conceal the neck of the scapula, the suprascapular vessels and nerve, and the capsule of the shoulder joint.

Teres Minor.—This small muscle **arises**, by fleshy fibres, from a raised, narrow strip situated on the dorsal surface of the scapula along the upper two-thirds of its lateral border, and from fascial septa that separate it from the infraspinatus and teres major muscles. It lies along the lateral border of the infraspinatus, and it is **inserted**, under cover of the deltoid, by a thick, flat tendon, into the lowest of the three facets on the greater tuberosity of the humerus and into the capsule of the shoulder joint, and, by fleshy fibres, into the back of the humerus below the tuberosity for about an inch.

It is separated from the teres major by the long head of the triceps and by the posterior circumflex humeral vessels and the circumflex nerve. At its origin it is pierced by the circumflex scapular vessels. The muscle is invested by the fascia of the infraspinatus, and is sometimes inseparable from that muscle.

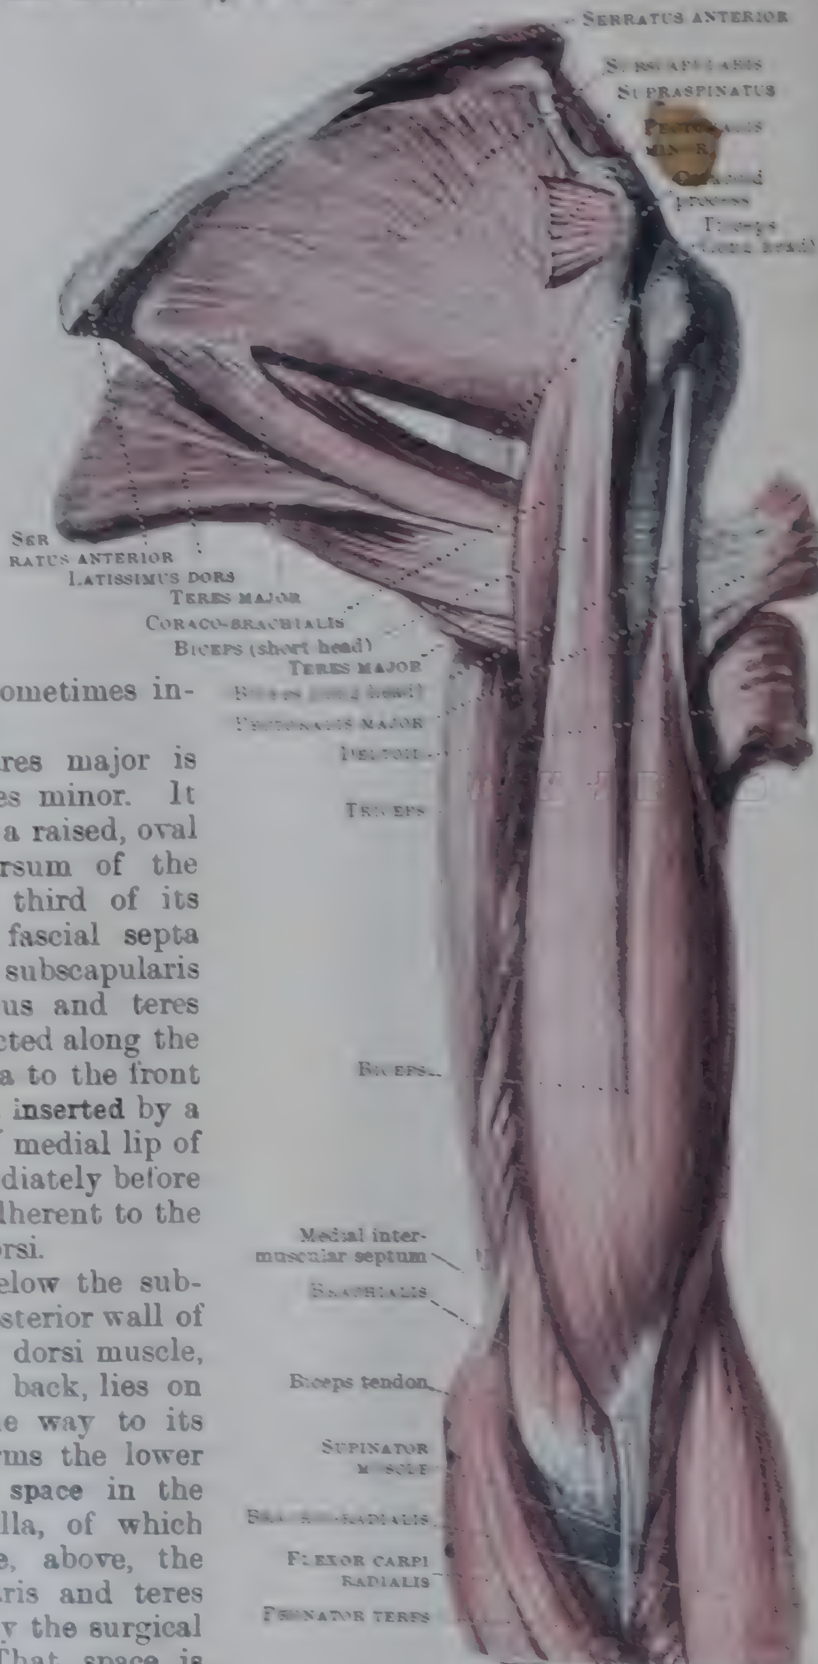

FIG. 414.—MUSCLES OF POSTERIOR WALL OF LEFT AXILLA AND FRONT OF ARM.

Teres Major.—The teres major is much larger than the teres minor. It **arises** by fleshy fibres from a raised, oval area situated on the dorsum of the scapula along the lower third of its lateral border, and from fascial septa which separate it from the subscapularis and from the infraspinatus and teres minor. The muscle is directed along the lateral border of the scapula to the front of the humerus, where it is **inserted** by a broad, flat tendon into the medial lip of the bicipital groove. Immediately before its insertion it is closely adherent to the tendon of the latissimus dorsi.

The teres major lies below the subscapularis muscle in the posterior wall of the axilla. The latissimus dorsi muscle, sweeping round from the back, lies on its axillary surface on the way to its insertion. The muscle forms the lower boundary of a **triangular space** in the posterior wall of the axilla, of which the other boundaries are, above, the borders of the subscapularis and teres minor muscles, and laterally the surgical neck of the humerus. That space is divided by the long head of the triceps, which passes behind the teres major muscle, into (*a*) a **quadrangular space** laterally, for the passage of the circumflex nerve and posterior humeral circumflex vessels, and (*b*) a smaller triangular space medially for the circumflex scapular vessels.

Subscapularis.—The subscapularis is a large triangular muscle which covers

the costal surface of the scapula. It **arises**, by fleshy fibres, from the whole of the floor of the subscapular fossa and the groove along the lateral border, excepting the surfaces at the angles of the bone. Several fibrous septa that spring from ridges in the fossa project into the substance of the muscle and increase the extent of its attachment. Converging on the upper end of the humerus, the muscular fibres are **inserted** by a broad, thick tendon into the lesser tuberosity of the humerus and into the capsule of the shoulder joint, and, by fleshy fibres, into the front of the humerus below the tuberosity for about an inch, under cover of the coraco-brachialis and short head of the biceps.

This muscle forms the greater part of the posterior wall of the axilla. Its medial or anterior surface is in contact with the serratus anterior and the axillary vessels and nerves. It is separated from the neck of the scapula by the *subscapular bursa*, which communicates with the shoulder joint.

Nerve-Supply.—All muscles of the shoulder are supplied by the anterior primary rami of the **fifth** and **sixth cervical nerves** through branches of the brachial plexus. The supraspinatus and infraspinatus are supplied by the **suprascapular nerve**, which takes origin from the upper trunk of the plexus; the remaining muscles by branches from the posterior cord. The deltoid is supplied by the terminal branches of the **circumflex nerve**; that nerve supplies also the teres minor by a branch which is distinguished by a fibrous swelling or 'pseudo-ganglion' on its trunk. The subscapularis is supplied by the two **subscapular nerves**; the upper subscapular is often double, and the lower subscapular, after supplying the lower lateral portion of the subscapularis, ends in the teres major.

The Actions of Muscles in Movements at the Shoulder Joint.—Free movements at the shoulder joint are always accompanied by movements of the acromio-clavicular and sterno-clavicular joints. When the limb is raised till it points upwards, about 90° of the movement takes place at the shoulder joint and the other 90° at the joints of the shoulder girdle, but the joints of the girdle are in action from the beginning (Cathcart, 1884; Lockhart, 1930, 1933; Martin 1932, 1940; Johnston, 1937). (Pl. XXXII, p. 347, Figs. 1, 2, 3, show relative positions of the bones at these joints when the limb has been raised from the dependent position to the horizontal, and then to the erect position.) The deltoid, trapezius, and the serratus anterior are in contraction throughout the whole movement. With the humerus fixed, the shoulder muscles, reversing their action, assist in forced respiration. The shoulder joint is called into use also in many of the movements carried out mainly at joints lower down in the limb, for example, supination and pronation, and even fine movements of the fingers. Paralysis of the infraspinatus and the teres minor prevents a person from writing a continuous line without lifting the hand along every two or three words or else pulling the paper to the left.

The muscles of the shoulder joint have been divided into functional groups: 1. The subscapularis, supraspinatus, infraspinatus and teres minor keep the head of the humerus in contact with the glenoid cavity during all movements at the joint executed not only by them but also by other muscles of the arm. Dislocation occurs when these muscles, described as *articular muscles* by Winslow (1743), are taken off their guard or when their strength is overcome. 2. The deltoid, pectoralis major, latissimus dorsi and teres major are the chief effectors of humero-glenoid movement. 3. The deltoid, triceps, biceps and coraco-brachialis, and also the articular muscles, especially supraspinatus, by tonic action, assist in sustaining the weight of the limb in the erect posture.

The **deltoid muscle** is the most powerful abductor of the shoulder joint, but it is important to note that the initiation of this movement depends upon the **supraspinatus**, which helps to prevent displacement of the head of the humerus during strong deltoid action. In paralysis of the deltoid, abduction is limited to about 45°. The anterior fibres of the deltoid assist the clavicular part of pectoralis major in flexion and medial rotation of the humerus; the posterior fibres act with the extensors and lateral rotators. In paralysis of the supraspinatus the patient secures the initial abduction required for elevation of the arm by leaning slightly to the side, thereby harnessing gravity to replace the missing supraspinatus.

The **pectoralis major** is a powerful adductor and medial rotator of the upper arm. The clavicular part assists the anterior fibres of the deltoid to flex the humerus, a movement in which the limb is carried forwards and medially; the sterno-costal part takes part in flexion from full extension until the arm reaches the side, but is a powerful extensor of the fully flexed humerus.

The **latissimus dorsi** is a powerful adductor and extensor of the humerus, its characteristic action being well illustrated in the downstroke in swimming. It assists also in medial rotation of the upper arm.

The **teres major** acts with the pectoralis major and the latissimus dorsi in adduction and medial rotation of the humerus.

In addition to their general action of keeping the head of the humerus in close relation with the glenoid cavity, the muscles immediately surrounding the joint have special actions according to their situation. The **supraspinatus** is an abductor of the arm, the **infraspinatus** a lateral rotator, and the **teres minor** a lateral rotator and an adductor. The **subscapularis** is a medial rotator of the humerus, and when the arm is abducted through 90° it acts with the pectoralis major in drawing the arm horizontally forwards. Its chief function, however, is to prevent forward displacement of the head of the humerus.

The biceps, coraco-brachialis, and triceps also act upon the shoulder joint. The actions of the **biceps** on the joint are weak; the short head helps in flexion and adduction, and the long head in abduction; but the long head has an additional, mechanical influence in steadying the movements at the joint. The **coraco-brachialis** assists in flexion and adduction of the arm, and, when the humerus is rotated laterally, it can produce medial rotation until the position of rest is reached. The long head of the **triceps** acts as an adductor of the humerus. (See Pl. XLII, Fig. 2, p. 513.)

FASCIA OF SHOULDER

The **deep fascia** of the shoulder region is especially strong where it covers the infraspinatus and teres minor muscles below the posterior border of the deltoid. In that situation it is tendinous in appearance and character, and is firmly attached to the medial and lateral borders of the scapula. Superiorly it ensheaths the deltoid and is attached to the clavicle, the acromion, and the spine of the scapula.

MUSCLES AND FASCIÆ OF UPPER ARM

Muscles of Upper Arm

The muscles of the upper arm are the biceps, coraco-brachialis, and brachialis on the front, and the triceps on the back. Except at its ends, the biceps is superficial, and it forms a rounded fleshy mass on the front of the arm. The coraco-brachialis is visible in the proximal half of the upper arm on its medial side, particularly when the limb is raised. The brachialis is concealed by the biceps. The triceps is the thick mass of muscle on the back of the upper arm.

Coraco-Brachialis.—The coraco-brachialis **arises**, under cover of the deltoid, from the tip of the coracoid process, by fleshy fibres, in common with the short head of the biceps. The fleshy belly is pierced by the musculo-cutaneous nerve, and it ends in a flat tendon which is **inserted** into a faint linear impression about an inch in length on the middle of the medial border of the shaft of the humerus (Fig. 415). Some fibres are often continued into the medial intermuscular septum.

The **coraco-brachialis** is the remains of a *threefold muscle.* Usually only two elements are present in man, but in anomalous cases all the parts may be more or less fully developed. The passage of the musculo-cutaneous nerve through the muscle is an indication of its separation into the persisting middle and distal elements. In the commonest variation the more superficial part of the muscle (*coraco-brachialis inferior* or *longus*) extends farther down than usual, so as to be inserted into the medial intermuscular septum, or even into the medial epicondyle of the humerus. A third slip (*coraco-brachialis superior* or *brevis*) may more rarely be present; it springs from the root of the coracoid process and is inserted into the medial side of the humerus immediately below the capsule of the shoulder joint.

Biceps Brachii.—The biceps muscle **arises** by two tendinous *heads.* The **short head** is attached in common with the coraco-brachialis to the tip of the coracoid process of the scapula (Fig. 411, p. 482). Concealed by the deltoid and tendinous at first, this head forms a separate fleshy belly which is united to the long head by an investment of the deep fascia. The **long head** arises by a round tendon from the supraglenoid tubercle and from the labrum glenoidale. Its tendon lies within the capsule of the shoulder joint, and (invested by a prolongation of the synovial membrane) emerges from the joint beneath the transverse ligament. It then occupies the bicipital groove of the humerus, where it is covered by a fascial prolongation of the tendon of the pectoralis major; emerging from the

groove, it forms a fleshy belly which unites with the short head immediately below the middle of the upper arm.

The **insertion** also is twofold. (1) The united bellies become connected to a strong *tendon*, which, in the supine position of the forearm, is twisted upon itself —its anterior surface being directed laterally—as it passes deeply in the hollow of the elbow to be attached to the posterior part of the tuberosity of the radius (Figs. 422, 425, pp. 494, 497). A small bursa (*bicipito-radial*) separates the tendon from the anterior portion of the tuberosity. As the forearm is pronated the tendon of the biceps is untwisted. (2) From the medial and anterior part of the tendon, and partly in continuity with the fleshy fibres of the muscle, a strong membranous band spreads downwards and medially over the hollow of the elbow to join the deep fascia covering the origins of the flexor and pronator muscles of the forearm. This band is called the *bicipital aponeurosis*; its upper part is thickened and can be felt subcutaneously as a crescentic border which crosses in front of the brachial artery and the median nerve.

The biceps conceals the brachialis muscle and the musculo-cutaneous nerve. Its medial border is the guide to the position of the brachial artery and median nerve.

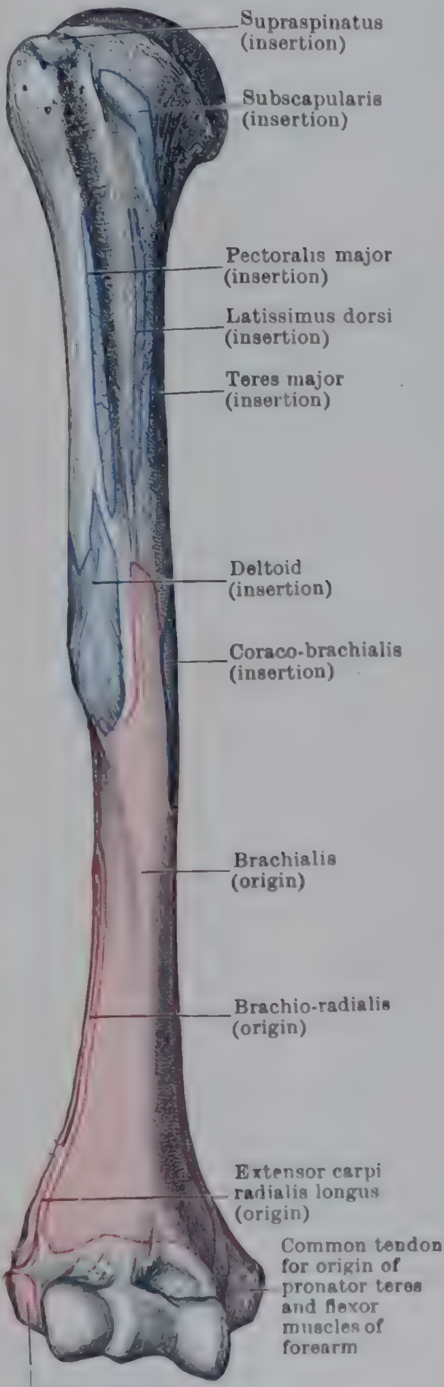

FIG. 415.—MUSCLE-ATTACHMENTS TO FRONT OF RIGHT HUMERUS.

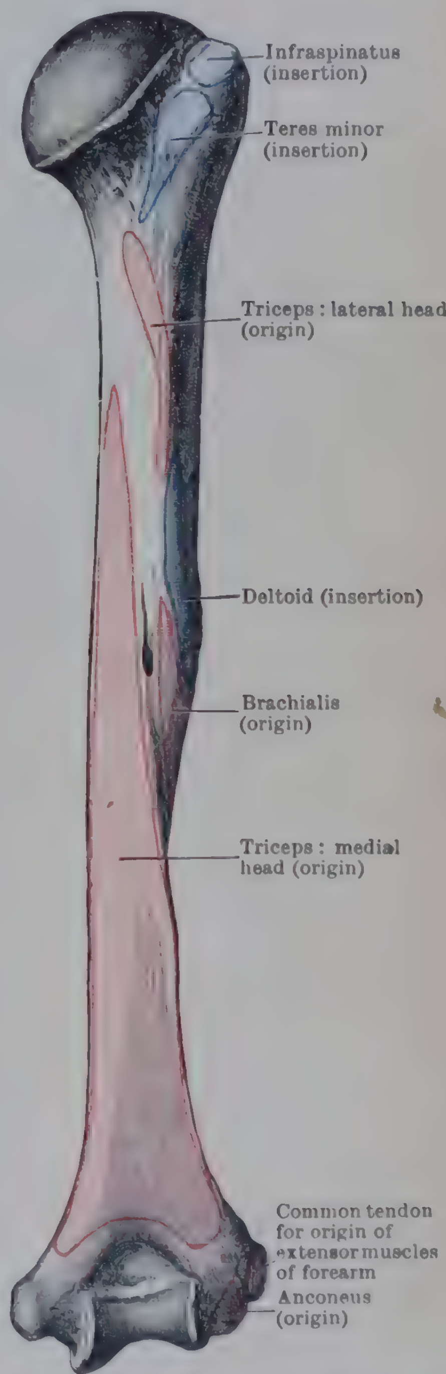

FIG. 416.—MUSCLE-ATTACHMENTS TO BACK OF RIGHT HUMERUS.

A third (or humeral) **head** is a common variation of the biceps (10 per cent); its usual site of origin is at the insertion of the coraco-brachialis, and it is inserted mainly with the bicipital aponeurosis. Two or even three additional heads may be present in the same subject. The long head of the muscle may be absent, or it may take origin from the bicipital groove. The muscle may have an additional insertion into the medial epicondyle of the humerus or into the fascia of the forearm.

Brachialis.—This large muscle **arises** from the distal two-thirds of the front of the shaft of the humerus and from the intermuscular septum on each side

(Fig. 415). Its proximal end clasps the insertion of the deltoid, and it ends distally in a strong tendon which is **inserted** into the lower surface of the coronoid process and into the tuberosity of the ulna (Fig. 425). Some fleshy fibres are inserted into the anterior ligament of the elbow joint; and the lateral part of the muscle, arising from the lateral supracondylar ridge and lateral intermuscular septum, forms a slip, more or less separate, which may be partially fused with the brachio-radialis muscle.

It is concealed for the most part by the biceps in the upper arm. Its distal part lies on the capsular ligament of the elbow joint and in the floor of the intermuscular depression in front of the elbow called the *cubital fossa*.

Triceps.—The triceps is the only muscle on the back of the upper arm. It **arises** by three heads—*lateral* and *medial* from the humerus, and *long* from the scapula. (1) The **long head** springs by a strong tendon from the infraglenoid tubercle of the scapula, and, giving rise to a fleshy belly, it passes between the teres major and teres minor muscles to occupy the middle of the back of the upper arm (Fig. 413, p. 485, and Fig. 417). (2) The **lateral head** arises by tendinous and fleshy fibres from the lateral border of the humerus between the insertion of the teres minor proximally and the spiral groove distally, and it receives additional fibres from the back of the lateral intermuscular septum; it is directed downwards and medially over the spiral groove—concealing the radial nerve, the profunda brachii vessels, and the medial head of the muscle (Figs. 416, 417). (3) The **medial head** arises, by fleshy fibres, from an elongated triangular area on the back of the humerus between the insertion of the teres major and the olecranon fossa, and also extensively from the back of the intermuscular septa—the whole length of the medial septum (Fig. 418), and from the part of the lateral septum below the passage of the radial nerve.

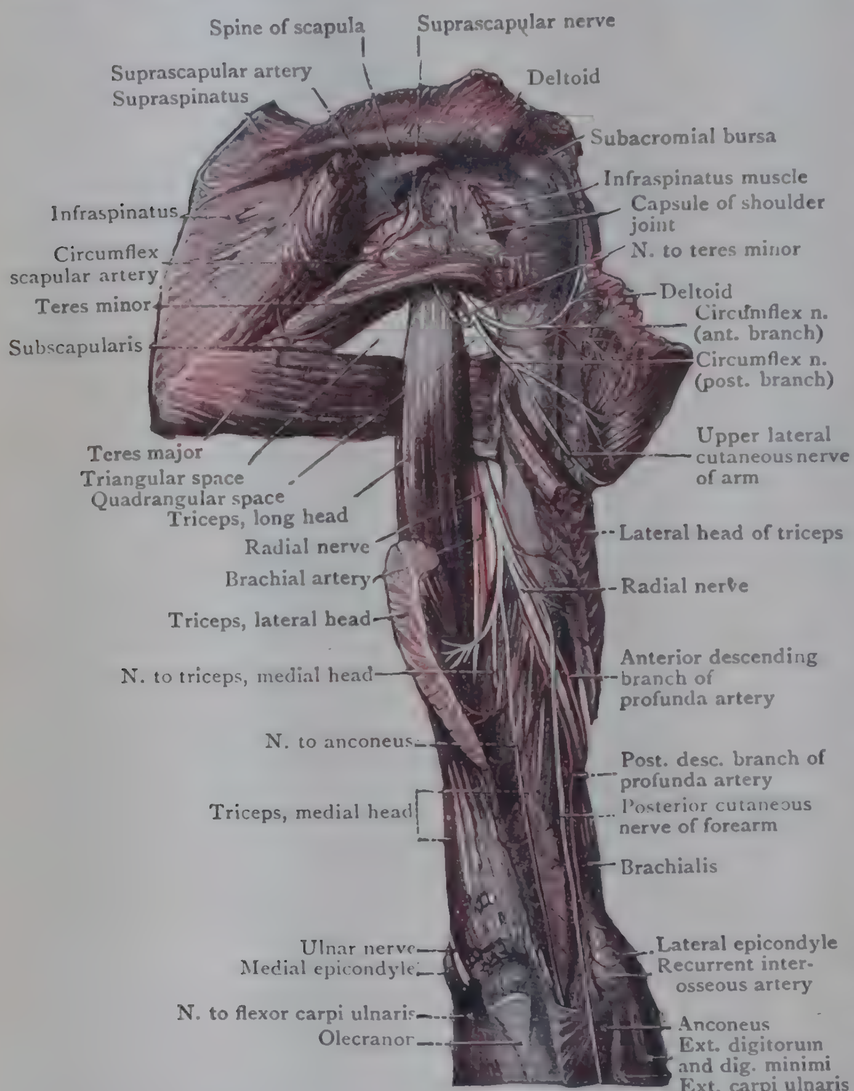

FIG. 417.—DISSECTION OF BACK OF SHOULDER AND UPPER ARM.

The three heads of origin are **inserted**, by a broad, flattened common tendon, into an impression occupying the posterior part of the proximal surface of the olecranon, and into the deep fascia of the forearm on each side of it. Occasionally a small part (**subanconeus**) of the medial head is inserted into the posterior ligament of the elbow joint. The long and lateral heads join the borders of the tendon, and the medial head is attached to its deep surface. A small, thick-walled *bursa of the tendon of the triceps* separates the tendon from the posterior ligament of the elbow joint.

The triceps is superficial in almost its whole extent (Pl. XL, p. 457, Fig. 3)

The long head is concealed at its origin by the deltoid and teres minor muscles; and the medial head is covered by the other two heads and by the tendon of insertion. The upper part of the lateral head intervenes between the circumflex nerve and the

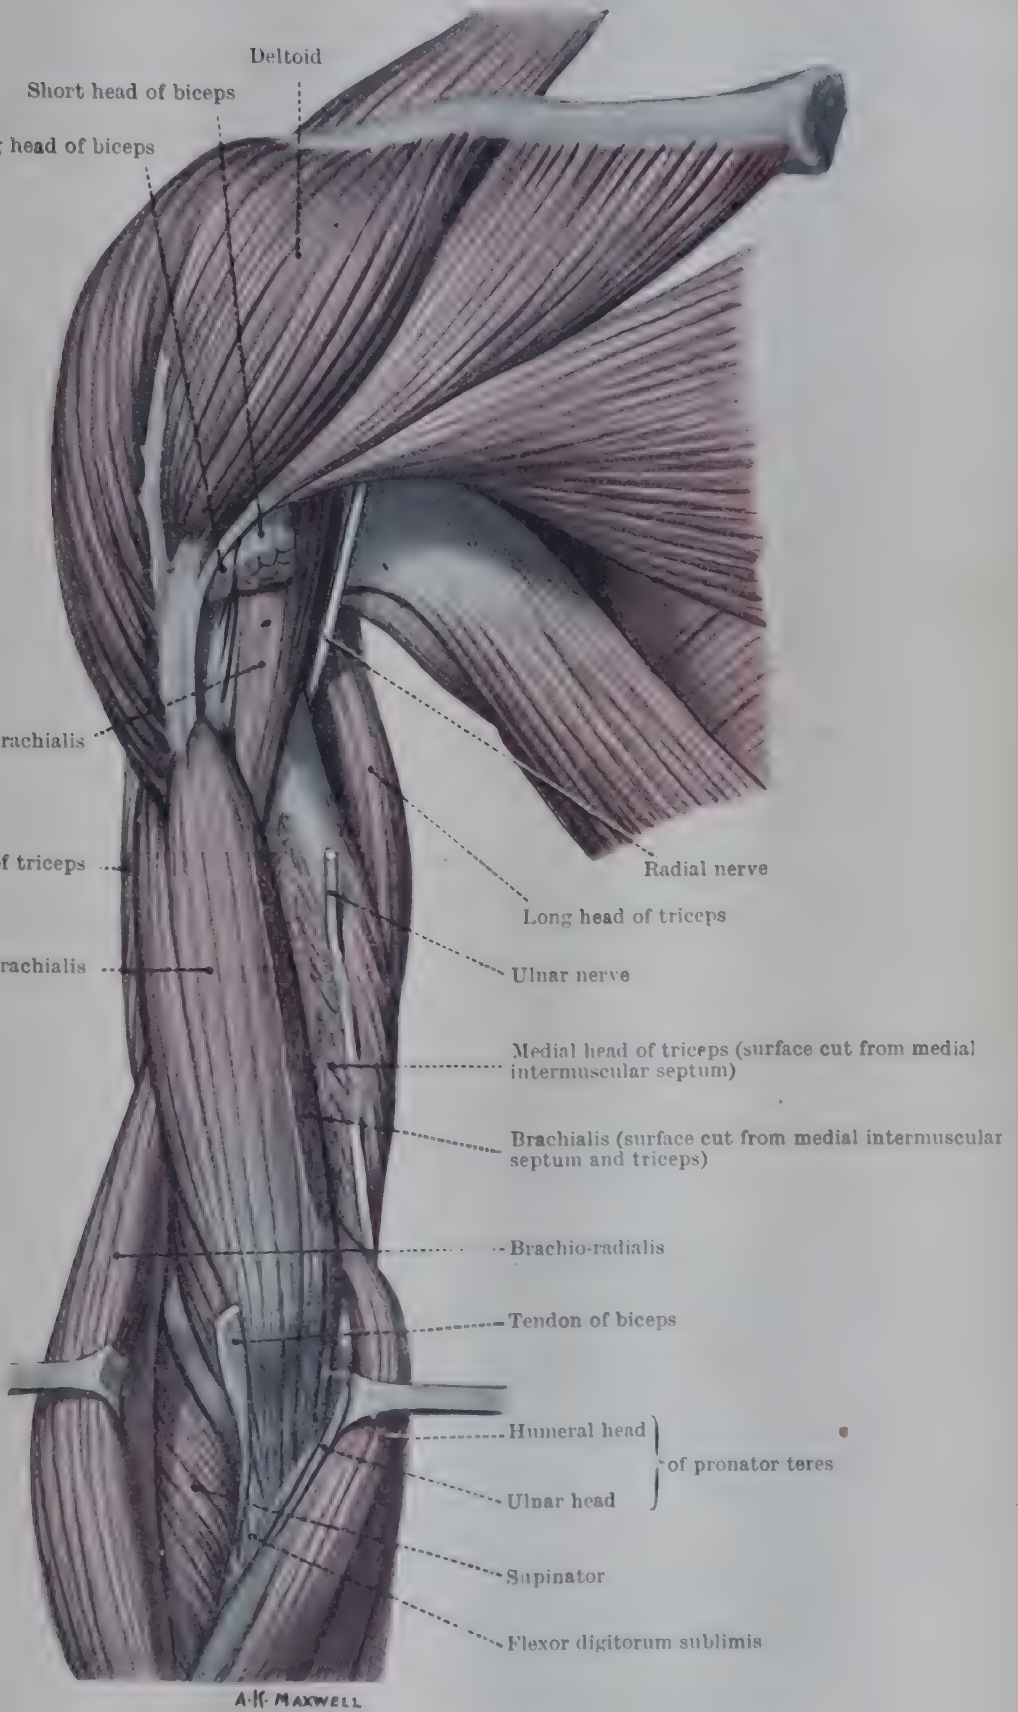

FIG. 418.—DISSECTION OF MUSCLES OF FRONT OF UPPER ARM.
The biceps has been removed to show the brachialis.

shaft of the humerus; and the upper part of the medial head intervenes between the radial nerve and the shaft of the bone.

Anconeus.—The anconeus is a small, triangular muscle which arises from the distal part of the back of the lateral epicondyle of the humerus and from the

posterior ligament of the elbow joint. It partially conceals the posterior ligament, the annular ligament of the radius, and the upper part of the ulna; and it is **inserted**, by fleshy fibres, into a triangular surface on the lateral side of the olecranon and posterior surface of the ulna as far down as the oblique line (Fig. 428, p. 500), and also into the fascia which covers it.

Nerve-Supply.—The nerves of supply to the muscles of the upper arm are derived from cervical nerves, 5, 6, 7, 8, through the lateral and posterior cords of the brachial plexus. The muscles in the anterior (flexor) part of the limb are supplied by branches of the lateral cord, and those on the back (extensor) from the posterior cord through the radial nerve.

The **nerve to the coraco-brachialis** (C. (6), 7) is usually incorporated with the musculo-cutaneous, from which it separates to supply the muscle before the latter nerve pierces it. A branch from the **musculo-cutaneous** (C. 5, 6) divides to supply each head of the biceps, and other branches supply the brachialis. As a rule, the brachialis receives at its lateral border a fine, additional branch (C (5), 6) from the **radial nerve** which may indicate a double origin of the muscle (cf. the biceps muscle of the thigh); but it may be an afferent nerve.

The several heads of the triceps are supplied separately by branches of the **radial nerve**. The lateral head receives fibres from C. (6), 7, 8, the long and medial heads from C. 7, 8. The medial head has a double nerve-supply: one branch has a long extra-muscular course before it enters the distal part of the muscle; the main nerve to the medial head enters its proximal part and is continued through the muscle to terminate in the anconeus.

Actions of Muscles in Movements at the Elbow Joint.—The **biceps** and the **brachialis** act together in flexion of the forearm, and are assisted in that action by the **brachio-radialis** and the **pronator teres**, and in lesser degrees by members of the flexor and extensor groups of the forearm that arise from the medial and lateral epicondyles of the humerus; for example, the radial extensors of the carpus may also assist in flexion at the elbow (see p. 408). It is of clinical interest to note that the biceps may retain its power of flexion when its supinating action is lost (Beevor). The brachialis, a pure flexor, is the most powerful flexor at the elbow, while the biceps acts also in flexion of the shoulder joint, and on the radio-ulnar joints as a supinator. The brachio-radialis is primarily a flexor of the elbow joint. It may also act as a semi-pronator and semi-supinator of the forearm, bringing the limb from a supine or prone position into an intermediate position.

The **triceps**, assisted by the **anconeus**, is the extensor of the elbow joint. It is said that the lateral head of the triceps, mainly with pale fibres, contracts quickly, the medial head with red fibres slowly (p. 409). (See Pl. XLII, Fig. 2, p. 513.)

FASCIÆ OF UPPER ARM

The **superficial fascia** is separated from the back of the olecranon by a subcutaneous *bursa*, and occasionally by others from the epicondyles of the humerus.

The **deep fascia** forms a strong tubular investment for the muscles on the front and back of the humerus. It is continuous above with the deep fascia of the shoulder and axilla, and it is strengthened by fibres derived from the insertions of the pectoralis major, latissimus dorsi, and deltoid muscles. At the elbow it gains attachment to the epicondyles of the humerus and the olecranon; and becomes continuous with the deep fascia of the forearm. It is strengthened also by important bands associated with the insertions of the biceps anteriorly and the triceps posteriorly. About the middle of the upper arm on the medial side, it is perforated by the basilic vein and the medial cutaneous nerve of the forearm.

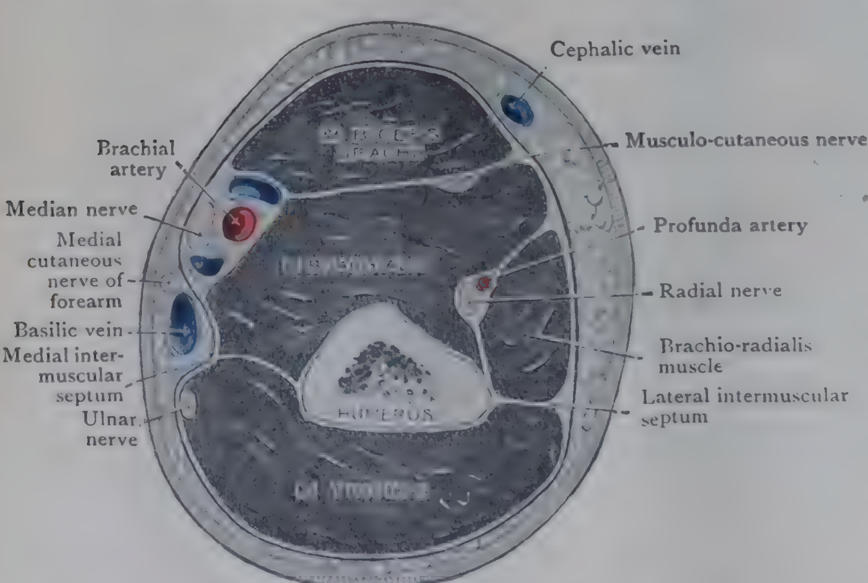

FIG. 419.—SECTION THROUGH DISTAL THIRD OF RIGHT UPPER ARM.

The **intermuscular septa** are processes of the deep fascia attached to the supracondylar ridges of the humerus. The **medial septum** (of the upper arm) is the stronger. It is placed between the brachialis and the medial head of the triceps and gives origin to both (Fig. 418). It extends up to the insertion of the coraco-brachialis (which is often continued into it), and its upper part is pierced by the ulnar nerve and ulnar collateral vessels. The **lateral septum** separates the brachialis and brachio-radialis from the medial and lateral heads of the triceps and gives origin to all of them. It extends up to the insertion of the deltoid, and is pierced by the radial nerve and profunda brachii vessels.

MUSCLES AND FASCIÆ OF FOREARM AND HAND

Muscles on Front and Medial Side of Forearm

The muscles on the front and medial side of the forearm are the pronators and the flexors of the wrist and fingers. In the forearm they are arranged in three strata: (1) A superficial layer of four muscles which radiate from a common tendon attached to the medial epicondyle of the humerus. They are named, from radial to ulnar side, pronator teres, flexor carpi radialis, palmaris longus, and flexor carpi ulnaris. They conceal the muscle which by itself constitutes (2) the middle stratum—the flexor digitorum sublimis. That in turn conceals, for the most part, (3) the deep layer of muscles comprising the flexor digitorum profundus on the ulna, the flexor pollicis longus on the radius, and the pronator quadratus, which is more deeply placed and stretches across the forearm between the distal portions of the radius and ulna.

1. SUPERFICIAL LAYER

Pronator Teres.—The pronator teres, the shortest muscle of this group, has a double **origin.** The **humeral head** forms almost the whole muscle; it arises

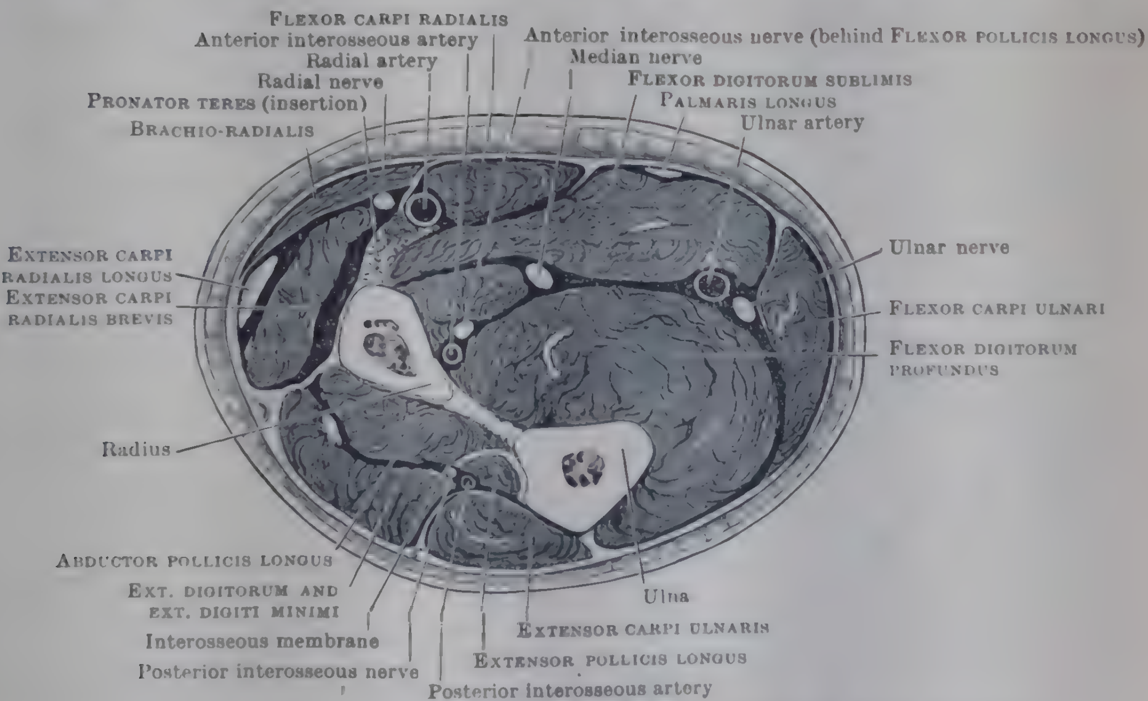

Fig. 420.—Distal Surface of Section through Middle Third of Left Forearm.

by fleshy and tendinous fibres from the lowest part of the medial supracondylar ridge and medial intermuscular septum, from the medial epicondyle of the humerus, from the fascia over it, and from the fascial septum between it and the flexor carpi radialis (Fig. 422). The **ulnar head** is a slender slip that springs from the coronoid process of the ulna and joins the humeral head on its deep surface (Fig. 422). The median nerve passes between the two heads.

The muscle passes downwards and laterally to be **inserted** by a flattened tendon

into an oval impression on the middle of the lateral surface of the shaft of the radius (Figs. 422, 425)—the most superficial humeral fibres passing to the distal part of the tendon of insertion.

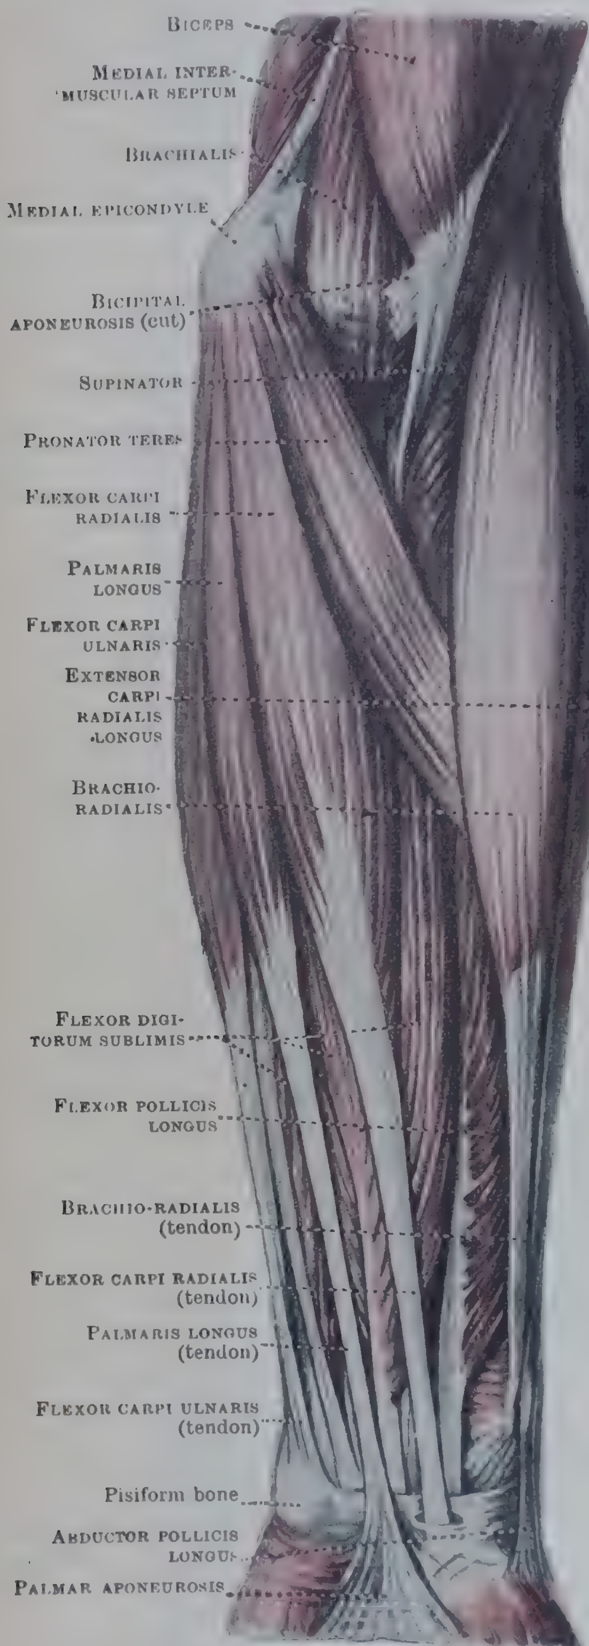

FIG. 421.—SUPERFICIAL MUSCLES OF FRONT OF LEFT FOREARM.

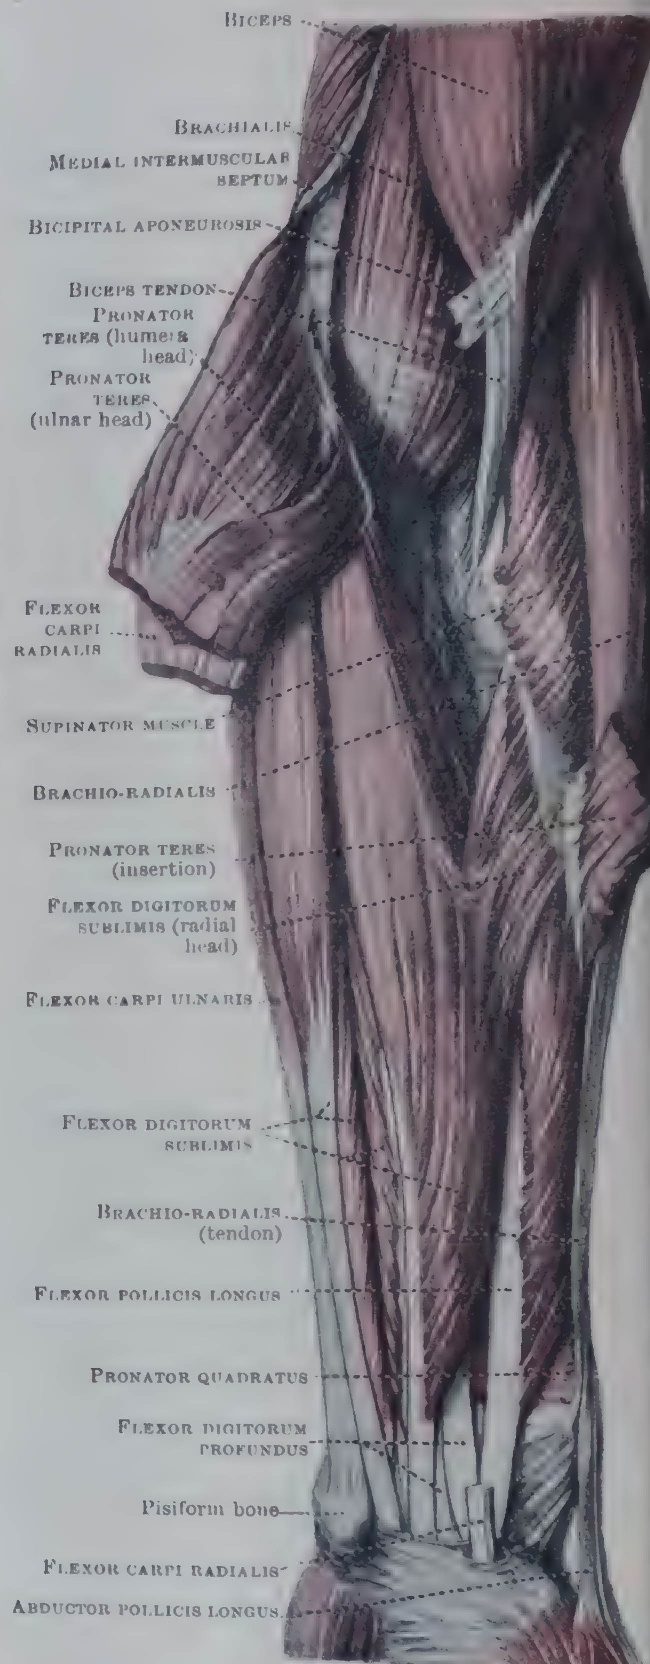

FIG. 422.—DEEPER MUSCLES OF FRONT OF LEFT FOREARM.

The pronator teres forms the medial boundary of the cubital fossa. It is superficially placed except near its insertion, where it is covered by the brachio-radialis muscle and by the radial vessels.

Flexor Carpi Radialis.—The flexor carpi radialis muscle takes **origin** from the medial epicondyle of the humerus by the common tendon, from the fascia

over it, and from the fascial septum on each side. About the middle of the forearm, the fleshy belly gives place to a flattened tendon which becomes more cord-like as it approaches the wrist. Passing into the hand, the tendon enters a special compartment in the lateral border of the flexor retinaculum, which it appears to split into two layers as it lies in the groove on the trapezium surrounded by a synovial sheath. Finally, it is **inserted** into the base of the second metacarpal bone and usually into the base of the third.

The muscle is superficial except near its insertion. Its tendon, in the distal half of the forearm, is an important guide to the radial vessels, which are placed to its radial side. After passing through the flexor retinaculum the tendon is concealed by the origins of the short muscles of the thumb, and is crossed, from medial to lateral side, by the tendon of the flexor pollicis longus. Besides the synovial sheath that envelops the tendon on the trapezium, a synovial *bursa* is placed behind the tendon at its insertion.

Palmaris Longus.—The palmaris longus also **arises** from the medial epicondyle of the humerus by the common flexor tendon, from the deep fascia, and the septum on each side. The fleshy belly is short and fusiform, and it ends at the middle of the forearm in a long, flat tendon. The tendon passes superficial to the flexor retinaculum and is **inserted** (1) into the surface of that band and (2) into the apex of the palmar aponeurosis. A tendinous slip is frequently sent to the short muscles of the thumb and the fascia covering them.

The palmaris longus is the most slender of the muscles of the front of the forearm. In the distal part of the forearm, the median nerve is behind its tendon, at the radial border of the tendons of the flexor digitorum sublimis.

The palmaris longus is the most variable muscle in the body, and is often absent (about 11 per cent). It represents a flexor of the proximal phalanges, but in Man it has become very much reduced, owing to differentiation of the other digital flexors and to finer control of the movements of the fingers by the lumbricals and interossei.

Flexor Carpi Ulnaris.—The flexor carpi ulnaris muscle **arises** by two heads—humeral and ulnar—joined by a tendinous arch, under cover of which the ulnar nerve enters the forearm. (1) The **humeral head** springs from the medial epicondyle of the humerus by the common tendon, from the covering fascia, and from a lateral intermuscular septum. (2) The **ulnar head**, by means of the deep fascia of the forearm, obtains an origin from the medial border of the olecranon and the posterior border of the ulna in its upper three-fifths. The fleshy fibres join a tendon which runs down the anterior border of the distal half of the muscle to be **inserted** into the pisiform bone, and thence, in the form of two ligamentous bands (piso-hamate and piso-metacarpal), into the hook of the hamate bone and the proximal end of the fifth metacarpal bone (Fig. 431, p. 505); a small slip often passes to the flexor retinaculum.

The muscle is superficially placed along the medial border of the forearm. It conceals the ulnar nerve and vessels (which lie on the lateral side of the tendon of insertion). The tendon serves as a guide to these structures in the distal half of the forearm.

M. Epitrochleo-anconeus.—This small muscle is seldom present; it **arises** from the back of the medial epicondyle and is **inserted** into the olecranon; it is usually represented by a band of transverse fibres in the fascia.

2. MIDDLE LAYER

Flexor Digitorum Sublimis.—The flexor digitorum sublimis **arises** by two heads—humero-ulnar and radial—connected by a fibrous bridge that crosses the median nerve and ulnar vessels. (1) The **humero-ulnar head**—the chief origin—springs from the medial epicondyle of the humerus by the common tendon, from adjacent fascial septa, from the medial ligament of the elbow joint, and by a slender slip from the medial border of the coronoid process (Fig. 425). (2) The **radial head** is a thin fibro-muscular sheet that takes origin from the upper two-thirds of the **anterior border** of the radius (Fig. 425).

In the distal third of the forearm the muscle gives rise to four tendons, one for each of the medial four digits. Those for the middle and ring fingers lie side by side and are superficial to the tendons for the index and the little finger. The upper part of the muscle is similarly divisible into two strata, of which the more superficial comprises the radial head and part of the humeral head. The whole of the radial head is usually destined for the middle finger alone, but sometimes also acts on the ring finger. The same arrangement holds at the wrist, where the tendons pass under cover of the flexor retinaculum and are enclosed in a large synovial sheath together with the tendons of the flexor digitorum profundus, which lie behind them.

Under cover of the palmar aponeurosis the tendons diverge. In company with the corresponding tendon of the deep flexor, each enters the fibrous flexor sheath of its own digit. Opposite the proximal phalanx each tendon splits into two parts which pass, with a spiral twist, round the sides of the tendon of the flexor profundus to be **inserted** into the margins of the palmar surface of the middle phalanx. The reversed edges of the two portions of the split tendon are partially

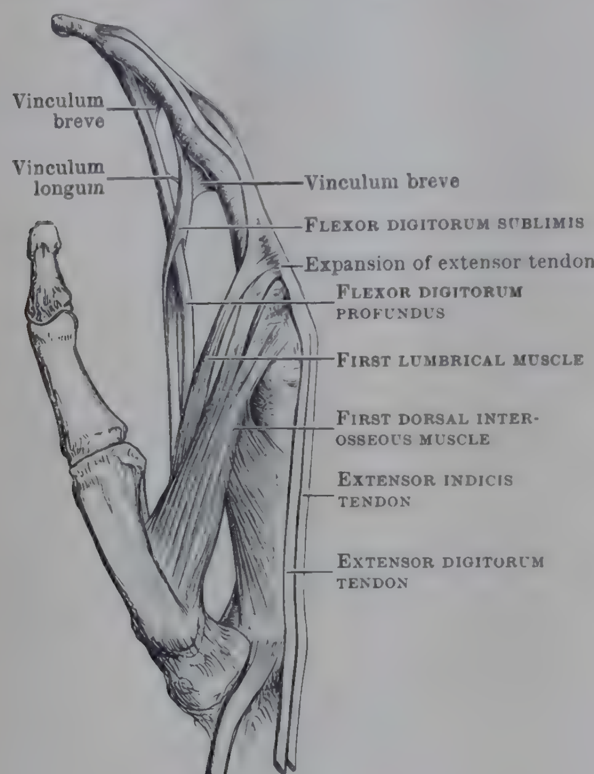

FIG. 423.—THE TENDONS ATTACHED TO THE INDEX FINGER.

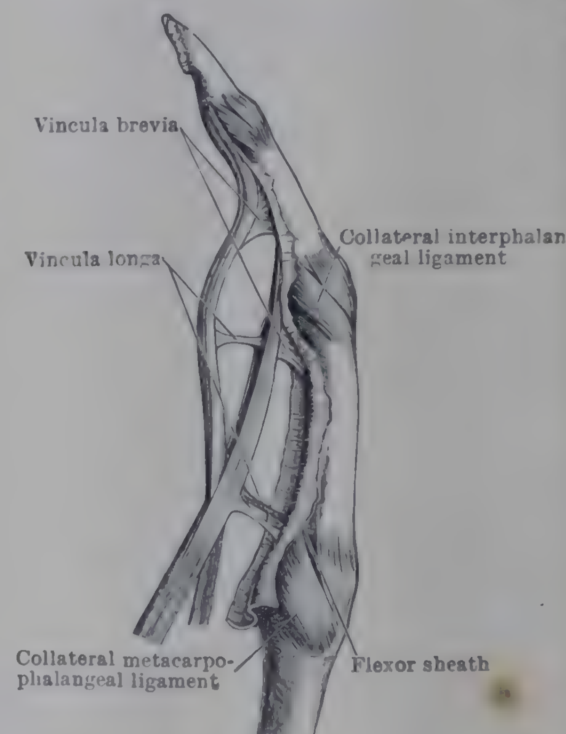

FIG. 424.—FLEXOR TENDONS OF FINGER WITH VINCULA TENDINUM.

reunited by decussating fibres behind the tendon of the flexor profundus: the oblique, tubular passage thus made in the tendon of the flexor sublimis, for the passage of the profundus tendon, is such that it cannot be obliterated by tension.

The **vincula tendinum** form additional attachments of the tendons, to which they also convey small blood-vessels. They are delicate bands of fibrous tissue enveloped in folds of the synovial sheath, and they are known as the **vincula longa** and **brevia**. Each vinculum breve is a triangular band of fibres containing yellow elastic tissue; it occupies the interval between the tendon and the digit for a short distance close to the insertion. It is attached to the front of the interphalangeal joint and the distal part of the proximal phalanx. The vinculum longum is a variable, narrow, double band that extends from the back of the tendon to the proximal part of the palmar surface of the proximal phalanx.

The upper part of the muscle lies deep to the brachio-radialis, pronator teres, flexor carpi radialis, palmaris longus and flexor carpi ulnaris: the lower part lies between the flexor carpi radialis and flexor carpi ulnaris, and is overlapped by the palmaris longus alone. It is crossed by the radial vessels, and it crosses the ulnar vessels and nerve. At the wrist, the tendons are medial to the tendon of flexor pollicis longus and the median nerve. In the hand, the tendons are superficial to the tendons of the flexor digitorum profundus and the lumbrical muscles,

and deep to the superficial palmar arch and the digital branches of the median and ulnar nerves.

3. DEEP LAYER

Flexor Digitorum Profundus.—The flexor digitorum profundus is a large muscle that **arises** from the ulna, the interosseous membrane, and the deep fascia of the forearm, under cover of the flexor digitorum sublimis and the flexor carpi ulnaris. The ulnar origin is the upper two-thirds of the medial and anterior surfaces of the ulna—reaching the medial side of the olecranon and embracing the insertion of the brachialis at the upper end and extending almost to the pronator quadratus below. It arises also, laterally, from the medial half of the interosseous membrane in its middle third (Figs. 425, 426), and medially from the deep fascia which attaches the flexor carpi ulnaris to the posterior border of the ulna.

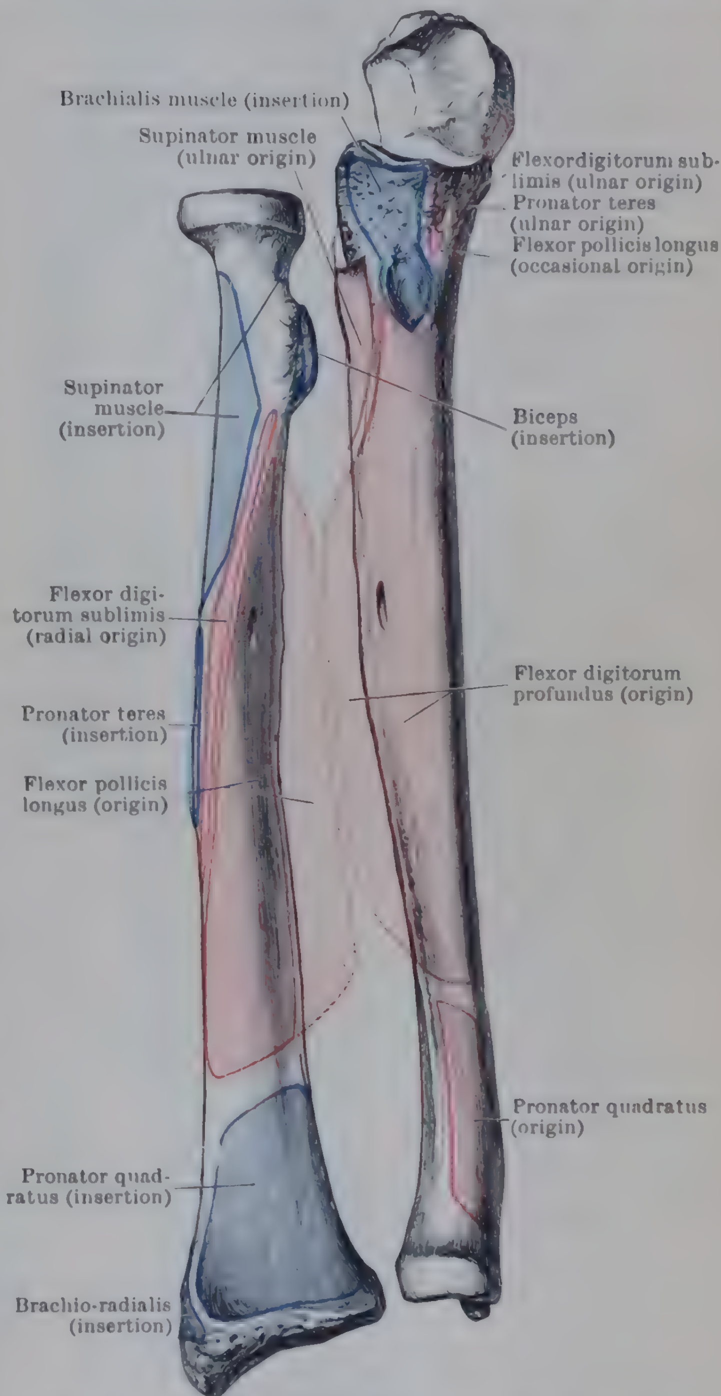

FIG. 425.—MUSCLE-ATTACHMENTS TO FRONT OF RIGHT RADIUS AND ULNA.

The muscle becomes a broad thick tendon which lies behind the tendons of the flexor digitorum sublimis and is enveloped with them in the common flexor synovial sheath; with them it descends behind the flexor retinaculum into the palm, where it divides into separate tendons for **insertion** into the distal phalanges of the four fingers. The tendon for the forefinger is, however, usually separate in its whole length, and it is mainly derived from those fibres which arise from the interosseous membrane.

Each tendon enters the fibrous flexor sheath of the finger, deep to the tendon of the flexor digitorum sublimis, which it pierces opposite the proximal phalanx, and is finally inserted into the base of the distal phalanx. Like the tendons of the flexor sublimis, those of the deep flexor are provided with **vincula**, viz., **vincula brevia** attached to the capsule of the second interphalangeal joint and **vincula longa** connected to the tendons of the flexor digitorum sublimis and their vincula brevia (Fig. 424).

Lumbricals.—The lumbricals are four small, cylindrical muscles associated with the tendons of the flexor digitorum profundus in the palm of the hand. *The lateral two muscles* **arise**, each by a single head, from the radial sides of the tendons of the flexor digitorum profundus destined respectively for the forefinger and middle finger; *the medial two muscles* **arise**, each by two heads, from the

adjacent sides of the tendons between which they lie (viz., the tendons of the middle, ring, and little fingers).

Each lumbrical becomes a slender, flattened tendon which passes obliquely backwards across the lateral side of the corresponding metacarpo-phalangeal joint in front of the deep transverse ligament of the palm and, becoming connected with the expansion of the extensor tendon, it is **inserted** with the tendon of an interosseous muscle into the base of a terminal phalanx. The lumbricals may be increased to six or diminished to two.

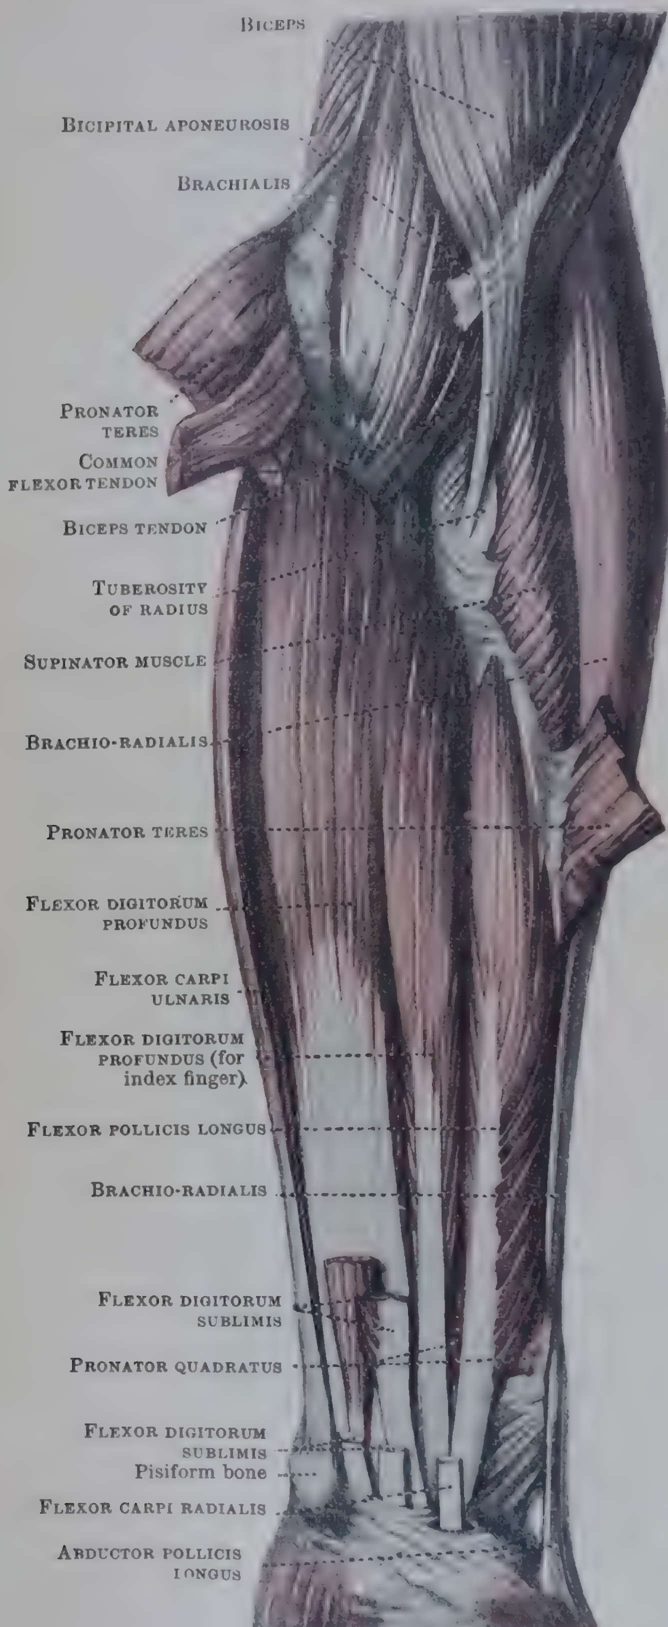

Fig. 426.—Deepest Muscles of Front of Left Forearm.

Flexor Pollicis Longus.—The flexor pollicis longus **arises**, by fleshy fibres, from the anterior surface of the shaft of the radius between the radial tuberosity and the upper border of the pronator quadratus, and also from a corresponding portion of the interosseous membrane. Usually it has a slip that arises in common with the flexor digitorum sublimis from the medial border of the coronoid process or the medial epicondyle, or from both.

Distally, the muscle is placed between the brachio-radialis laterally, the overlapping flexor carpi radialis medially, and the radial vessels anteriorly, while the anterior interosseous nerve and vessels descend on the interosseous membrane between the flexor pollicis longus and flexor digitorum profundus.

The muscle ends above the wrist in a tendon which passes in front of the pronator quadratus into the hand behind the flexor retinaculum, enveloped in a special synovial sheath.

In the hand, the tendon, directed downwards along the medial side of the thenar eminence between the flexor brevis and adductor muscles of the thumb, and between the two sesamoid bones of the metacarpo-phalangeal joint, enters a fibrous sheath to be **inserted** into the base of the distal phalanx of the thumb on its palmar surface.

Pronator Quadratus. — The pronator quadratus is a quadrilateral fleshy muscle that lies deeply in the distal part of the forearm behind the flexor tendons and the radial vessels. It **arises** from the distal fourth of the anterior border and surface of the ulna, and its fibres run transversely to be **inserted** into the distal fourth of the anterior surface of the radius, and into the narrow triangular area on its medial side in front of the attachment of the interosseous membrane (Fig. 235, p. 262).

The pronator quadratus is subject to considerable variation. It frequently consists of two strata separated by the terminal part of the anterior interosseous nerve; it may be increased in size, having an additional origin from radius or ulna, or from both bones, and an insertion into the carpus; it may even be absent. (In most of the lower mammals the two pronators form one muscle.)

Muscles on Back of Forearm

The muscles at the lateral side of the elbow and on the back of the forearm and hand are the supinator muscles of the forearm and the extensors of the wrist and digits, and they are divisible into a **superficial** and a **deep layer**.

The muscles of the **superficial layer**—seven in number and named from radial to ulnar side — are the brachio-radialis, the two radial extensors of the carpus, the extensor digitorum and extensor digiti minimi, the extensor carpi ulnaris, and the anconeus. With the exception of the brachio-radialis, extensor carpi radialis longus and the anconeus, they share a common tendon of origin, which is attached to the front and lateral border of the lateral epicondyle of the humerus (Fig. 415, p. 489).

Five muscles make up the **deep layer**: one —the supinator — extends between the proximal parts of the ulna and radius; the others are the special extensors of the thumb and forefinger, viz., the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis. They cover the posterior surface of the bones of the forearm and the interosseous membrane, and they are wholly concealed by the superficial muscles, with the exception of the abductor pollicis longus and the extensor pollicis brevis, which emerge between the radial extensors of the carpus and the extensor digitorum and become superficial in the distal part of the forearm.

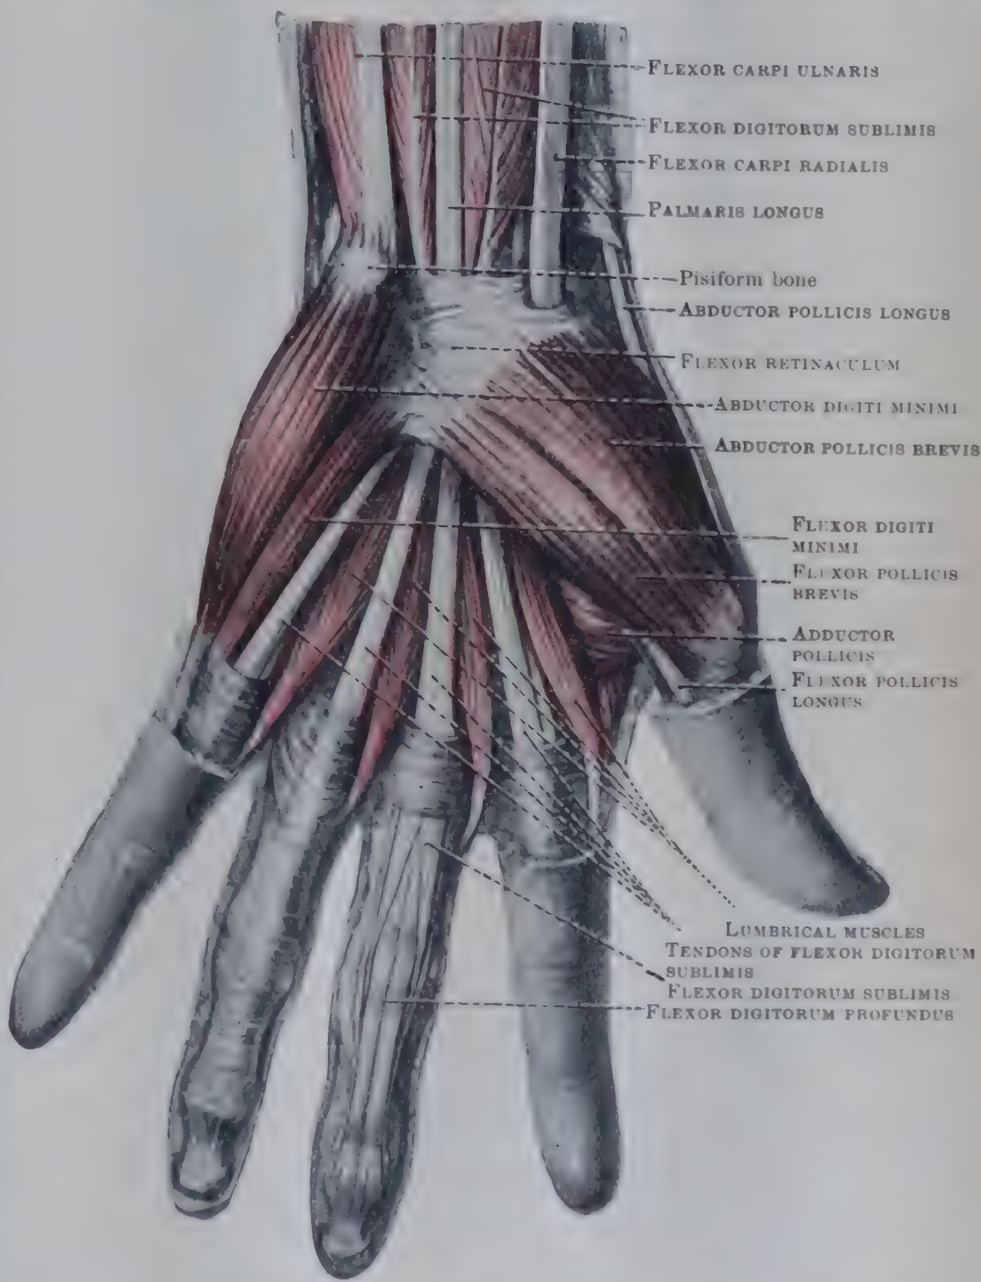

FIG. 427.—SUPERFICIAL MUSCLES AND TENDONS IN PALM OF LEFT HAND.

1. SUPERFICIAL LAYER

Brachio-Radialis.—The brachio-radialis **arises**, by fleshy fibres, from the proximal two-thirds of the front of the lateral supracondylar ridge of the humerus and the adjoining part of the lateral intermuscular septum—the radial nerve and anastomosing vessels intervening between it and the brachialis. Descending along the lateral border of the forearm, the muscle bounds the cubital fossa laterally, and ends about the middle of the forearm in a narrow flat tendon which is **inserted**, under cover of the tendons of the abductor pollicis longus and extensor pollicis brevis, into the lateral side of the lower end of the radius (Figs. 425, 428).

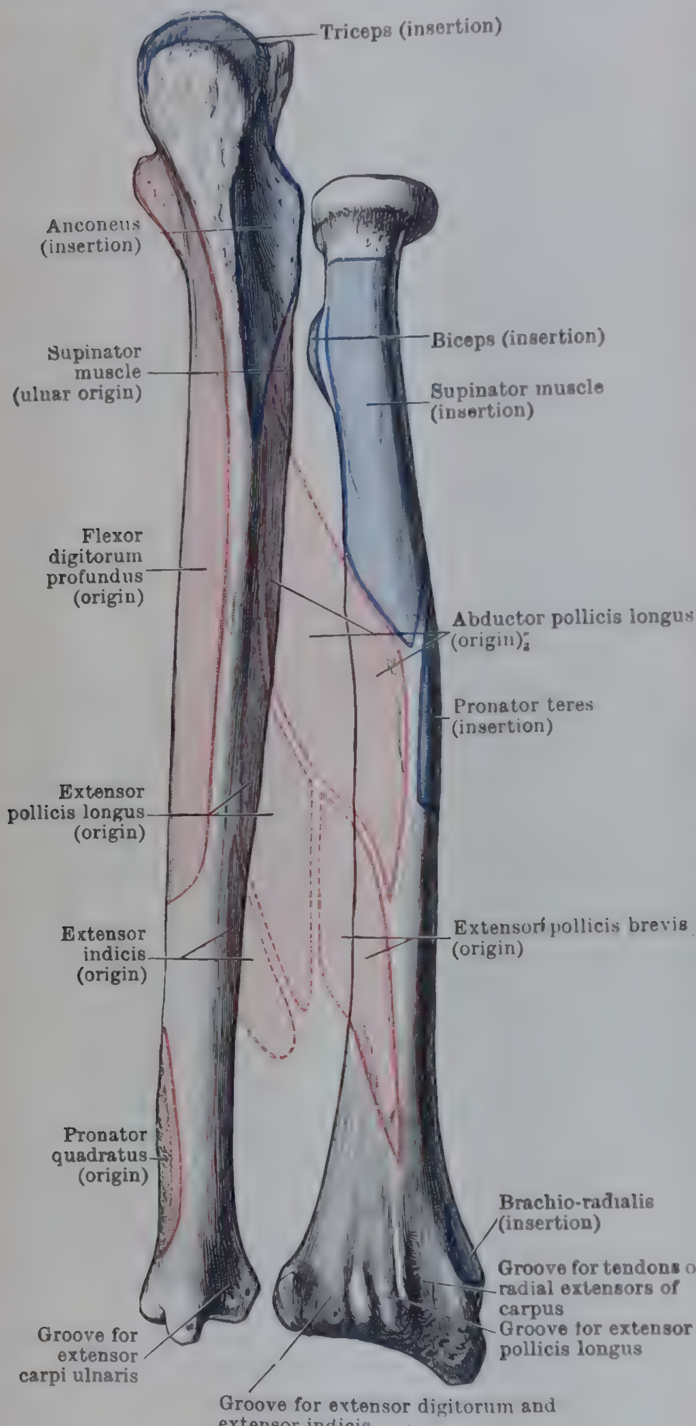

Fig. 428.—Muscle-Attachments to Back of Right Radius and Ulna.

Extensor Carpi Radialis Longus.—The extensor carpi radialis longus **arises**, by fleshy fibres, from the distal third of the front of the lateral supracondylar ridge of the humerus and from the adjoining part of the lateral intermuscular septum (Figs. 415 and 429).

In its upper part, the muscle lies close to the lateral side of the elbow joint, overlapped by the brachio-radialis and overlapping the extensor carpi radialis brevis, between which it descends into the forearm. About the middle of the forearm it ends in a flat tendon which, throughout, is closely applied to the lateral side of the extensor carpi radialis brevis; and as the two tendons descend they are crossed obliquely by the abductor pollicis longus and extensor pollicis brevis. Still side by side they pass under cover of the extensor retinaculum, where they are enclosed in a single synovial sheath and groove the distal end of the radius, and there are crossed obliquely by extensor pollicis longus; finally, the long extensor is **inserted** into the dorsal surface of the base of the second metacarpal bone on its radial side. A small *bursa* may be found under the tendon close to its insertion.

Extensor Carpi Radialis Brevis.—The extensor carpi radialis brevis **arises** from the common tendon, from the lateral ligament of the elbow joint, from the covering fascia, and from the intermuscular septum on each side. Accompanied by its long companion (the two are represented by one muscle in the lower mammals), it descends as just described, to be **inserted**, by a tendon, into the base of the third metacarpal bone—a small *bursa* lying between the tendon and the styloid process of the metacarpal bone. The tendons of the long and short radial

extensors of the wrist may split and both be attached to the second and third (Fig. 434) and sometimes the fourth metacarpal bones.

Extensor Digitorum.—The extensor digitorum lies between the radial extensors

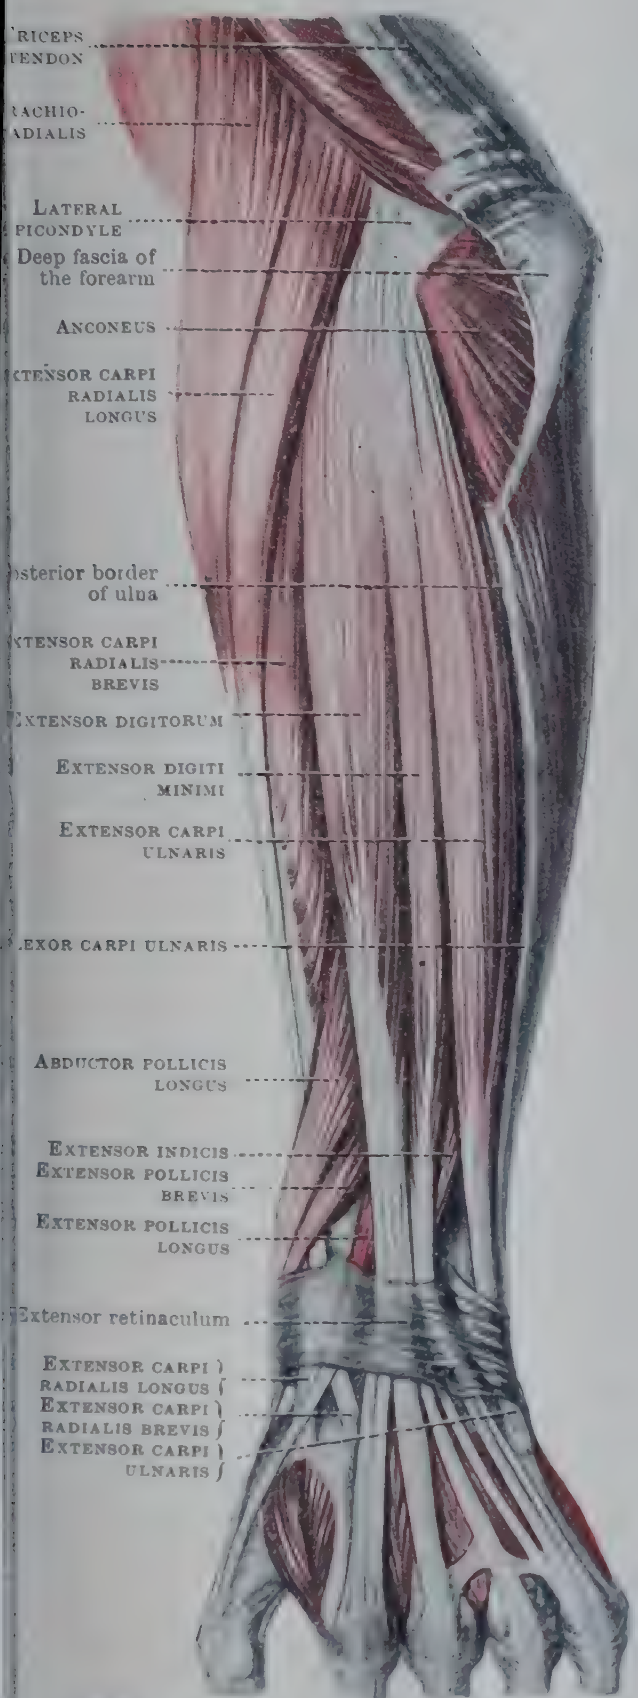

FIG. 429.—SUPERFICIAL MUSCLES ON DORSUM OF LEFT FOREARM.

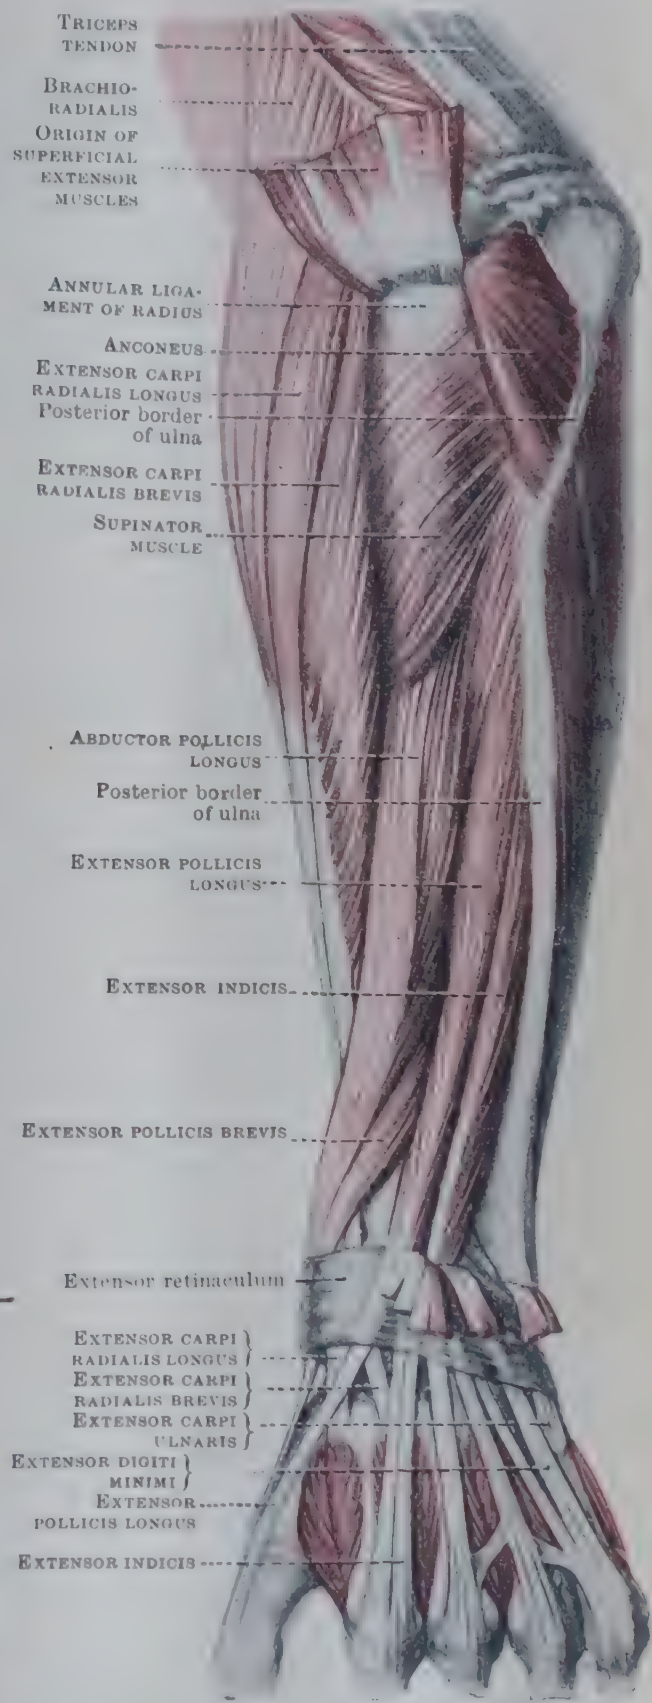

FIG. 430.—DEEP MUSCLES ON DORSUM OF LEFT FOREARM.

of the carpus and the extensor digiti minimi (Fig. 429). It **arises** from the common tendon, from the fascia over it, and from the intermuscular septa at its sides. Extending along the back of the forearm, it ends above the wrist in four tendons of which the most lateral often has a separate fleshy belly. After passing deep to

the extensor retinaculum, surrounded by a synovial sheath in the same compartment as the extensor indicis, the tendons separate on the back of the hand, where they are joined together in a variable manner by obliquely placed bands. One band passes downwards and laterally, and connects together the third and second tendons; another band, broader and shorter, passes downwards and medially, and joins the third to the fourth tendon. A band sometimes passes downwards and medially from the first to the second tendon; and, frequently, the tendon for the little finger is joined to the tendon for the ring finger, and separates from it only a short distance above the distal end of the metacarpal bone.

The tendons are **inserted** in the following manner: On the finger each tendon spreads out to form a membranous expansion over the knuckle and on the dorsum of the proximal phalanx. The border of the tendon is indefinite over the metacarpo-phalangeal joint, the dorsal ligament of which it replaces. On the back of the proximal phalanx the tendon receives at its sides the tendons of the interosseous and lumbrical muscles. At the distal end of the proximal phalanx it appears to split into ill-defined middle and collateral slips which pass over the back of the first interphalangeal joint, where they replace the dorsal ligament. The middle slip, which is directly continuous with the extensor tendon itself, is inserted into the dorsum of the base of the middle phalanx. The two collateral pieces are continuous with the tendons of the lumbrical muscles and the interossei; they all become united to form a membranous tendon on the back of the middle phalanx, which, after passing over the second interphalangeal joint, is inserted into the base of the distal phalanx.

Extensor Digiti Minimi.—The extensor digiti minimi **arises**, like the preceding muscle, from the common tendon, the fascia over it, and from intermuscular septa. It descends as a narrow fleshy slip between the extensor digitorum and the extensor carpi ulnaris, and ends in a tendon which occupies a groove between the radius and ulna in a special compartment of the extensor retinaculum and is enveloped in a long synovial sheath. On the back of the hand, the tendon is split into two parts, of which the more lateral is joined by the most medial tendon of the extensor digitorum, and both are **inserted** into the expansion of the extensor tendon on the back of the proximal phalanx of the little finger.

Extensor Carpi Ulnaris.—The extensor carpi ulnaris has a double **origin**: (1) from the lateral epicondyle of the humerus by the common tendon, from the fascia over it, and from the intermuscular septa; and (2), through the medium of the deep fascia, from the posterior border of the ulna in its middle two-fourths.

In the forearm it lies on the medial part of the posterior surface of the ulna; and it ends in a tendon which is enclosed in a synovial sheath and traverses a groove on the back of the lower end of the ulna in a special compartment of the extensor retinaculum, and is **inserted** into the medial side of the base of the fifth metacarpal bone (Fig. 434, p. 508).

2. DEEP LAYER

Supinator.—The supinator muscle is the highest of the deep layer, and is almost wholly concealed by the superficial muscles. It has a complex **origin**—(1) from the lateral epicondyle of the humerus; (2) from the lateral ligament of the elbow joint and the annular ligament of the radius; and (3) from the supinator crest and fossa of the ulna (Fig. 425, p. 497).

From that origin the muscle, spreading laterally and downwards behind the upper third of the radius, which it envelops almost completely, is **inserted** into its lateral surface which, in the upper third, encroaches on both the back and front of the bone. The attachment extends as far forwards as the tuberosity of the radius, as far upwards as the neck, and as far downwards as the oblique part of the anterior border and the insertion of the pronator teres (Figs. 425, p. 497, and 428).

The muscle is divisible into *superficial* and *deep layers*, with humeral and ulnar origins, between which the posterior interosseous nerve passes in its course to the back of the forearm.

Abductor Pollicis Longus.—The abductor pollicis longus **arises**, by fleshy fibres, distal to the supinator muscle, from the uppermost of the narrow impressions on the lateral half of the posterior surface of the ulna; from the middle third of the posterior surface of the radius, and from the intervening portion of the interosseous membrane (Fig. 428).

The muscle passes obliquely downwards and laterally, and it emerges between the radial extensors of the wrist and the extensor of the fingers to become superficial in the distal part of the forearm. With the extensor pollicis brevis tendon closely applied to its medial side, the tendon crosses extensor carpi radialis brevis and longus and covers the insertion of the brachio-radialis before passing through the most lateral compartment of the extensor retinaculum in a synovial sheath which communicates with that of extensor pollicis brevis. Then, covering the styloid process of the radius and the lateral ligament of the wrist joint, but separated from the ligament by the radial artery, it is **inserted** (sometimes by two tendons) into the lateral side of the base of the first metacarpal bone (Fig. 431). Close to its insertion, a tendinous slip passes from it to the abductor pollicis brevis and the fascia over the thenar eminence, and frequently another is attached to the trapezium.

Extensor Pollicis Brevis.—The extensor pollicis brevis, an essentially human muscle, is a specialized portion of the abductor longus. It **arises** from a rhomboid impression on the posterior surface of the radius, and from the interosseous membrane, distal to the abductor pollicis longus (Fig. 428). It is closely adherent to that muscle, and accompanies it, deep to the extensor retinaculum and over the radial artery, to the thumb. Its tendon is then continued along the back of the first metacarpal bone to be **inserted** into the dorsal surface of the base of the proximal phalanx of the thumb. Before reaching its insertion the tendon helps to form the capsule of the metacarpo-phalangeal joint.

Extensor Pollicis Longus.—The extensor pollicis longus **arises** from the lateral part of the posterior surface of the ulna in its middle third, and from the interosseous membrane distal to the abductor pollicis longus and overlapping the extensor pollicis brevis. Its tendon is enclosed in a synovial sheath and grooves the posterior surface of the radius as it descends through a special compartment of the extensor retinaculum (Figs. 428, 430). Extending obliquely across the back of the hand, the tendon crosses the tendons of the radial extensors of the carpus and the radial artery, helps to form the capsule of the first metacarpo-phalangeal joint, and is **inserted** into the dorsal surface of the base of the distal phalanx of the thumb.

At the wrist, the tendons of the muscles of the thumb—the abductor pollicis longus and extensor pollicis brevis laterally, and the extensor pollicis longus medially—bound a hollow (the "anatomical snuff-box") seen best when the thumb is extended. In this situation the pulsation of the radial artery can readily be felt.

Extensor Indicis.—The extensor indicis **arises**, distal to the extensor pollicis longus, from the lowest impression on the posterior surface of the ulna, and sometimes also from the interosseous membrane (Fig. 428). Its tendon passes through a compartment of the extensor retinaculum enclosed with the tendons of the extensor digitorum in a common synovial sheath. On the back of the hand the tendon lies on the ulnar side of the tendon of the extensor digitorum destined for the forefinger; and it is **inserted** into the membranous expansion of that tendon on the back of the proximal phalanx.

Nerve-Supply.—The muscles on the front (flexor surface) of the forearm are supplied, through the **median** and **ulnar nerves**, by the anterior—*i.e.*, lateral and medial—cords of the brachial plexus; and those on the back (extensor surface) by the posterior cord through the **radial nerve** and its **posterior interosseous** branch. The pronator teres (C. 6), flexor carpi radialis (C. 6), palmaris longus and flexor digitorum sublimis (C. 7, 8, T. 1) are all supplied by direct branches from the median nerve; the flexor pollicis longus and the pronator quadratus by its anterior interosseous branch (C. (7), 8, T. 1), and the flexor carpi ulnaris by the ulnar nerve (C. 8, T. 1). The flexor digitorum profundus and the associated lumbricals are supplied in a corresponding manner by nerves derived from the two main sources. The lateral part of the deep flexor is supplied by the interosseous branch of the median nerve (C. (7), 8, T. 1) and the lateral two lumbricals by twigs from digital branches of the median nerve (C. (7), 8, T. 1) in the hand; the

medial part of the deep flexor is supplied by the ulnar nerve (C. 8, T. 1) and the medial two lumbricals by twigs from the deep branch of the same nerve in the hand. The branches to the brachio-radialis (C. (5), 6) and the extensor carpi radialis longus (C. (5), 6, 7, (8)) are given off by the radial nerve itself above the elbow; the extensor carpi radialis brevis (C. (5), 6, 7, (8)) and the supinator (C. (5), 6) are supplied by branches of the posterior interosseous nerve before it pierces the supinator; all the remaining muscles are supplied by the posterior interosseous nerve (C. (6), 7, (8)) after it has pierced the supinator.

Actions of Muscles in Movements at the Radio-Ulnar Joints: Pronation and Supination.—The movement of pronation is performed by the **pronator** muscles—**teres** and **quadratus**—and of supination by the **biceps** and the **supinator**; other muscles which pass obliquely across the forearm from the ulnar to the radial side take part in these actions when they are performed against resistance—the **flexor carpi radialis** and **palmaris longus** assisting in pronation and the **extensors of the thumb** in supination. Both sets of muscles act at best advantage when the elbow is flexed to a right angle. The brachio-radialis also may act as a semi-pronator and semi-supinator as already mentioned. See also p. 492.

Actions of Muscles in Movements at the Wrist Joint.—The movements at the wrist joint are flexion and extension, abduction and adduction of the hand. The **radial and ulnar flexors and extensors of the carpus** are the muscles primarily concerned in these movements—abduction and adduction being performed by the combined action of the flexors and extensors of the radial and ulnar sides respectively. Other muscles of the forearm also assist in those actions.

The **flexores carpi radialis** and **ulnaris** act primarily to flex the wrist, assisted by the **palmaris longus** and by the **flexors of the fingers** (**sublimis** and **profundus**) when the movement is effected against strong resistance (Pl. XLII, Fig. 2, p. 513). The **abductor pollicis longus** also is a flexor of the wrist, being capable of performing this movement when the other flexors are paralysed.

The muscles primarily concerned in extension at the wrist are the **radial extensors of the carpus** (**longus** and **brevis**) and the **extensor carpi ulnaris**. The extensors of the fingers also act at the wrist joint.

Abduction of the hand is produced by the co-operation of the **flexor carpi radialis** with the **radial extensors of the carpus**, assisted by the **long abductor** and the **extensors of the thumb.** Adduction of the hand is similarly produced by the co-operation of the **flexor** and the **extensor carpi ulnaris**.

The flexor and extensor muscles of the carpus have, in addition to the actions just detailed, important synergic actions at the wrist joint. The flexor carpi radialis and flexor carpi ulnaris together steady the wrist during the extension of the fingers, *i.e.*, they are synergic muscles for the extensors of the digits. The flexor carpi ulnaris also steadies the pisiform bone during contractions of the abductor digiti minimi. The radial extensors of the carpus in association with the extensor carpi ulnaris are similarly synergic muscles for flexion of the fingers, as they counteract the effect which the digital flexors would otherwise produce at the wrist (cf. p. 407).

SHORT MUSCLES OF HAND

The short or intrinsic muscles of the hand (in addition to the lumbrical muscles, and a subcutaneous muscle called the palmaris brevis) are the four short muscles of the thumb (three of which form the thenar eminence), the three short muscles of the little finger, which form the hypothenar eminence, and the interosseous muscles, which are placed between the metacarpal bones.

Short Muscles of Thumb

The short muscles of the thumb are the abductor pollicis brevis, the opponens pollicis, and the flexor pollicis brevis, which form the thenar eminence, and the adductor pollicis, which lies deeply in the palm of the hand.

Abductor Pollicis Brevis.—The abductor pollicis brevis **arises**, by fleshy fibres, mainly from the anterior surface of the flexor retinaculum but also from the tubercle of the scaphoid bone, the crest of the trapezium and from tendinous slips derived from the insertions of the palmaris longus and abductor pollicis longus muscles (Fig. 427, p. 499). Strap-like in form and superficial in position, it is **inserted** by a short tendon into the radial side of the proximal phalanx of the

thumb at its upper end, and into the lateral border of the tendon of the extensor pollicis longus muscle.

Opponens Pollicis.—The opponens pollicis is partially concealed by the abductor, and is united with the flexor pollicis brevis, which lies along its medial side. It **arises**, by fleshy and tendinous fibres, from the anterior surface of the flexor retinaculum and from the crest on the trapezium; and it is **inserted** into the whole length of the radial border and the radial half of the anterior surface of the first metacarpal bone.

Flexor Pollicis Brevis.—The flexor pollicis brevis, also partly concealed by the abductor, **arises** by fleshy and tendinous fibres from the distal border of the flexor retinaculum, and sometimes from the crest of the trapezium. It is **inserted** into the radial side of the base of the proximal phalanx of the thumb, medial to and

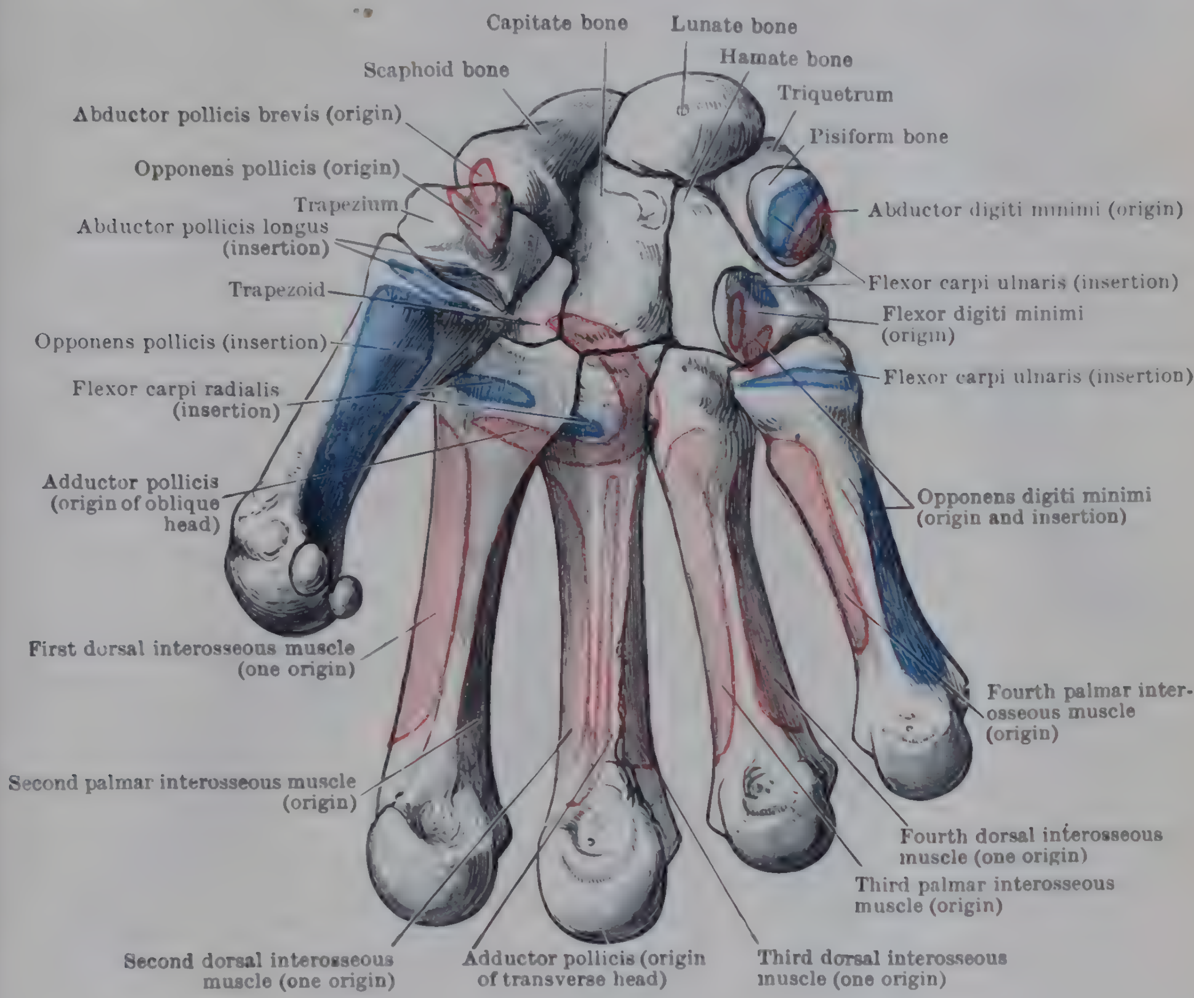

Fig. 431.—Muscle-Attachments to Front of Carpus and Metacarpus.

slightly overlapped by the insertion of abductor pollicis brevis. A *sesamoid bone* is present in the tendon of insertion.

Adductor Pollicis.—The adductor pollicis has two heads—oblique and transverse—separated at their origins by a gap that transmits the radial artery, but **inserted** together by a tendon (in which a sesamoid bone is developed) into the ulnar side of the base of the proximal phalanx of the thumb. Both heads lie deep in the palm behind the long flexor tendons.

The *oblique head* **arises** by fleshy fibres from the sheath of the tendon of the flexor carpi radialis, from the front of the trapezium, trapezoid and capitate bones and the bases of the second, third, and fourth metacarpal bones, and from the palmar ligaments that connect these bones. Usually a slip separates from its upper border, and, passing deep to the tendon of the flexor pollicis longus, is inserted with the flexor brevis into the radial side of the proximal phalanx. The *transverse head* **arises** from the longitudinal ridge on the front of the shaft of the third metacarpal bone, and its fibres converge on the common tendon of insertion.

Short Muscles of Little Finger

The short muscles of the little finger are the abductor, opponens, and flexor digiti minimi.

Abductor Digiti Minimi.—The abductor digiti minimi, the most superficial,

Fig. 432.—Palmar Muscles of Right Hand.

arises from the pisiform bone and from the tendon of the flexor carpi ulnaris and its ligamentous continuations (Figs. 427, 431). It is **inserted** by tendon into the medial side of the base of the proximal phalanx of the little finger—sending a slip to the extensor tendon.

Opponens Digiti Minimi.—The opponens digiti minimi **arises** under cover of the abductor by tendinous fibres from the flexor retinaculum and from the hook

of the hamate bone. It is **inserted** into the medial margin and medial half of the palmar surface of the fifth metacarpal bone in its distal three-fourths (Fig. 431).

Flexor Digiti Minimi. — The flexor digiti minimi may be absent or incorporated with either the opponens or the abductor digiti minimi. It **arises**, by tendinous fibres, from the flexor retinaculum and from the hook of the hamate bone (Figs. 427, 431), and it is **inserted** along with the abductor.

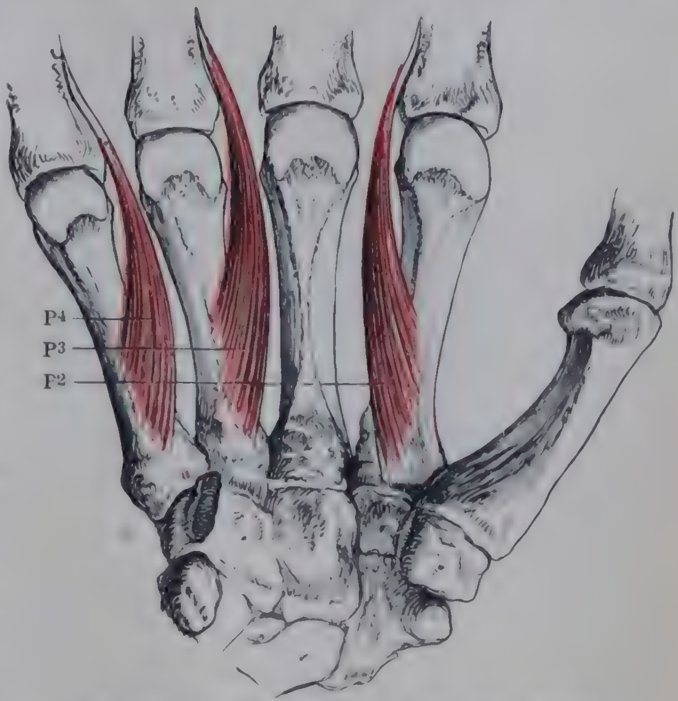

FIG. 433.—THE 2ND, 3RD, AND 4TH PALMAR INTEROSSEOUS MUSCLES (Right Side).

See Fig. 435, p. 509, for 1st palmar interosseous muscle.

Interosseous Muscles

The interosseous muscles of the hand, placed between the metacarpal bones, are arranged in two sets—palmar and dorsal—which are respectively adductors and abductors to or from a line through the middle finger.

Palmar Interossei.—The palmar interossei are four in number. Each **arises** by a single head from the metacarpal bone of the digit which it moves. The muscular fibres of the second, third, and fourth converge on tendons that begin a little proximal to the metacarpo-phalangeal joint. Each tendon passes behind the deep transverse ligament of the palm and is **inserted** partly into the base of the proximal phalanx and partly into the extensor tendon (the continuation of the extensor expansion to the base of the distal phalanx being formed chiefly by the tendons of the interossei and lumbricals, cf. p. 498). The **second** arises from the ulnar side of the shaft of the second metacarpal bone, the **third** and **fourth** from the radial sides of the shafts of the fourth and fifth metacarpal bones respectively, and are inserted into the corresponding sides of the fingers (Figs. 431, 432). Therefore, if the fingers are outspread and the middle finger is held, each muscle adducts its finger to the middle finger. That digit does not require palmar adductors because, when the index and ring fingers are held apart, the middle finger is drawn to one or the other by the alternate action of its two dorsal interossei muscles.

The **first** palmar interosseous muscle ("deep head of flexor pollicis brevis") is a slender slip that springs from the ulnar side of the base of the first metacarpal bone, passes deeply between the first dorsal interosseous muscle and the oblique head of the adductor pollicis to be inserted into the ulnar side of the base of the proximal phalanx of the thumb, in common with the adductor muscle (Fig. 435).

Dorsal Interossei.—The dorsal interossei are larger than the palmar group, and also are four in number. Each **arises** by two heads from the adjacent sides of its two metacarpal bones (Figs. 431, 434, 435). Their heads converge in a bipennate manner on four membranous tendons which descend to the four fingers to be **inserted** in the same way as the tendons of the palmar muscles—the medial three tendons passing behind the deep transverse ligaments of the palm. The insertion of the *first* dorsal interosseous muscle is on the radial side of the index finger; the *second* muscle passes to the radial side of the middle finger; the *third* muscle to the ulnar side of the same finger; and the *fourth* muscle to the ulnar side of the ring finger.

The first dorsal interosseous muscle is larger than the others, and there is a wider interval between its heads, through which the radial artery passes into the palm, while a perforating branch from the deep palmar arch runs between the two heads of each of the other muscles. Between the tendons of the interossei and the joints small *intermetacarpo-phalangeal bursæ* are interposed. The interosseous muscles of the hand are occasionally arranged like those of the foot.

Nerve-Supply.—The intrinsic muscles of the hand, like the muscles on the flexor surface of the forearm, are all supplied by nerves derived from the anterior (*i.e.*, lateral and medial) cords of the brachial plexus through the **median and ulnar nerves**. The ulnar nerve, however, takes a much greater part in the supply of the muscles of the hand—its deep branch extending across the palm to supply all the muscles on the ulnar side of the line of the tendon of the flexor pollicis longus (with the exception of the lateral two lumbricals).

The abductor brevis, the opponens and the flexor brevis of the thumb and the lateral two lumbricals are supplied by the median (C. 6, 7); the medial two lumbricals, the adductor pollicis, the short muscles of the little finger, and all the interossei are supplied by the ulnar (C. 8, T. 1). (Clinical evidence suggests, however, that all the small muscles of the hand may receive their motor supply from T. 1, (Highet, 1943); see also p. 1079.)

Actions of Muscles in Movements of the Fingers.—The movements of the fingers are controlled by the long flexors and extensors, whose tendons pass over the wrist from the forearm, and by the series of short muscles situated in the hand itself, including the interossei, which act on the medial four fingers, and the special muscles of the thumb and little finger. (See Wood Jones, 1941.)

The **flexor digitorum sublimis** is a flexor of the proximal interphalangeal joints and the metacarpo-phalangeal joints of the medial four fingers; the **flexor digitorum profundus**

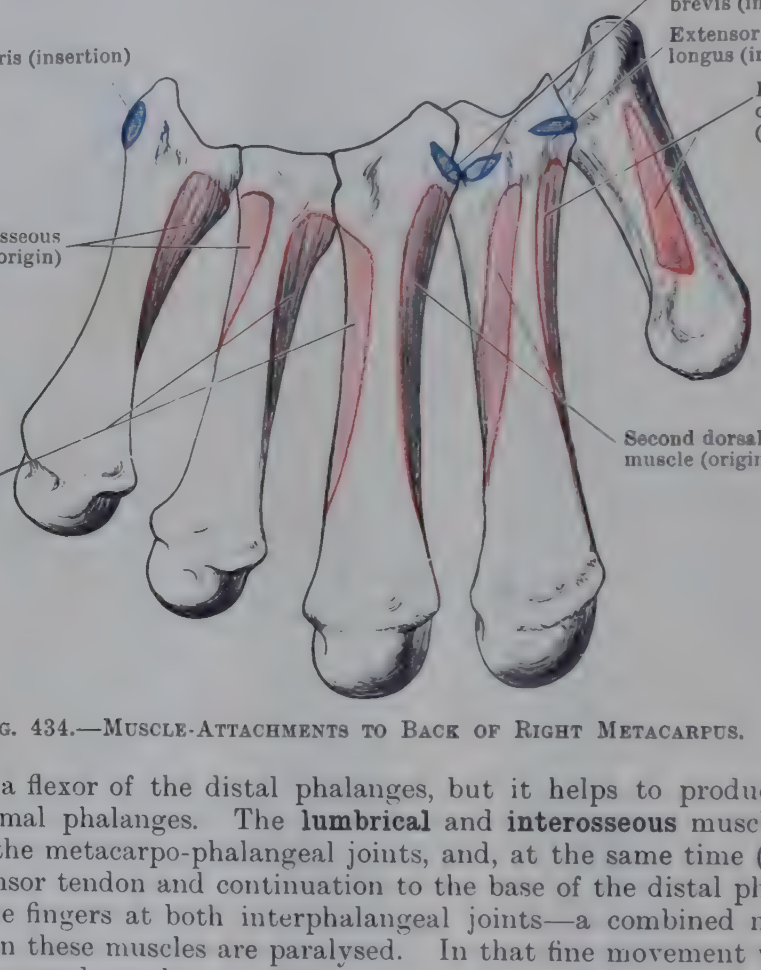

FIG. 434.—MUSCLE-ATTACHMENTS TO BACK OF RIGHT METACARPUS.

acts primarily as a flexor of the distal phalanges, but it helps to produce flexion of the middle and proximal phalanges. The **lumbrical** and **interosseous** muscles act as flexors of the fingers at the metacarpo-phalangeal joints, and, at the same time (by their attachment to the extensor tendon and continuation to the base of the distal phalanx), they act as extensors of the fingers at both interphalangeal joints—a combined movement which is impossible when these muscles are paralysed. In that fine movement which is utilized in making the upward stroke in writing, the interossei participate as well as the lumbricals.

The **extensor digitorum**, assisted by the extensors of the index and the little finger, is the extensor of the fingers. On account of the connexion of the tendons for the third, fourth and fifth digits with one another by means of accessory bands on the back of the hand, these three fingers cannot be fully extended separately, but extension of the index finger can take place independently. In extension of the interphalangeal joints the muscle is aided by the interossei and lumbrical muscles, but in paralysis of the lumbricals and interossei (claw hand), the intact extensor cannot extend the distal phalanges until the metacarpo-phalangeal joints have been passively flexed from the hyperextended position enforced upon them by the extensor, now freed from the antagonism of the lumbricals and interossei in its action on these joints. When the dorsal interossei are paralysed, the fingers can be abducted by the extensor digitorum—a movement always associated with hyperextension at the metacarpo-phalangeal joints.

The free movements of the thumb are of very great importance in the mechanism of

the human hand; they are controlled by special muscles which are quite independent of the common flexors and extensors of the other digits. The **flexor pollicis longus** acts in flexion of the thumb on the metacarpal bone and of both phalanges; the **extensor pollicis longus** acts in a similar way to extend the thumb, while the **extensor pollicis brevis** acts on the metacarpal bone and the proximal phalanx. The **abductor pollicis longus** abducts and extends the metacarpal bone of the thumb; its action in assisting **flexion** of the wrist has already been noted.

The short muscles of the thumb are concerned with the movements of flexion, abduction and adduction, and the characteristic movement of opposition. The **abductor pollicis brevis** acts on all the joints of the thumb. The movement of abduction which it produces occurs at the carpo-metacarpal joint, and the thumb moves in the direction of its radial border. Owing to the fact that the first metacarpal bone is placed with its palmar surface directed medially, abduction of the thumb carries it forwards away from the palm. In addition, the muscle assists in flexion of the metacarpo-phalangeal joint and, through its insertion into the long extensor, in extension of the interphalangeal joint. The **opponens pollicis** acts solely on the metacarpal bone of the thumb, which is drawn medially and forwards and at the same time rotated medially. As a result of the combined movements, in which the long and short flexors and the adductor pollicis participate,

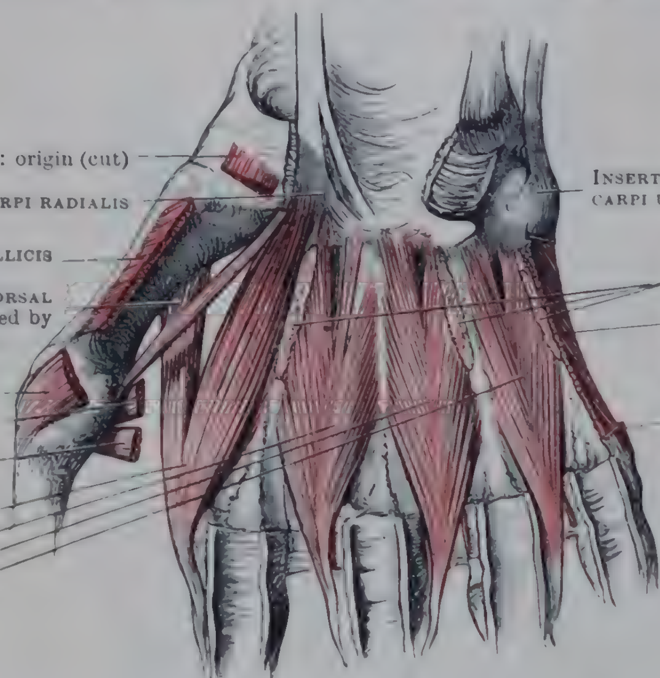

FIG. 435.—DORSAL INTEROSSEOUS MUSCLES OF RIGHT HAND (seen from the Palmar Aspect).

the thumb can be opposed to each of the other digits. The **flexor pollicis brevis** is a flexor of the thumb and assists also in the movement of opposition of the thumb. The **adductor pollicis** adducts and assists in opposition of the thumb.

The short muscles of the little finger are much less important than those of the thumb. The **abductor digiti minimi** abducts the little finger from the ring finger, and assists in flexion at the metacarpo-phalangeal joints. The **opponens** acts only on the metacarpal bone, drawing it forward so as to deepen the hollow of the hand. The **flexor** flexes the little finger at the metacarpo-phalangeal joint.

The interosseous muscles act like the lumbricals and along with them—flexing the fingers at the metacarpo-phalangeal joints and extending them at the interphalangeal joints. In addition, the **dorsal** interossei serve to **abduct** the fingers into which they are inserted from the line through the middle finger; the **palmar** muscles, on the other hand, **adduct** the fingers into which they are inserted towards the middle finger.

Movements of Upper Limb as a Whole.—The characteristic features of the movements of the upper limb are their range and refinement. The hand, in addition to its intrinsic powers, can be moved through a wide range and in several planes by the muscles that act on the wrist and radio-ulnar joints; that range is increased by the fore-and-aft movements at the elbow joint, and the extensive movements of which the shoulder joint and clavicular joints are capable. The result is that the hand can be brought into a position to cover and guard any portion of the body. Precision and refinement of movement are made possible by the co-ordinate actions of the various muscles upon the several joints, so that actions can be performed (as raising the food to the mouth) in which

all the joints of the limb are brought into play; while others (such as writing) are possible by movements at the joints of the wrist and fingers along with fixation of the elbow joint and rotation at the shoulder joint.

The power of the grip, which is such an important feature of the human hand, is due, in no small measure, to the ability to oppose the thumb to the other digits. This movement is possible only (1) because the metacarpal bone of the thumb is set in a plane at right angles to the plane in which the other metacarpals lie, and (2) because the carpo-metacarpal joint of the thumb allows a wide range of movement. As a result of the set of the thumb, flexion carries it medially across the palm, and a very small degree of rotation of its metacarpal bone enables the movement of opposition to be effected. When the fingers encircle a small object, the grip is strengthened by the overlapping thumb, which can then be opposed to the dorsal aspect of the distal phalanges and, if the object is small enough, to the middle phalanges of the index and middle fingers.

FASCIÆ OF FOREARM AND HAND

Superficial Fascia.—In the forearm this layer presents no exceptional features. On the back of the hand it is loose and thin, but in the palm its development into pads to assist the grip and protect underlying structures is characteristic of Man. In reflecting the palmar skin, the knife rasps through tough fibrous strands which enclose the fat in loculi and connect the palmar aponeurosis with the skin, especially along the lines of flexure. Thin and dense in the middle of the palm, and forming thicker and less fibrous pads in the thenar, hypothenar, and metacarpo-phalangeal regions, it plays an important rôle as a cushion readily adaptable to the contour of the various objects grasped. A band of transverse fibres (*superficial transverse ligament of the palm*) crosses the distal part of the palm, enclosed within the skin-folds which form the webs of the fingers and connected to the palmar surfaces of the fibrous flexor sheaths.

FIG. 436.—PALMAR APONEUROSIS.

Palmaris Brevis.—The palmaris brevis is a quadrilateral, subcutaneous muscle which lies in the hypothenar eminence under the superficial fascia. It arises from

the medial border of the palmar aponeurosis and from the palmar surface of the flexor retinaculum, and is **inserted** into the skin of the medial border of the hand for a variable distance. It covers the ulnar artery and nerve, branches of which supply it. Its action is to wrinkle the skin of the medial border of the hand, and, by raising up the skin and superficial fascia, to deepen the hollow of the hand and prevent flattening of the hypothenar eminence by pressure—thus assisting a firm palmar grip (Kirk, 1924).

Deep Fascia.—The deep fascia of the forearm and hand is continuous above with the deep fascia of the upper arm. In the proximal part of the forearm it is strengthened, in front, by fibres from the bicipital aponeurosis; behind, by the fascial insertions of the triceps; and at the sides by fibres derived from the humeral epicondyles in relation to the common tendons of origin of the flexor and extensor muscles of the forearm, which in part take their origin from them. It is attached to the posterior border of the ulna, and affords increased attachment to the flexor and extensor carpi ulnaris and the flexor digitorum profundus. On the back of the wrist, the deep fascia, strengthened by a number of oblique fibres, forms the extensor retinaculum. On the front of the carpus its deep surface blends with a layer that covers the front of the flexor digitorum sublimis, and it also thickens to form the flexor retinaculum; the general fascial sheath of the forearm blends with its superficial surface and covers the tendon of the palmaris longus as the tendon descends in front of the retinaculum to merge with the peak of the palmar aponeurosis.

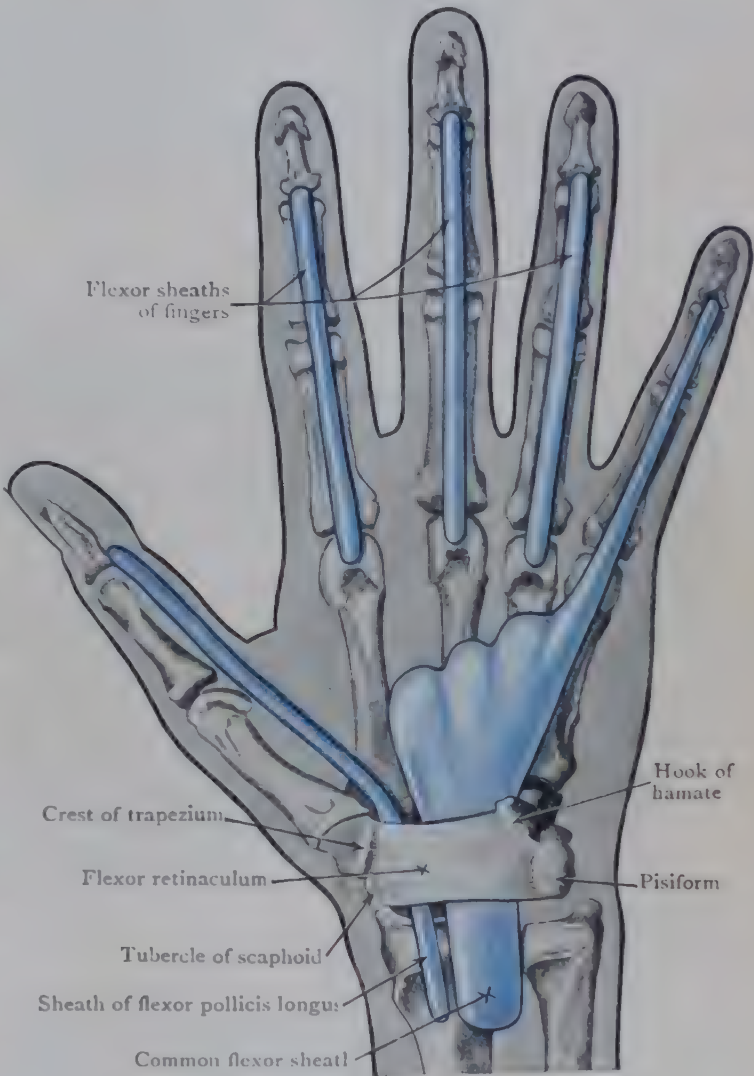

FIG. 437.—SYNOVIAL SHEATHS OF FLEXOR TENDONS OF DIGITS.

Flexor Retinaculum.—The flexor retinaculum is a band about an inch in length and in breadth, continuous with the deep fascia of the forearm and the palm of the hand, but upon a slightly deeper plane; it is attached laterally to the scaphoid and trapezium bones, medially to the pisiform and hamate bones. It is a fibrous restraining arch that binds down, in the hollow of the carpus, the flexor pollicis longus tendon and its synovial sheath, the flexor tendons of the fingers and their synovial sheath, and the median nerve. The attachment to the trapezium is to both lips of the groove on the front of that bone. The fibres attached to the crest cross the groove and convert it into a tunnel which is traversed by the flexor carpi radialis tendon and its synovial sheath. The upper border of the retinaculum is continuous with the deep fascia of the forearm; the distal border is continuous with the palmar aponeurosis in the middle, and at each side it gives origin to some fibres of the muscles of the thenar and hypothenar eminences. The anterior surface of the ligament gives further origin to these muscles, and is largely covered by them. It is also crossed by the palmar branches of the median and ulnar nerves, and by

the tendon of the palmaris longus muscle, which is partly inserted into the surface; the ulnar nerve and vessels descend on to its medial part, and are crossed by the *superficial part of the retinaculum.* This band (not always present) passes to the pisiform bone from the front of the retinaculum and is continuous with the deep fascia that overlies the palmaris longus.

Extensor Retinaculum.—The extensor retinaculum is a thickening of the deep fascia of the back of the limb, partly on the forearm and partly on the wrist, and therefore at a higher level than the flexor retinaculum. It is an oblique band of fibres, about an inch broad, continuous with the deep fasciæ of the forearm and hand. It is attached laterally to the distal part of the anterior border of the radius, and medially to the distal end of the ulna (styloid process), the carpus, and the medial ligament of the wrist. It is crossed by veins, by the radial nerve, and by the dorsal branch of the ulnar nerve. *Six compartments* are formed deep to it by the attachment of septal bands to the distal ends of the radius and ulna. Each compartment is provided with a synovial sheath; and they serve to transmit the

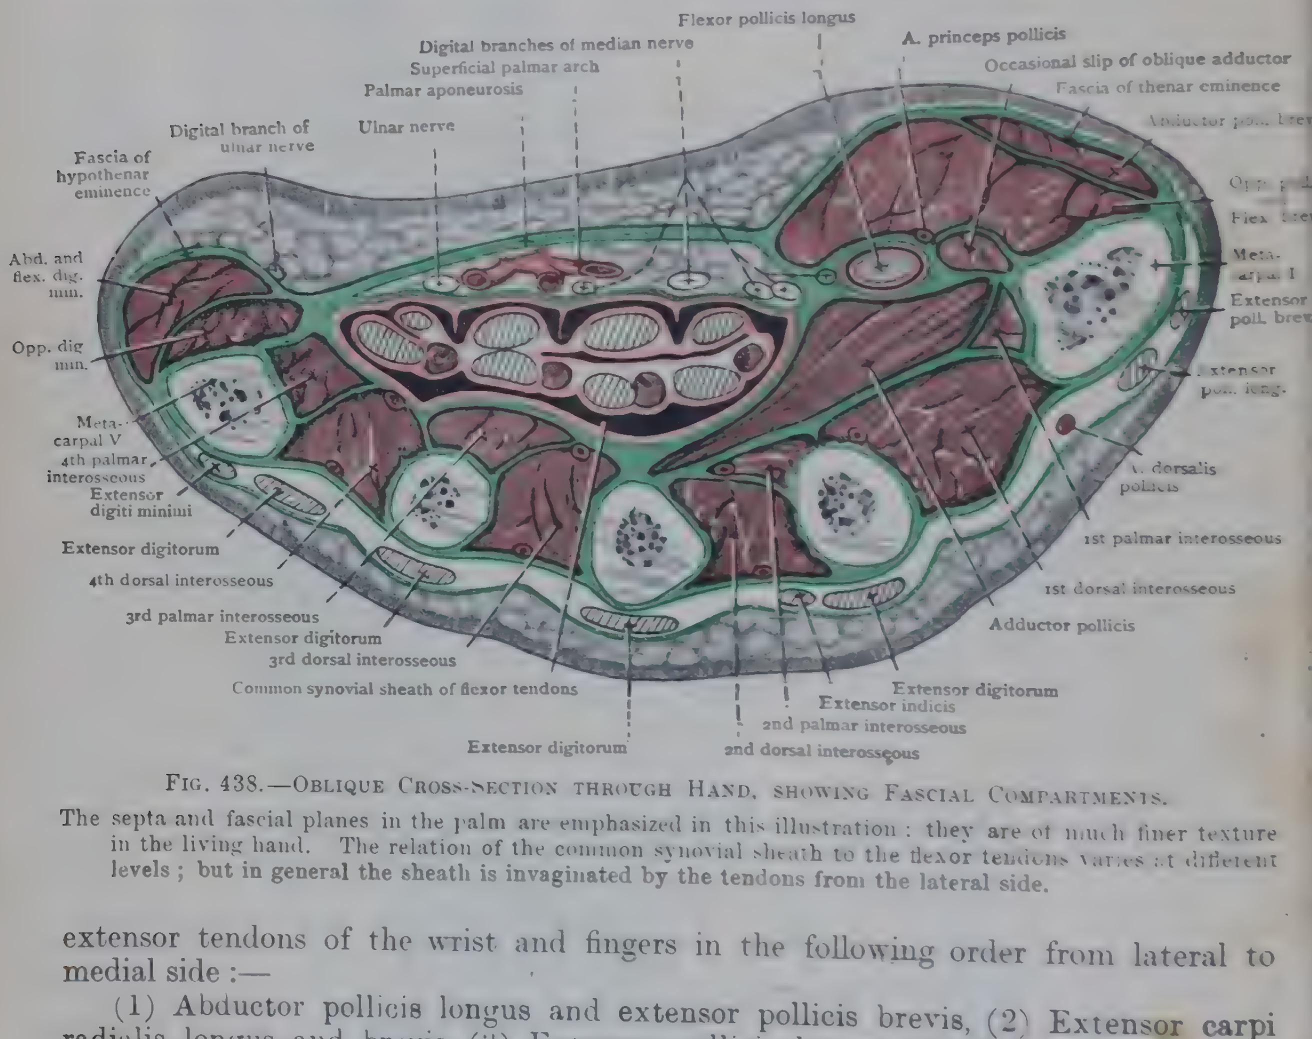

FIG. 438.—OBLIQUE CROSS-SECTION THROUGH HAND, SHOWING FASCIAL COMPARTMENTS.

The septa and fascial planes in the palm are emphasized in this illustration: they are of much finer texture in the living hand. The relation of the common synovial sheath to the flexor tendons varies at different levels; but in general the sheath is invaginated by the tendons from the lateral side.

extensor tendons of the wrist and fingers in the following order from lateral to medial side:—

(1) Abductor pollicis longus and extensor pollicis brevis, (2) Extensor carpi radialis longus and brevis, (3) Extensor pollicis longus, (4) Extensor digitorum and extensor indicis, (5) Extensor digiti minimi, (6) Extensor carpi ulnaris.

The **deep fascia of the dorsum of the hand** is arranged in two layers—superficial and deep—transmitting between them the tendons in their synovial sheaths and the branches of the radial artery. (1) The superficial layer, very thin, and continuous with the distal border of the extensor retinaculum, descends over the tendons to fuse with them upon the fingers; (2) the deep layer is thicker and overlies the interossei—blending with the superficial layer at the clefts between the digits.

The **deep fascia of the palm of the hand** also is in two layers: (1) A superficial layer which displays a central, thick *palmar aponeurosis* (described below), continuous with two thin side-parts on the thenar and hypothenar eminences; (2) a deep layer spread over the interosseous muscles and enclosing the adductor

PLATE XLII

FIG. 1.—ACTIONS OF THE PECTORALIS MAJOR.

The subject's right arm is being raised and the left arm depressed against resistance. The clavicular part of the muscle is active on the right, inactive on the left; the reverse is the case with the sterno-costal part.

FIG. 2.—FLEXORS OF WRIST AND ELBOW IN ACTION.

In the top left figure the median nerve, escaping from under flexor carpi radialis to lie upon sublimis tendons, is seen well because palmaris longus is absent.

PLATE XLII. PHOTOGRAPHIC ILLUSTRATIONS OF MUSCLES IN ACTION. (From Lockhart's *Living Anatomy*, 1948, by permission of Messrs. Faber & Faber.)

[Facing p. 513

of the thumb; certain fibres of the two layers blend between the heads of the metacarpal bones.

The flexor retinaculum, the palmar aponeurosis, and the fibrous flexor sheaths form a continuous sheet which serves to increase the efficiency of the flexor muscles of the digits and wrist and to increase the power of prehension. The fascial thickenings retain the tendons in position and provide pulleys over which they act, so that when the flexor muscles of the digits contract, their tendons do not produce ridges of the skin which would interfere with the efficiency of the hand as a gripping instrument; and the extent of the movements of the phalanges is directly proportional to the amount of shortening of the muscles that act upon them.

Palmar Aponeurosis.—The palmar aponeurosis is a dense, strong, triangular membrane that underlies the superficial fascia in the middle of the palm, and consists mainly of longitudinal fibres. Its apex joins the lower edge of the flexor retinaculum, and, more superficially, the tendon of the palmaris longus is inserted into it. The base is scalloped into four slips—one for each finger—and the slips are connected together on their deep surfaces by transverse fibres which cross in front of the lumbrical muscles and the digital nerves and vessels. Beyond the transverse fibres, each slip separates into two parts which pass backwards to be connected to the sides of the metacarpo-phalangeal joint and the proximal phalanx of the finger, their distal edges being continuous with the proximal end of the fibrous flexor sheath. The borders of the aponeurosis are continuous with the thin fascia that covers and ensheaths the thenar and hypothenar muscles; and the proximal part of the medial border gives origin to the palmaris brevis. Further, a septum passes backwards from each border to fuse with the fascia on the interosseous muscles, and the palm is divided by them into three compartments—a *lateral* compartment containing the short muscles of the thumb and its long flexor tendon; a *medial*, with the short muscles of the little finger; and an *intermediate* compartment containing the long flexor tendons.

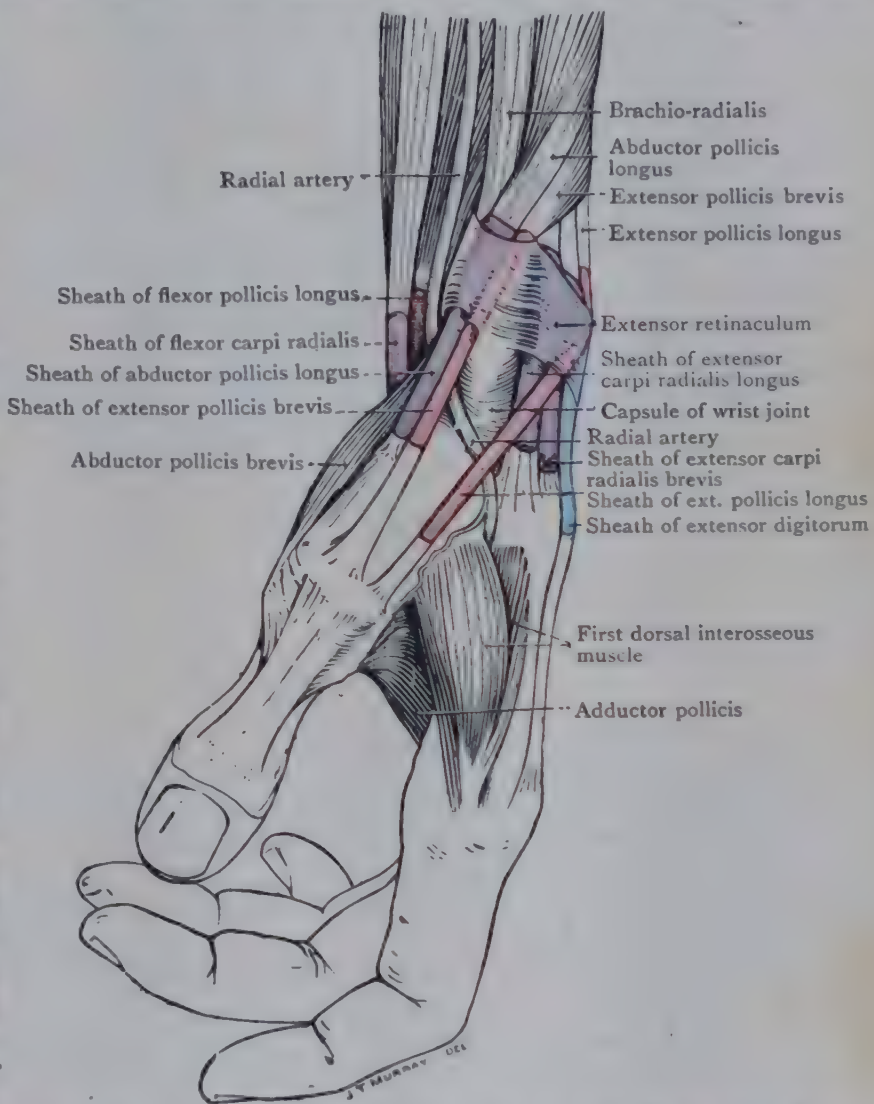

Fig. 439.—Dissection of Lateral Side of Left Wrist and Hand showing Synovial Sheaths of Tendons.

Fascial "Spaces".—The arrangement of the deep fascia in the hand is of great importance in determining the mode of spread of infection and the sites of abscesses. In particular, certain "spaces" may be formed in the fascial plane deep to the flexor tendons. These "spaces" are specially named by the surgeon, and they are not to be confused with the anatomical "compartments" described with the palmar aponeurosis. (See the Section on Surface and Surgical Anatomy and Fig. 1240, p. 1538.).

Fibrous Flexor Sheaths (Fig. 432).—The fibrous sheaths of the long flexors of the digits are arches of dense fibrous tissue that hold the tendons in place on the palmar surfaces of the digits. Each sheath is attached to the margins of the proximal and middle phalanges (in the thumb, proximal only) and interphalangeal joints and to the palmar surface of the distal phalanx; and its proximal end is continuous with a divided slip of the palmar aponeurosis. Opposite the joints it is thin and loose and attached to the skin, but opposite each phalanx it is thick and strong, and serves to keep the tendons closely applied to the bone during flexion of the digit. The canal formed by the phalanges and the fibrous sheath contains not only the tendons but also the synovial sheath that surrounds them.

Synovial Sheaths.—These sheaths have two layers—one around the tendon

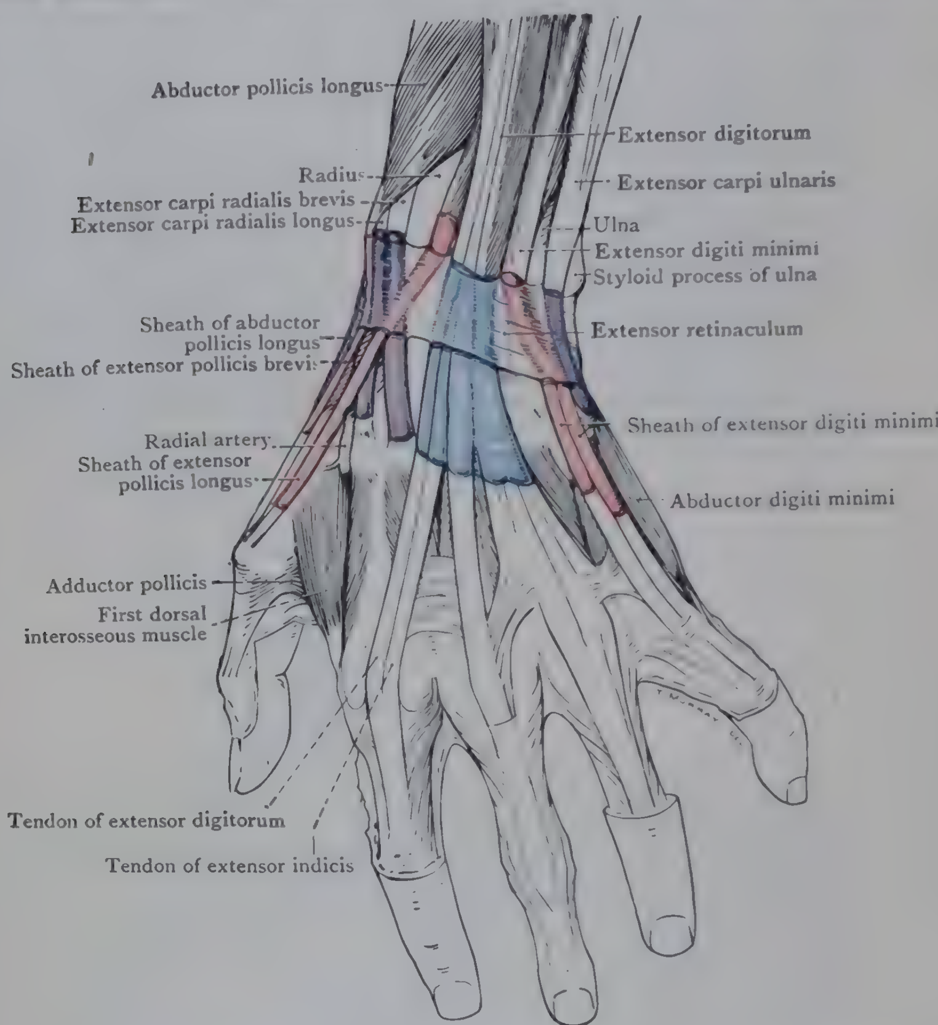

Fig. 440.—Dissection of Back of Forearm, Wrist, and Hand, showing Synovial Sheaths of Tendons.

or tendons, the other applied to the walls of the spaces which the tendons occupy; and the two layers are continuous with each other at the ends of the sheath.

The **common synovial flexor sheath** is by far the largest and envelops the tendons of the flexor sublimis and flexor profundus. It begins about an inch above the flexor retinaculum and passes into the palm—the larger part of it ending at the middle of the palm, but the part related to the tendons of the little finger extends to the base of its distal phalanx. The tendons invaginate the synovial sac from the lateral side to produce the two layers, but the arrangement is complicated by a recess that passes in from the medial side to separate the tendons of the flexor sublimis from those of the profundus.

The **synovial sheaths of the flexor pollicis longus** and the **flexor carpi radialis** begin about an inch above the flexor retinaculum and extend to the insertion of the tendons. The sheath of the flexor pollicis sometimes communicates with the common sheath above the retinaculum.

The **synovial flexor sheaths of the fingers** extend as far as the insertion of the

tendons. The sheath of the little finger is a prolongation from the common sheath. The sheaths of the other fingers begin at the middle of the palm at a variable distance below the common sheath (Fig. 437).

The **synovial extensor sheaths** begin at or a little above the extensor retinaculum and extend downwards for varying distances. The tendons inserted into the metacarpus are usually ensheathed as far as their insertions; the other sheaths extend half-way down the hand.

MUSCLES OF LOWER LIMB

The muscles of the lower limb are divisible (according to their regional arrangement and functional uses) into series and groups corresponding in general to those of the upper limb. In contrast, however, to the freely movable shoulder girdle acted upon by the series of muscles which connect it to the trunk, the pelvic girdle is fixed to the vertebral column, and no corresponding functional series of muscles exists.

Those muscles of the lower limb which pass from the vertebral column (psoas, piriformis, and gluteus maximus) to the femur act upon the hip joint, and are included in the first two of the groups to be described:—1. Muscles of the Groin. 2. Muscles of the Hip and Buttock (Gluteal region). 3. Muscles of the Thigh (Flexor, Extensor, and Adductor Groups). 4. Muscles of the Leg (Flexor and Extensor Groups). 5. Muscles in the Sole of the Foot.

MUSCLES AND FASCIÆ OF THIGH AND GLUTEAL REGION

Muscles of the Groin

The **ilio-psoas** is a compound muscle, consisting of two elements—**psoas (major and minor)**—which connects the femur and pelvic girdle to the axial skeleton; and another element—the **iliacus**—which extends between the hip bone and the femur. The muscles lie chiefly in the posterior wall of the abdomen; only their lower parts appear in the thigh, below the inguinal ligament in the lateral part of the femoral triangle; they are related to a large number of important structures.

Psoas Major.—The psoas major is a long, thick, fusiform muscle with an extensive origin from the lumbar part of the vertebral column. It **arises** by fleshy fibres—(1) from the intervertebral disc above each lumbar vertebra, and the adjacent margins of the vertebræ—from the lower border of the twelfth thoracic to the upper border of the fifth lumbar; (2) from four membranous arches which pass over the sides of the bodies of the upper four lumbar vertebræ; and (3) from the transverse processes of all the lumbar vertebræ (Fig. 385, p. 451). The muscle lies at first on the fronts of the transverse processes closely applied to the side of the vertebral bodies; then, narrowing to pass along the brim of the true pelvis, it enters the thigh behind the inguinal ligament and ends in a tendon which is **inserted** into the lesser trochanter of the femur (Fig. 441). A *bursa*, which may be continuous with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the hip joint.

Psoas Minor.—The psoas minor is an inconstant muscle, being absent in about 40 per cent of bodies. It **arises** from the intervertebral disc between the last thoracic and first lumbar vertebræ and from the contiguous margins of those vertebræ. The muscle is closely applied to the anterior surface of the psoas major. It has a short, slender fleshy belly, and it is **inserted** by a long, narrow tendon into the arcuate line and ilio-pubic eminence, its margins blending with the fascia that covers the psoas major.

Iliacus.—The iliacus is a large fan-shaped muscle that lies along the lateral side of the psoas major. It **arises**, by fleshy fibres, mainly from the floor of the iliac fossa, and it has additional origins from the ala of the sacrum, the anterior sacro-iliac, lumbo-sacral, and ilio-lumbar ligaments, and, outside the pelvis, from the ilio-femoral ligament. Emerging from the abdomen, it descends in front of the hip joint, tapering to be **inserted**, by fleshy fibres—(1) into the lateral side of

the tendon of the psoas major; (2) into the lesser trochanter; (3) into the femur below the lesser trochanter for about an inch; and (4), by its most lateral fibres, into the capsule of the hip joint. These fibres are often separate, forming the iliacus minor or ilio-capsularis.

Nerve-Supply.—The psoas major is supplied directly by branches from the anterior primary rami of the second and third lumbar nerves, with additional branches in some cases from the first and fourth. The psoas minor receives a nerve from the first or the second lumbar nerve. The iliacus is supplied by branches from the femoral nerve (L. 2. 3. 4.) within the abdomen.

Muscles of Gluteal Region

This group comprises the three gluteal muscles, the tensor fasciæ latæ, piriformis, obturator internus and gemelli, and the quadratus femoris.

The gluteus maximus and tensor fasciæ latæ muscles—both ensheathed in deep fascia—are in the same plane. The gluteus medius, partially covered by the gluteus maximus, conceals the gluteus minimus; and the piriformis, obturator internus, gemelli, and quadratus femoris intervene between the gluteus maximus and the posterior surface of the hip joint.

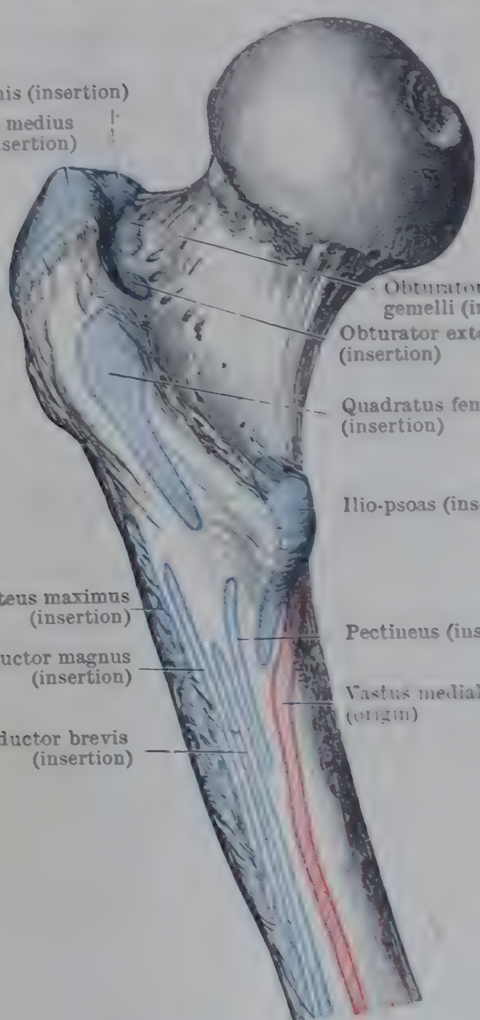

FIG. 441.—MUSCLE-ATTACHMENTS TO BACK OF UPPER PART OF LEFT FEMUR.

Gluteus Maximus.—The gluteus maximus, superficial throughout its extent, and the heaviest and most coarsely fibred muscle of the body, contributing by its weight to form the fold of the buttock, is a peculiarly human muscle, being associated with the adoption of the erect posture. It **arises** from (1) the upper part of the area behind the posterior gluteal line of the ilium; (2) the tendon of the sacrospinalis; (3) the dorsal surface of the sacrum and coccyx; (4) the posterior surface of the sacrotuberous ligament; and (5) the deep fascia ensheathing it.

It extends obliquely downwards and laterally to be **inserted**, by short tendinous fibres, partly into the gluteal tuberosity of the femur (Fig. 441), but mainly, over the greater trochanter, into the ilio-tibial tract. The tract receives the insertion of the whole of the superficial fibres of the muscle and the upper half of the deep fibres, thereby enabling the muscle to obtain a powerful hold over the thigh as a whole, and a virtual insertion into the tibia (Fig. 270, p. 302). The lower half of the deep portion of the muscle is inserted, for the most part, into the gluteal tuberosity; but the lowest fibres of all are inserted into the fascia lata and are thence connected with the lateral intermuscular septum of the thigh and the origin of the short head of the biceps.

A great part of the gluteus medius is visible at its upper border; and at its lower border the hamstring muscles and the sciatic nerve appear as they enter the thigh. This border is crossed by the fold of the buttock. In addition to the muscles already enumerated, it covers the ischial tuberosity, greater trochanter

origins of biceps femoris, semitendinosus, semimembranosus and the adductor magnus. The superficial part of the superior gluteal artery passes between the gluteus medius and the piriformis to reach its deep surface, and, between the piriformis and the superior gemellus, the inferior gluteal and internal pudendal vessels, and the sciatic, pudendal, and posterior cutaneous nerves and muscular branches from the sacral plexus emerge. Three *bursæ* are deep to it: one (not always present) over the ischial tuberosity, a second over the lateral side of the greater trochanter, and a third over the vastus lateralis. The fibres of the gluteus maximus that arise from the coccyx may form a separate muscle (**coccygeo-femoralis** or **agitator caudæ**), and there may be an additional slip from the ischial tuberosity (**ischio-femoralis**).

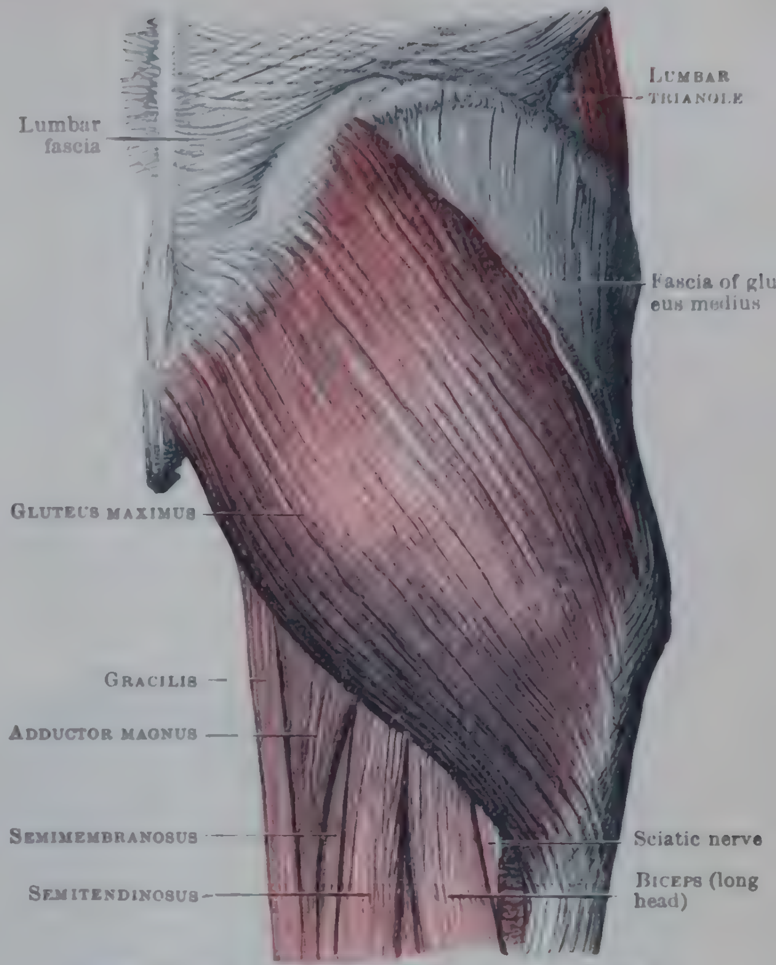

FIG. 442.—RIGHT GLUTEUS MAXIMUS MUSCLE.

Tensor Fasciæ Latæ. — The tensor fasciæ latæ (Pl. XLIV, p. 529, Fig. 3) arises from the outer lip of the fore part of the iliac crest and the anterior border of the ilium, and passes downwards and slightly backwards to be inserted into the ilio-tibial tract (p. 534) a little below the level of the greater trochanter. It is enclosed between two layers of deep fascia, of which the deep layer extends medially to fuse with the heads of the rectus femoris and the capsule of the hip joint; and both layers blend with the ilio-tibial

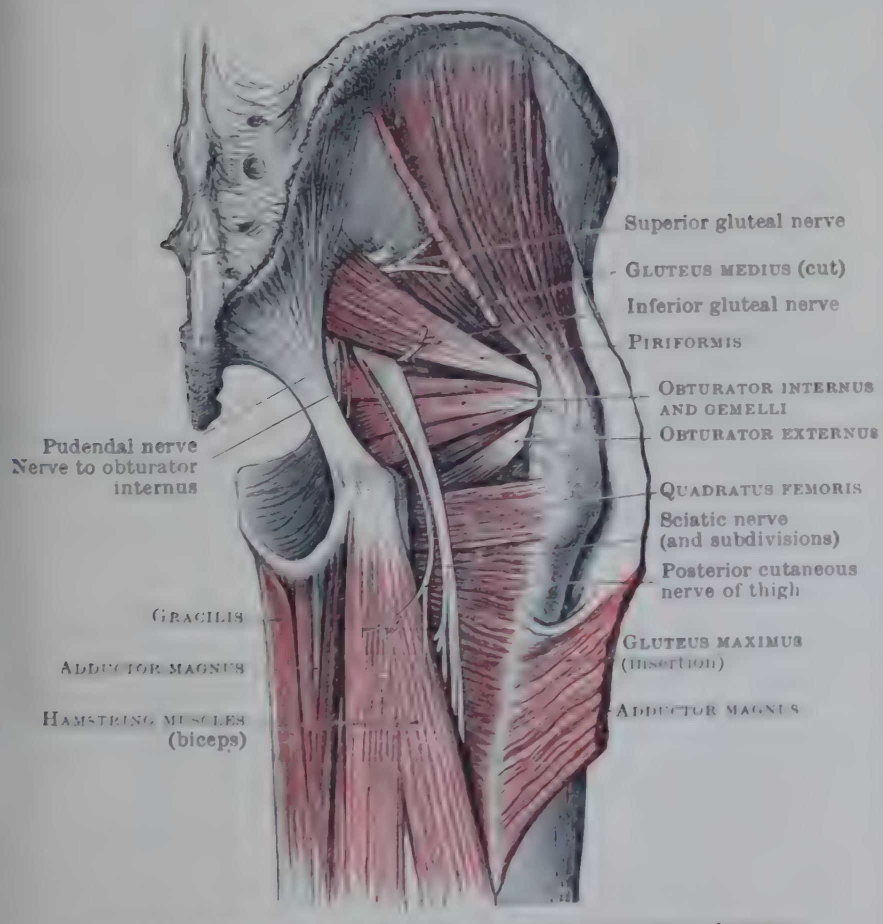

FIG. 443.—MUSCLES AND NERVES OF RIGHT GLUTEAL REGION.
The gluteus maximus is reflected; and the gluteus medius is cut to show a part of the gluteus minimus.

tract along the posterior border of the muscle. Posteriorly the muscle is related to the gluteus medius and minimus, and the vastus lateralis. Anteriorly it is closely related to the sartorius at its origin; but these two muscles diverge from each other as they descend, and the rectus femoris appears in the widening cleft between them (Fig. 448).

Gluteus Medius.—The gluteus medius **arises** from (1) the area of the ilium between the iliac crest and posterior gluteal line above and the middle gluteal line below and (2) the strong fascia that covers its anterior part. It is a fan-shaped muscle whose fibres converge on the greater trochanter to be **inserted** by a strong, short tendon into the postero-superior angle of the greater trochanter and into a well-marked diagonal line on its lateral surface—the most anterior fibres reaching the lowest level (Fig. 443). A *bursa* is placed between the tendon and the trochanter in front of the insertion. The muscle is partly superficial and partly concealed by the gluteus maximus. It covers the gluteus minimus, the superior gluteal nerve and the deep branches of the superior gluteal artery.

Gluteus Minimus.—The gluteus minimus **arises** by fleshy fibres from the gluteal surface of the ilium between the middle and inferior gluteal lines. It is a fan-shaped muscle and its fibres converge on the antero-superior angle of the greater trochanter, covering the upper surface of the capsule of the hip joint. It is **inserted** into the anterior surface of the trochanter (Fig. 450). A *bursa* (trochanteric bursa of gluteus minimus) is placed deep to the tendon in front of the medial part of the anterior surface of the greater trochanter.

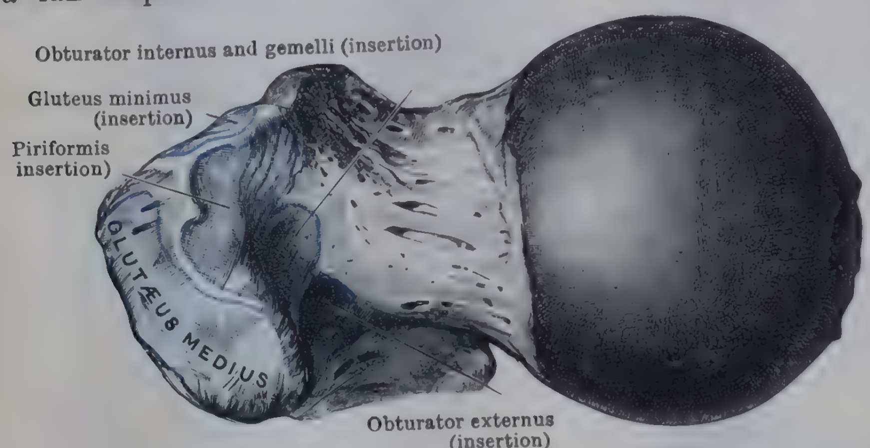

FIG. 444.—FEMUR (LOOKED AT FROM ABOVE) SHOWING MUSCLE-ATTACHMENTS TO GREATER TROCHANTER.

Piriformis.—The piriformis is one of the few muscles that connect the lower limb to the axial skeleton. It **arises** mainly (1) from the pelvic surfaces of the second, third, and fourth sacral vertebræ; but as it passes out through the greater sciatic foramen, it receives additional origins from (2) the upper margin of the greater sciatic notch and (3) the pelvic surface of the sacro-tuberous ligament. In the buttock it forms a rounded tendon which is **inserted**, under cover of the gluteus medius, into the upper border and medial side of the greater trochanter (Fig. 444).

The piriformis, at its origin, covers part of the inner surface of the dorsal wall of the true pelvis, and is related anteriorly to the rectum and the lower part of sacral plexus. In the buttock it is covered by the gluteus maximus and lies between the gluteus medius and superior gemellus on the back of the hip joint. It is frequently pierced by the lateral popliteal nerve when that nerve emerges separately from the pelvis.

Obturator Internus.—The obturator internus **arises** from (1) the whole of the margin of the obturator foramen (except the obturator groove); (2) the inner surface of the obturator membrane; (3) the pelvic surface of the hip bone behind and above the obturator foramen; and (4) the *obturator fascia*, which covers it. It is a fan-shaped muscle whose fibres converge to pass through the lesser sciatic foramen. Its tendon begins on the surface next the bone as four or five separate slips; and as the muscle changes its direction at an acute angle by hooking round the margin of the lesser sciatic notch deep to the sacro-tuberous ligament, these tendinous slips also converge to play over corresponding grooves in the cartilage-covered, pulley-like surface of the bone—a large *bursa*, attached to the margins of the tendon and the cartilage-covered surface of the bone, facilitating this movement. The tendon, after passing over the back of

the hip joint, is **inserted** into the medial surface of the greater trochanter above the trochanteric fossa (Fig. 444).

The fleshy part of the muscle is covered with the obturator fascia, which gives origin to a great part of the levator ani; the part above the levator is related to the cavity of the pelvis and the part below to the ischio-rectal fossa. In the buttock the tendon is embraced by the gemelli muscles which meet deep to it as it emerges from the foramen and more or less conceal its superficial surface as it passes to its insertion.

Gemelli.—The gemelli muscles form accessory portions of the obturator internus, providing it with an additional 'twin' origin from the margins of the lesser sciatic notch. The **superior gemellus arises** from the gluteal surface of the ischial spine and the **inferior gemellus** from the upper part of the ischial tuberosity; each is **inserted** into the corresponding margin and the superficial surface of the tendon of the obturator internus muscle.

Quadratus Femoris.—The quadratus femoris **arises** from the lateral margin of the ischial tuberosity, and is **inserted** into the quadrate tubercle of the femur and into a line leading down from it. The posterior surface is covered by the hamstring muscles, the sciatic nerve, the posterior cutaneous nerve of thigh, the inferior gluteal nerve and artery and the gluteus maximus; the anterior surface is related to the obturator externus muscle and to the lesser trochanter of the femur (a *bursa* intervening); its upper border meets the lower border of the inferior gemellus; and its lower border meets the upper border of the adductor magnus —fusion of these two being not infrequent.

Nerve-Supply.—The **piriformis muscle** is supplied by branches direct from the anterior primary rami of the **first** and **second sacral nerves**; the remaining muscles of the group are supplied by four nerves, two of which arise from the back of the sacral plexus, and the other two have corresponding origins from the front. The **superior gluteal nerve** (L. 4. 5. S. 1.) supplies the **gluteus medius** and **gluteus minimus** and ends in the **tensor fasciæ latæ**; the **inferior gluteal nerve** (L. 5. S. 1. 2.) is concerned solely with the supply of the **gluteus maximus.** Both those nerves arise from the back of the plexus and are associated with the roots of origin of the lateral popliteal nerve. The **quadratus femoris** (with the **inferior gemellus**) and the **obturator internus** (with the **superior gemellus**) are supplied by special nerves which arise respectively from the same nerves of the plexus as the gluteal nerves, but from the front of it, and are associated with the roots of origin of the medial popliteal nerve. The **nerve to the quadratus femoris** (L. 4. 5. S. 1.), after giving a twig to the inferior gemellus, enters the deep (anterior) surface of its muscle; the **nerve to the obturator internus** (L. 5. S. 1. 2.) gives a twig to the superior gemellus and enters its muscle on its perineal surface.

MUSCLES OF THIGH

The muscles of the thigh are divisible into three main groups by their situation, action, and nerve-supply. On the **back** (flexor surface) of the thigh are the hamstring muscles; on the **front** (extensor surface) of the thigh are the quadriceps femoris and the sartorius; on the **medial side** of the thigh are the pectineus and the adductor muscles.

The muscles of the thigh, like the muscles of the upper arm, have a nerve-supply by groups, from the ventral and dorsal offsets of the nerve-plexuses concerned, according to their relation to the flexor and extensor surfaces of the thigh. The flexor and extensor surfaces of the thigh, however, are reversed in position by the developmental rotation of the limb, and become posterior and anterior respectively. There is, moreover, a special adductor group which is represented in the upper arm by the coraco-brachialis only, and is supplied (like that muscle) by ventral branches of the plexus.

The group supply is as follows: *Ventral branches of the plexus*—**Flexors** (hamstrings) by the **sciatic nerve** (medial popliteal division) (L. 4. 5. S. 1. 2. 3.); **Adductors** by the **obturator nerve** (L. 2. 3. 4.). *Dorsal branches of the plexus*—**Extensors** by the **femoral nerve** (L. 2. 3. 4.). In addition to this general statement, the nerve-supply of three muscles is to be specially noted —the adductor magnus, the pectineus, and the short head of the biceps.

Muscles of Back of Thigh

The muscles of this group—the biceps femoris, semitendinosus, and semimembranosus—are known colloquially as the **hamstring muscles.** Morphologically,

the ischio-condylar portion of the adductor magnus, as evidenced by its nerve-supply, also belongs to this group. The origins of the hamstring muscles from the ischial tuberosity are concealed by the gluteus maximus. In the back of the thigh, enveloped by the fascia lata, they are placed behind the adductor magnus—the semitendinosus and semimembranosus medially, the biceps laterally. Towards the knee they diverge to bound the popliteal fossa, the former two muscles on its medial side, the biceps on its lateral side; behind the knee these tendons may be felt as the "hamstrings".

Biceps Femoris.—The biceps femoris has a double **origin**. (1) Its *long head* **arises**, by means of a tendon, in common with the semitendinosus, from the upper medial impression on the ischial tuberosity (Figs. 443, 445) and from

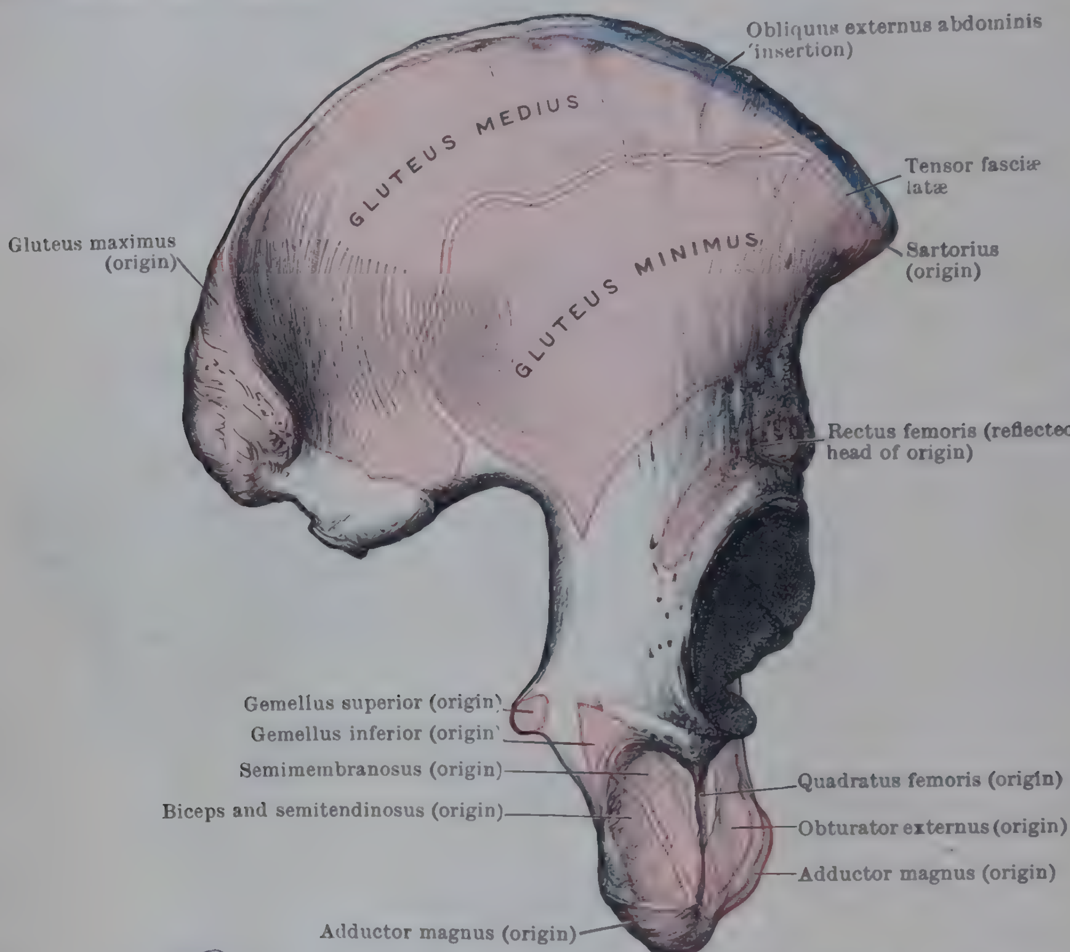

FIG. 445.—MUSCLE-ATTACHMENTS TO OUTER SURFACE OF RIGHT HIP-BONE.

the sacro-tuberous ligament. This head, united for a distance of two or three inches with the semitendinosus, forms a separate fleshy mass which extends to the distal third of the thigh to end in a flattened tendon joined by the short head of the muscle. (2) The *short head* **arises** separately from (i) the whole length of the lateral lip of the linea aspera and the upper half of the lateral supra-condylar line of the femur, and (ii) the lateral intermuscular septum: its upper-most fibres are sometimes blended with the insertion of the lowest fibres of the gluteus maximus. The tendon of the long head, joined by the fibres of the short head, becomes rounded at the knee and is then split into two parts by the lateral ligament of the knee joint as it is **inserted**—(1) into the head of the fibula, and by extensions, (2) forwards to the lateral condyle of the tibia, and (3) to the deep fascia on the lateral side of the leg.

There is a *bursa* between the tendon and the lateral ligament of the knee.

The short head may be absent; there may be an additional origin from the ischium or the femur; and the long head may send a slip to the gastrocnemius or to the tendo calcaneus (**tensor fasciæ suralis**).

Semitendinosus. — The semitendinosus **arises**, in common with the long head of the biceps, from the upper medial impression on the ischial tuberosity

(Fig. 445). Separating from the common tendon of origin, the muscle forms a long band which becomes tendinous in the middle third of the thigh and ends in the distal third in a long, cord-like tendon. Descending over the surface of the semimembranosus and over the medial side of the knee the tendon spreads out to be **inserted** (1) into the upper part of the medial surface of the shaft of the tibia behind the gracilis and sartorius (Fig. 447), and (2) into the deep fascia of the leg. A *bursa* (tibial intertendinous) separates it along with the gracilis from the sartorius superficially, and a *second bursa*, common to it and the gracilis, lies deep to its insertion. The belly of the muscle is marked by an oblique tendinous intersection.

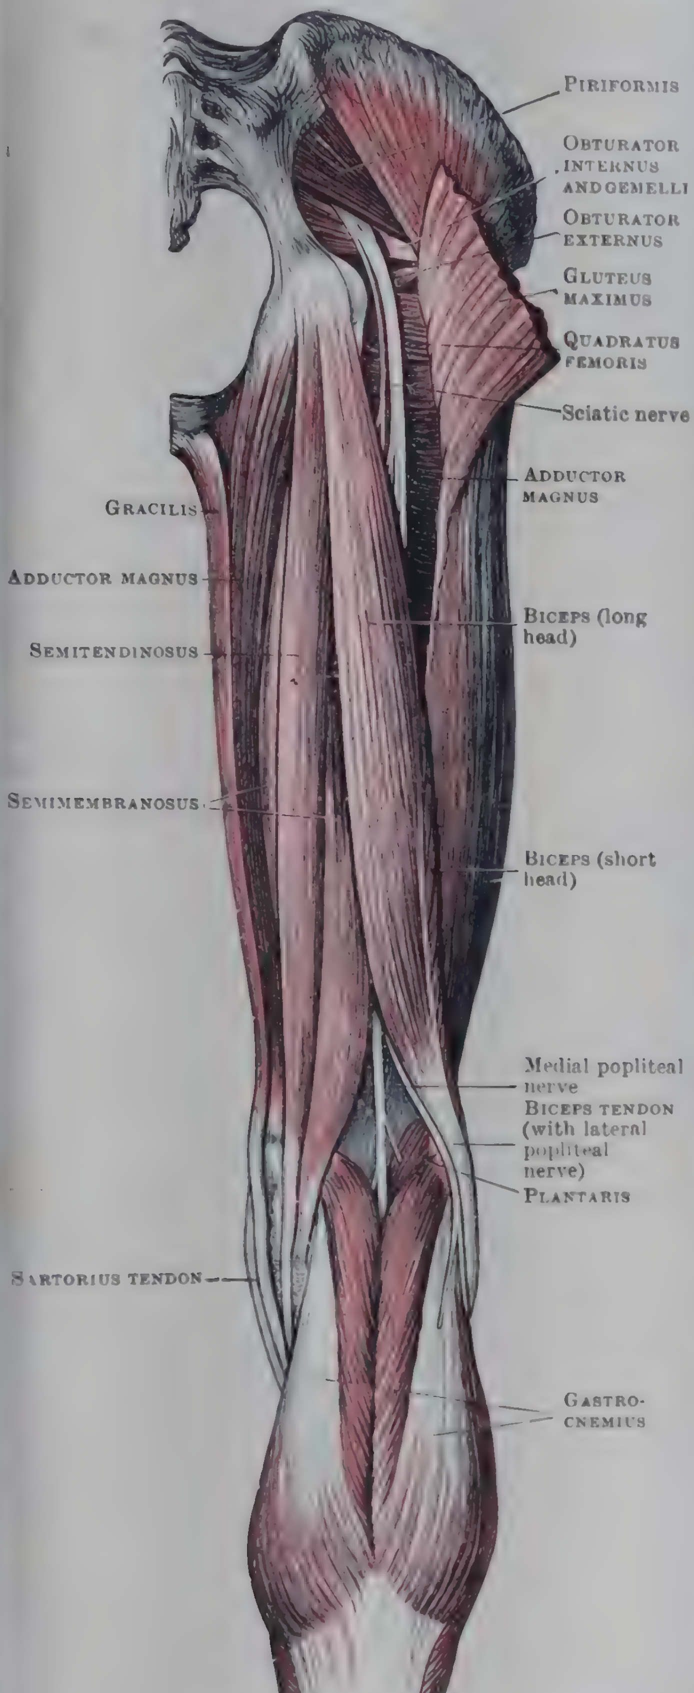

FIG. 446.—MUSCLES OF BACK OF RIGHT THIGH.

Semimembranosus.—The semimembranosus **arises** from the upper lateral facet on the ischial tuberosity (Fig. 445) by a strong membranous tendon from which the muscle

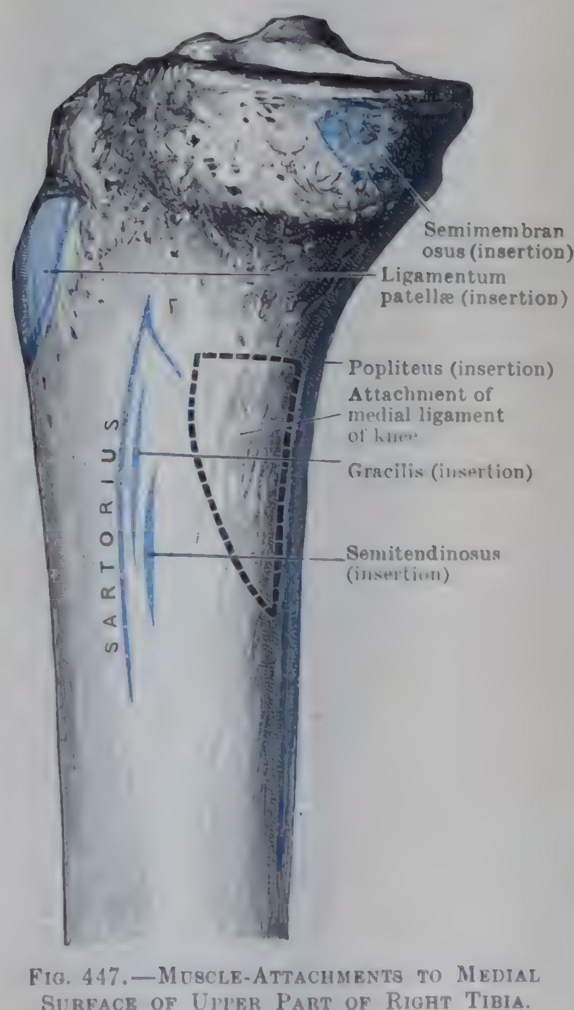

FIG. 447.—MUSCLE-ATTACHMENTS TO MEDIAL SURFACE OF UPPER PART OF RIGHT TIBIA.

derives its name. This membranous sheet is continued downwards along the lateral margin of the muscle, tapering to a point below the middle of the thigh, and giving origin to the rounded fleshy belly which, in the upper third of the thigh, lies in front of the semitendinosus and the long head of the biceps. Inclining medially, with the semitendinosus on its posterior surface, it ends, at the back of

the knee, in a thick, flattened tendon which is separated from the medial head of the gastrocnemius by a *bursa*, and is **inserted** into the horizontal groove on the postero-medial surface of the medial condyle of the tibia (Figs. 340, p. 384, and 447)—another *bursa* lying deep to the tendon near its insertion. It has three *additional membranous insertions*: (1) a fascial band extends downwards and medially to join the posterior border of the *medial ligament* of the knee joint; (2) another fascial band, extending downwards and laterally, forms the fascia on the popliteus muscle, and is attached to the soleal line of the tibia; and (3) a third strong band, extending upwards and laterally to the back of the lateral condyle of the femur, forms the *oblique posterior ligament* of the knee joint (Fig. 339).

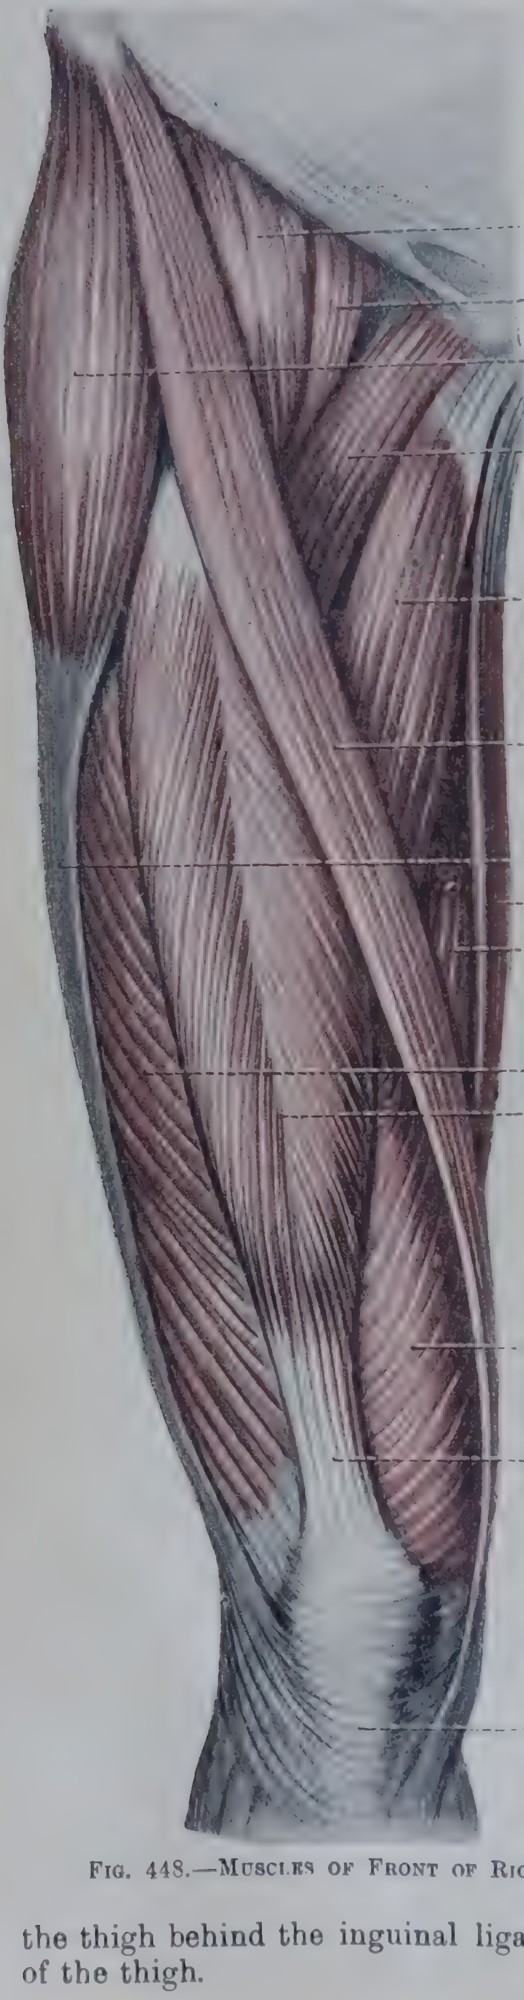

Fig. 448.—Muscles of Front of Right Thigh.

Nerve-Supply.—The hamstring muscles are all supplied by the **sciatic nerve**, by fibres from L. 4, 5, S. 1, 2, 3; when there is a high division of this nerve the fact is disclosed that, with the exception of the nerve to the short head of the biceps, the supply is derived from the part which becomes the medial popliteal nerve. The **semitendinosus** receives two branches—one above and the other below its tendinous intersection.

The **ischio-condylar portion of the adductor magnus** also is supplied from the sciatic nerve by a branch which usually arises in common with the nerve to the **semimembranosus**.

The **short head of the biceps** is separately supplied by a branch from the lateral popliteal part of the sciatic nerve (L. 5, S. 1, 2). (Cf. the supply of a portion of the brachialis in the arm by the radial nerve, p. 492.) The morphological significance of the association of the origin of the short head of the biceps with the insertion of the gluteus maximus is emphasized by the fact that its nerve may arise direct from the sacral plexus in common with the inferior gluteal nerve.

Muscles of Front of Thigh

The chief muscle of the front of the thigh is the quadriceps femoris. The sartorius descends obliquely between the quadriceps femoris and the adductor muscles. The ilio-psoas, after passing into the thigh behind the inguinal ligament, lies in the upper lateral part of the front of the thigh.

Sartorius.—The sartorius, a long strap-like muscle, **arises** from the anterior superior iliac spine and half of the margin of the notch below (Pl. XLIV, p. 529, Fig. 3). It passes obliquely across the front of the thigh, and, reaching its medial side, descends vertically across the medial side of the knee; it then inclines forwards to be **inserted**, by aponeurotic fibres, into the upper part of the medial surface of the shaft of the tibia above and in front of the insertions of the gracilis and the semitendinosus, and by its borders into fascial expansions which join the capsule and the medial ligament of the knee joint and the fascia of the leg.

The sartorius is superficial in its whole extent. Its upper third forms the lateral boundary of the femoral triangle; its middle third lies on the roof of the subsartorial canal which covers the femoral vessels; and its lower third is separated from the tendon of the gracilis muscle by the saphenous nerve and the saphenous branch of the descending genicular artery. The *tibial intertendinous bursa* lies deep to the tendon at its insertion, separating it from the tendons of the gracilis and semitendinosus.

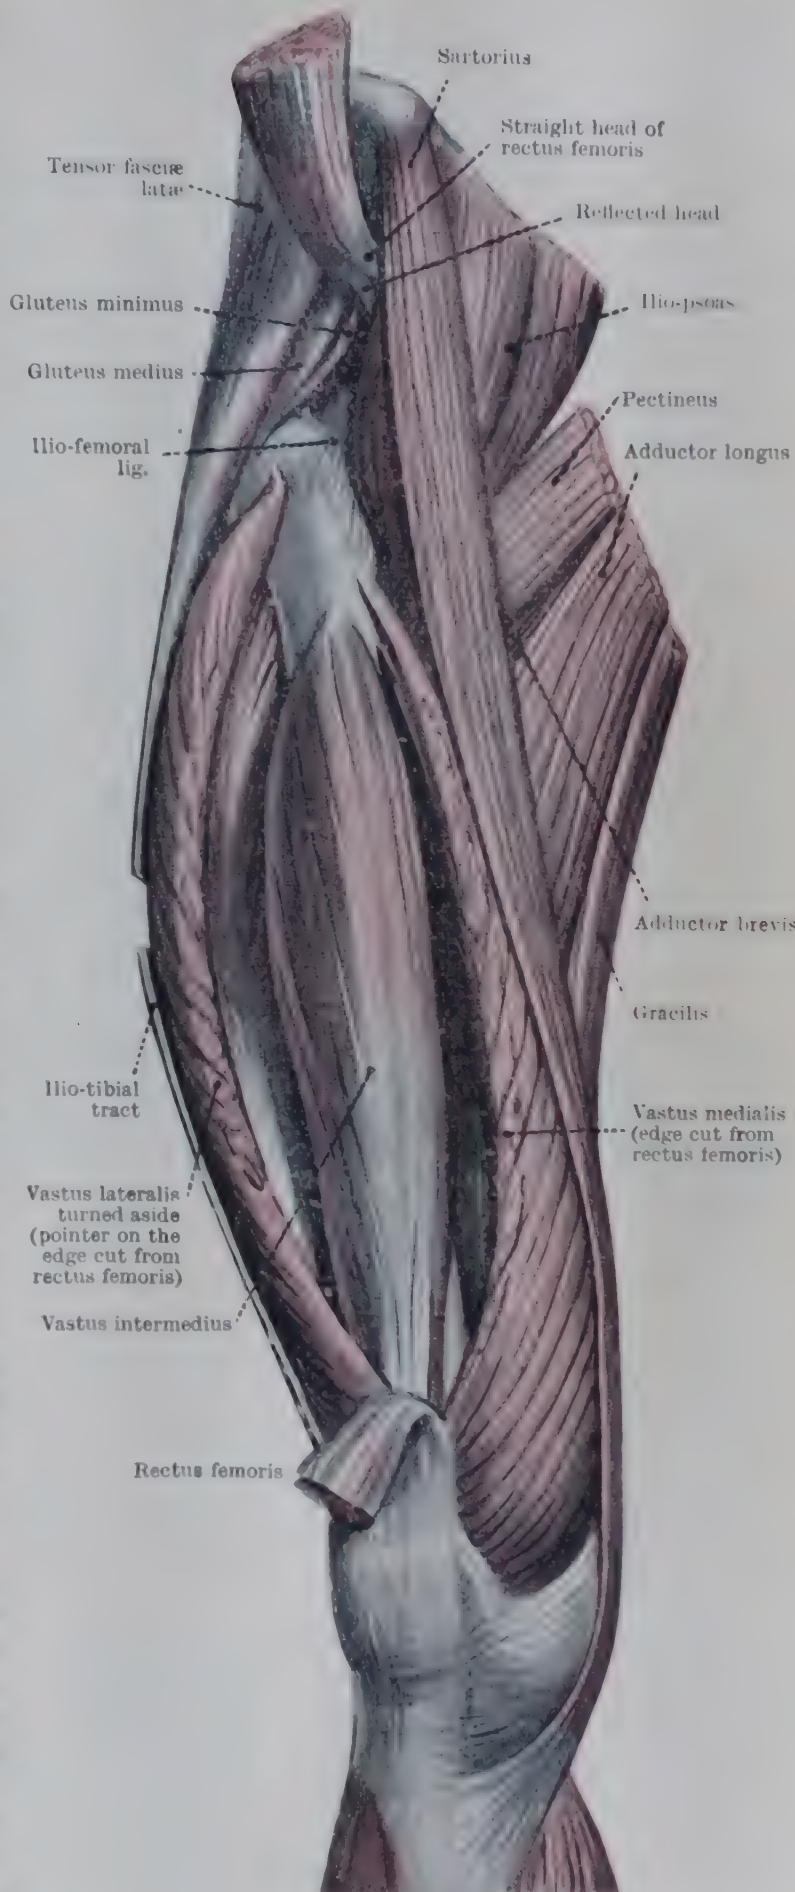

Fig. 449.—Dissection of Muscles of Front of Right Thigh.
The rectus femoris has been removed and the vastus lateralis and vastus medialis pulled apart to show the vastus intermedius.

Quadriceps Femoris.—The quadriceps femoris is composed of four muscles—rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis. The vastus intermedius clothes the shaft of the femur and is overlain by the rectus in front and the other vasti laterally and medially (Fig. 449).

Rectus Femoris.—The rectus femoris, a flattened spindle-shaped muscle, has a double, tendinous **origin** by a *straight head* from the anterior inferior iliac

spine, and a *reflected head* from a rough groove on the ilium immediately above the acetabulum—a *bursa* lying deep to this origin. The two heads are bound together and connected to the capsule of the hip joint by the band of fascia derived from the fascia on the deep surface of the tensor fasciæ latæ, and they give rise to a single tendon. The tendon, at first deeply placed, appears in the cleft between the sartorius and the tensor fasciæ latæ and swells out into the fleshy belly, which descends over the front of the vastus intermedius and the margins of the other two vasti. Becoming a tendon again, it is **inserted** into the upper border of the patella. The tendon of origin spreads for some distance over the front of the muscle and sends a tendinous septum into the middle of its substance as far down as the middle of the thigh. The muscle-fibres arise from the tendon and the septum in a bipenniform fashion, and end chiefly in a prolongation which extends from the tendon of insertion upwards over the lower two-thirds of the back of the muscle. The tendon of insertion gradually narrows as it descends but widens out again near the patella; and it receives parts of the insertion of the vasti on its margins and deep surface.

Vastus Lateralis.—The vastus lateralis—a thick, broad muscle—has an **origin**, partly fleshy, partly membranous, from (1) the capsule of the hip joint, (2) the upper part of the trochanteric line, (3) the lower border of the greater trochanter, (4) the lateral margin of the gluteal tuberosity, (5) the upper half of the linea aspera, and (6) the fascia lata and the lateral intermuscular septum (Figs. 261, 262, pp. 294, 295).

Its fibres are directed downwards and forwards, and are **inserted** by a broad membranous tendon into (1) the tendon of the rectus femoris, (2) the upper and lateral borders of the patella, and (3) the front of the lateral condyle of the tibia—covering, and to a large extent replacing, the antero-lateral part of the capsule of the knee joint.

Vastus Medialis.—The vastus medialis is larger than the vastus lateralis; it has an extensive **origin** from (1) the lower half of the trochanteric line, the spiral line, the linea aspera, and the upper two-thirds of the medial supracondylar line; and (2) the medial intermuscular septum and the tendon of the adductor magnus (Figs. 261, p. 294, and 262, p. 295).

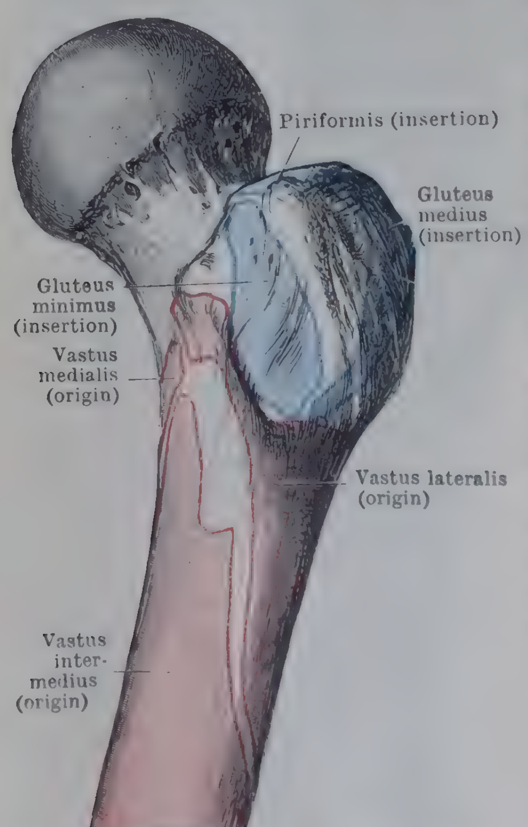

Fig. 450.—Muscle-Attachments to Front of Upper Part of Left Femur.

The muscle is directed downwards and laterally towards the knee, the lowest fibres being nearly horizontal. It is **inserted** by a strong aponeurotic tendon into (1) the rectus tendon, (2) the upper and medial borders of the patella, and (3) the front of the medial condyle of the tibia—covering and replacing the antero-medial part of the capsule of the knee joint. The muscle conceals the medial side of the shaft of the femur and the vastus intermedius, with which it is closely incorporated in its distal two-thirds.

Vastus Intermedius.—The vastus intermedius **arises** by fleshy fibres from—(1) the upper two-thirds of the shaft of the femur on the anterior and lateral surfaces—but not the medial surface; (2) the lower half of the lateral lip of the linea aspera and the upper part of the lateral supracondylar line; and (3) a corresponding portion of the lateral intermuscular septum (Figs. 261 and 262).

For the most part deeply placed, the muscle descends to an **insertion** into the deep surface of the tendons of the rectus and the other vasti muscles by fibres

which join a membranous expansion on its surface. It is closely adherent to the vastus lateralis muscle in the middle third of the thigh, and it is inseparable from the vastus medialis below the upper third. In the lower third it conceals the articularis genu muscle, and the *suprapatellar bursa*—an upward prolongation of the synovial membrane of the knee joint.

Articularis Genu.—This muscle consists merely of a number of small separate bundles that **arise**, deep to the vastus intermedius, from the lower fourth of the front of the femur and are **inserted** into the synovial membrane of the knee joint.

The four parts of the quadriceps femoris muscle have been traced in their convergence to the patella. Their ultimate **insertion** is into the tubercle of the tibia (Fig. 447), by means of the **ligamentum patellæ**; and the vasti muscles are in addition connected with the **retinacula of the patella**. The patella, indeed, is a *sesamoid bone*, playing the part of a lever and roller-bearing, formed in the

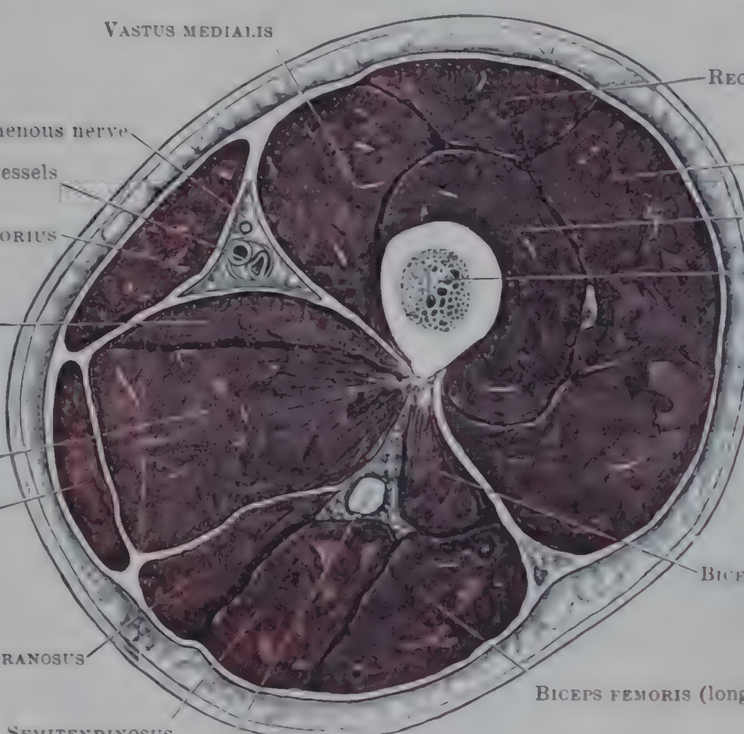

FIG. 451.—TRANSVERSE SECTION OF THIGH THROUGH THE SUBSARTORIAL CANAL.

tendon of the muscle, the ligamentum patellæ being the real tendon of insertion, and the retinacula being membranous expansions from its borders. The ligamentum patellæ replaces the anterior part of the capsule of the knee joint.

Nerve-Supply.—The four parts of the quadriceps femoris are supplied by separate branches of the **femoral nerve** (L. 3, 4); the sartorius receives its supply through two sets of nerves, in association with the lateral and medial parts of the intermediate cutaneous branch of the femoral nerve (L. 2, 3).

Muscles of Medial Side of Thigh

The muscles of the medial side of the thigh are the pectineus, the adductor muscles (longus, brevis, and magnus), the gracilis, and the obturator externus. The pectineus is included because of its situation and action, although it is supplied by the femoral nerve; and the obturator externus because of its situation and its nerve-supply from the obturator nerve.

The gracilis is superficially placed along the medial side of the thigh. The adductor muscles, situated in the medial part of the thigh between the hip bone and the femur, are in different vertical planes. The adductor longus is in the same plane as the pectineus and lies superficially in the femoral triangle; the adductor brevis, on a more posterior plane, is in contact with the obturator externus, and, with it, is largely concealed by the pectineus and adductor longus; the adductor

magnus, the largest and most posterior of these muscles, is in contact with the other adductors and the sartorius anteriorly, while its posterior surface is in relation to the hamstring muscles.

Gracilis.—The gracilis muscle, a long, flat band placed on the medial side of the thigh and knee, and superficial throughout its length, **arises** by a tendon, short, thin, and wide, from the lower half of the edge of the pubic symphysis and for a similar distance along the border of the pubic arch. Its tapering belly descends along the medial side of the thigh to lie between sartorius and semi-membranosus above the knee, and, at the knee, between the sartorius and semi-tendinosus; it ends in a tendon which expands to be **inserted** into the upper part of

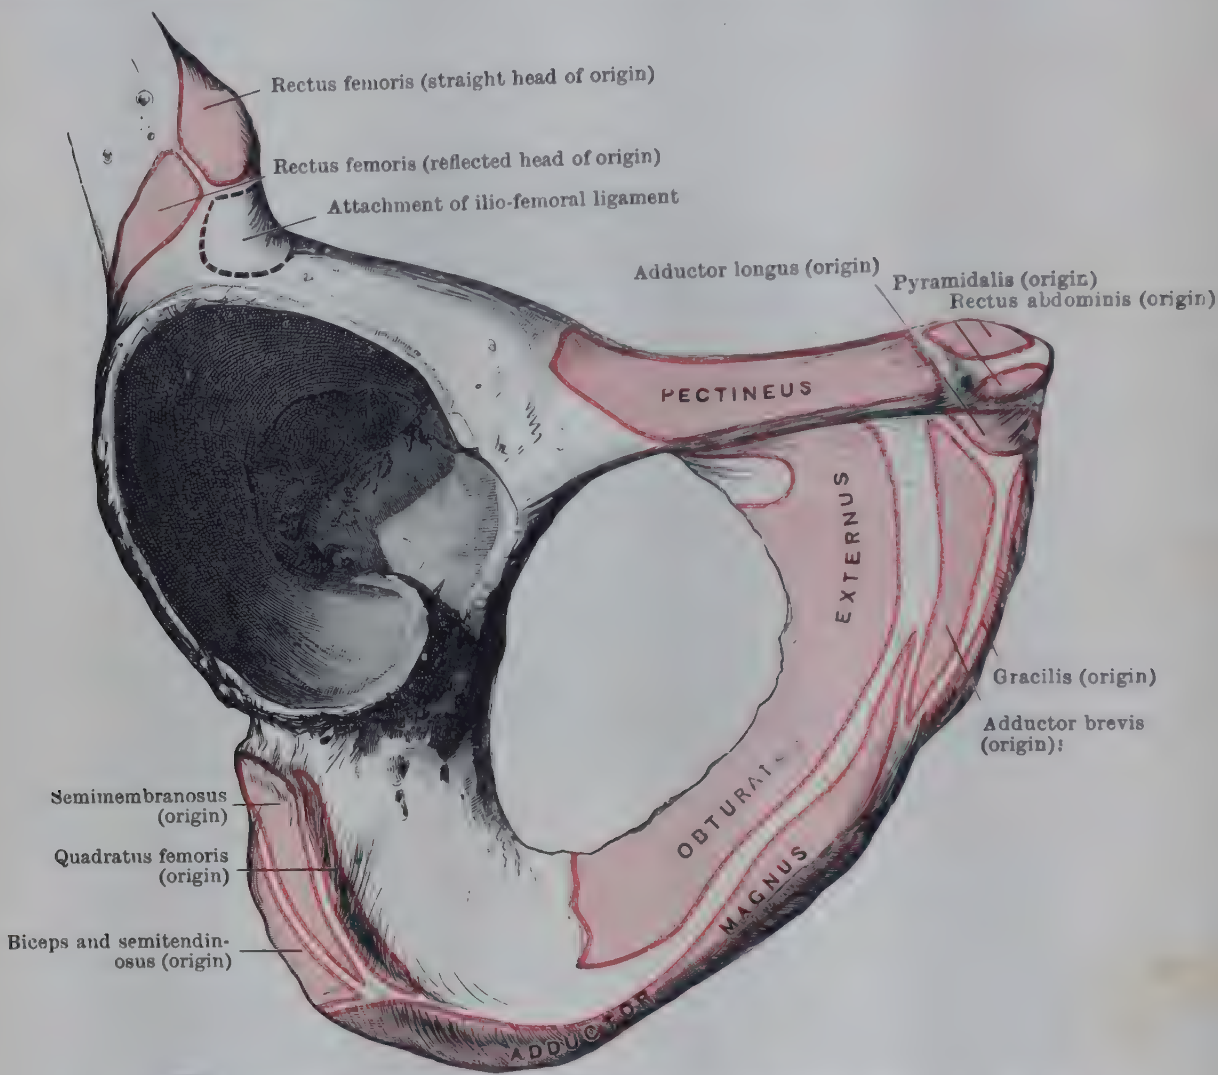

FIG. 452.—MUSCLE-ATTACHMENTS TO OUTER SURFACE OF RIGHT PUBIS AND ISCHIUM.
The actual origin of the pectineus is not so extensive as shown ; it arises from the upper part of the pectineal surface of the pubis and overlies the remainder.

the medial surface of the shaft of the tibia between the sartorius and the semi-tendinosus (Fig. 447). With semitendinosus, it is separated from the sartorius tendon by the *tibial intertendinous bursa*, and deep to its tendon there is a second *bursa* common to it and the semitendinosus.

Pectineus.—The pectineus muscle **arises** by fleshy fibres from the pectineal line and a small area on the medial part of the pectineal surface of the pubis and from the deep fascia which covers it. Forming a broad muscular band which lies in the floor of the femoral triangle between the psoas major and the adductor longus, it is **inserted** by a thin tendon, about two inches in width, into the upper half of a line that leads from the back of the lesser trochanter to the linea aspera (Fig. 441). The muscle is occasionally divided into medial and lateral parts—the medial innervated by the obturator, the lateral by the femoral nerve.

Adductor Longus.—The adductor longus—a triangular muscle, lying in the floors of the femoral triangle and subsartorial canal—**arises** by a strong tendon

from the femoral surface of the body of the pubis in the angle between the crest and symphysis (Fig. 452). Extending downwards and laterally, it spreads out to be **inserted** by a very thin, wide tendon into the medial lip of the linea aspera between the adductor magnus and vastus medialis. It lies between the pectineus and the gracilis, in front of the adductor brevis and magnus and the profunda vessels; superficially, its upper part is covered only with fascia and skin (but is crossed near its origin by the spermatic cord), and its lower part is related to the sartorius, the vastus medialis and the femoral vessels.

Adductor Brevis.—The adductor brevis is a large muscle which **arises** from an elongated area on the femoral surface of the body and inferior ramus of the

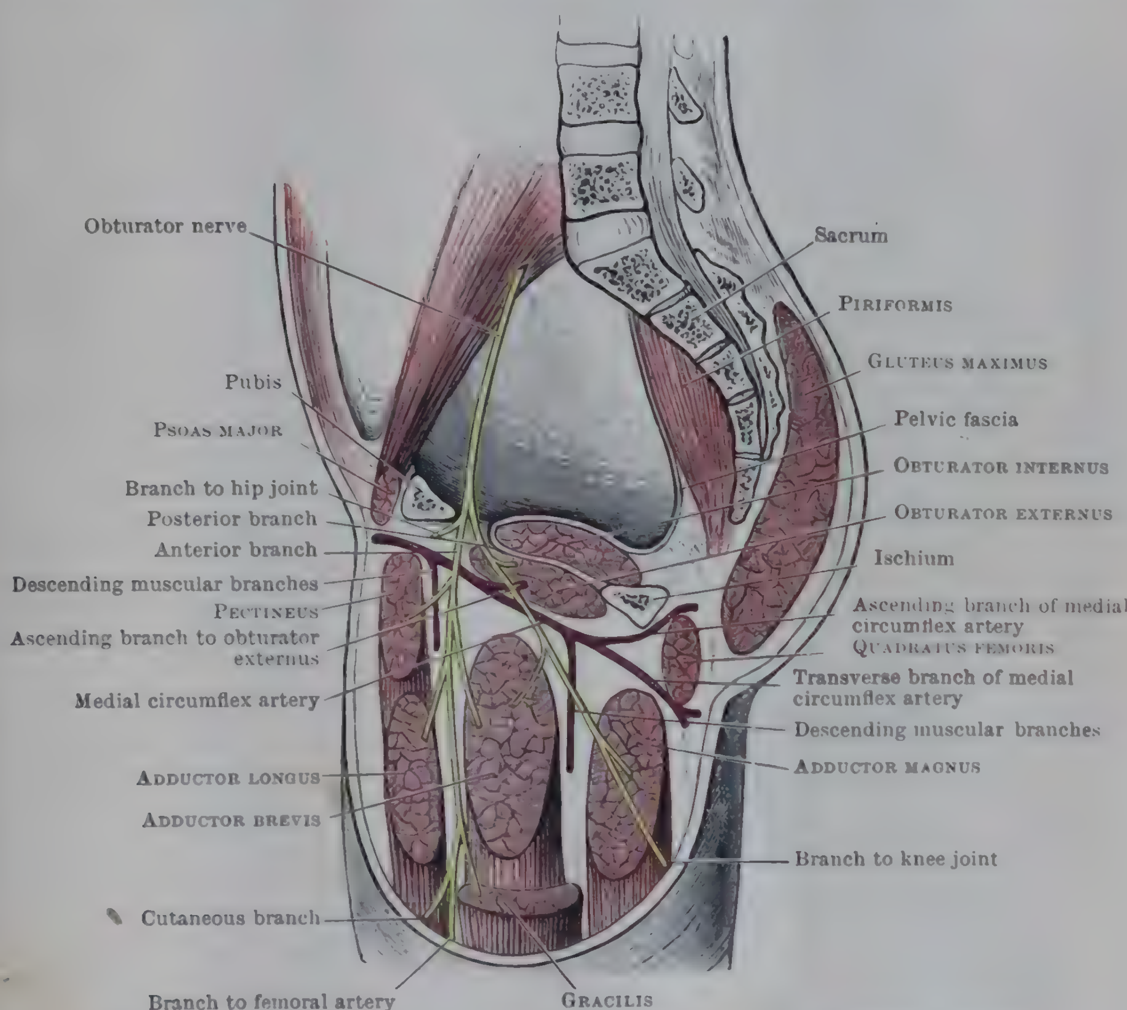

Fig. 453.—Scheme of Adductor Group of Muscles and Obturator Nerve.

pubis, surrounded by the other muscles of this group (Fig. 452). Directed downwards and laterally, the muscle expands to be **inserted**, by a short, aponeurotic tendon, behind the insertions of the pectineus and adductor longus, into the lower two-thirds of the line leading from the lesser trochanter to the linea aspera, and to the upper half of the linea aspera itself (Fig. 441, p. 516). It is in relation anteriorly with the pectineus and adductor longus, posteriorly with the adductor magnus; its upper border is crossed by the obturator externus and the tendon of the ilio-psoas; and its lower border is applied to the gracilis and adductor magnus.

Adductor Magnus.—This is the largest muscle of the adductor group and is triangular in outline. It **arises**, mainly by fleshy fibres, from the lower lateral impression on the ischial tuberosity and from the conjoined rami of the ischium and pubis—its most anterior fibres arising between the obturator externus and adductor brevis (Fig. 452). Its upper fibres are directed horizontally and laterally from the pubic bone towards the upper part of the femur; the lowest fibres descend from the ischial tuberosity to the medial condyle of the femur; and the intervening fibres radiate obliquely laterally and downwards. The muscle is **inserted** into the femur by tendinous fibres—(1) into a line extending from the

insertion of the quadratus femoris, medial to the gluteal tuberosity, to the linea aspera; (2) into the whole length of the linea aspera; (3) into the medial supracondylar line; and (4) into the adductor tubercle by a strong tendon derived from the fibres which arise from the ischial tuberosity. The tendon is bound to the medial supracondylar line by a tendinous sheet, and is partly continuous below with the medial ligament of the knee joint. The attachment to the linea aspera is interrupted by a series of tendinous arches which are thrown over the perforating branches of the profunda femoris artery, and the attachment to the supracondylar line is similarly interrupted by a larger archway—the **opening in the adductor magnus**—for the passage of the femoral vessels into the popliteal fossa.

Fig. 454.—Deep Muscles of Back of Right Thigh.

The part of the muscle attached between the insertion of the quadratus femoris and the linea aspera is often separated from the rest as the **adductor minimus.**

The muscle is covered anteriorly by the other adductors and by the sartorius muscle. The adductor brevis and the profunda femoris vessels lie between it and the adductor longus muscle; and the femoral vessels are in contact with it in the distal part of the subsartorial canal. The posterior surface of the muscle is in relation with the hamstring muscles and the sciatic nerve.

Obturator Externus.—The obturator externus, placed deeply, under cover of the preceding muscles, is a fan-shaped muscle that lies horizontally in the angle between the hip bone and the neck of the femur. It **arises** from the surfaces of the pubis and ischium which form the medial half of the margin of the obturator foramen, and from the corresponding portion of the superficial surface of the obturator membrane (Figs. 452, and 253, p. 287). The fibres of the muscle converge on the wide groove below the acetabulum and end in a stout tendon which passes obliquely across the back of the neck of the femur to be **inserted** into the trochanteric fossa (Fig. 441, p. 516); in its course it overlaps the capsule of the hip joint, from which it is usually separated by the synovial *bursa of the obturator externus.*

Nerve-Supply.—The principal nerve of supply to the adductor group of muscles is the **obturator** (L. 2, 3, 4); the anterior branch (L. 2, 3, (4)) is distributed to the **gracilis**, the **adduct**

PLATE XLIII

PLATE XLIII.—PHOTOGRAPHIC ILLUSTRATION OF MUSCLES IN ACTION. (From Lockhart's *Living Anatomy*, 1948, by permission of Messrs. Faber & Faber.)

The subject is 'setting' the muscles of the leg. Note the concavity of the popliteal fossa behind the flexed knee and the fullness of that region behind the straight knee.

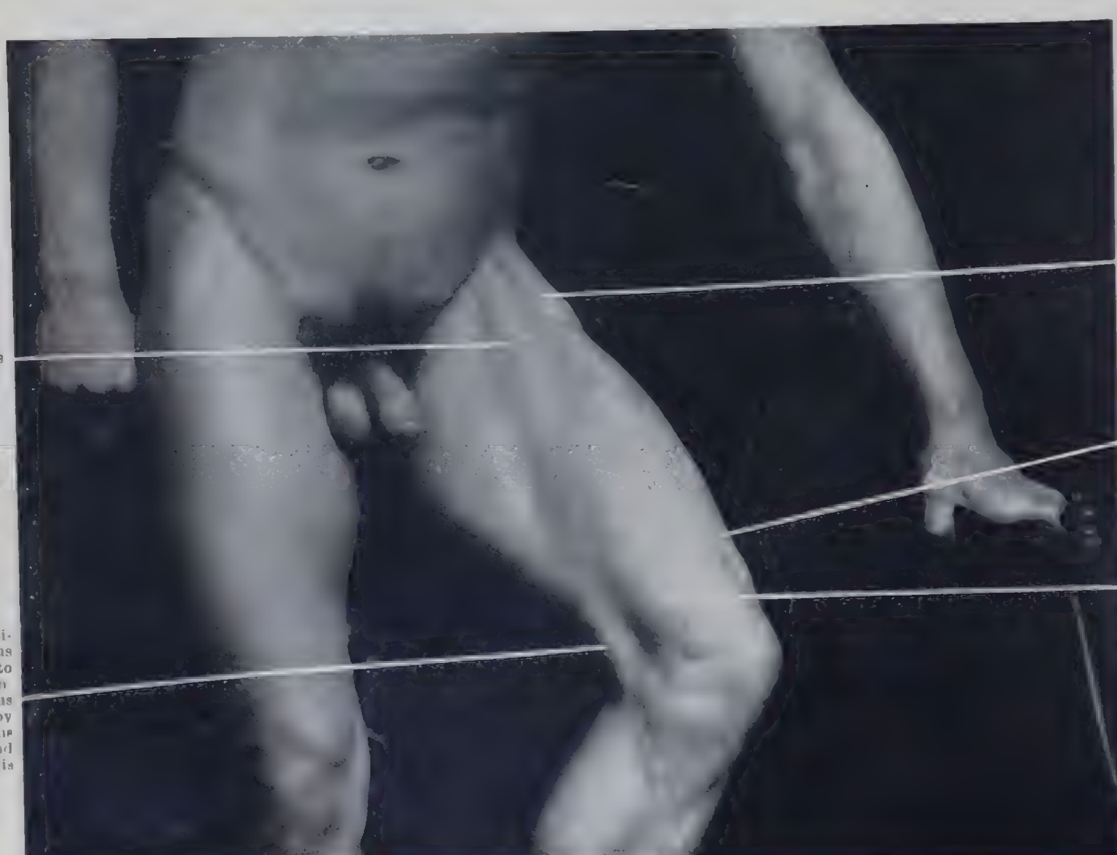

Fig. 3.—The Sartorius in Action.

Plate XLIV.—Photographic Illustrations of Muscles in Action.

[Facing

longus, and the **adductor brevis**; the posterior branch (L. 3, 4) to the **obturator externus** and the **adductor magnus**. The **adductor magnus** is, however, a double muscle and has a double nerve-supply. The *adductor* portion is supplied (on its anterior surface) by the posterior branch of the obturator: the *ischio-condylar* portion, associated with the hamstring group of muscles, is supplied (on its posterior surface) by a branch from the sciatic nerve (L. 4, 5 (S. 1)).

The **pectineus**, although it belongs functionally to the adductor group on account of its situation and action, is always supplied by a branch of the **femoral nerve** (L. 2, 3)—an indication of its morphological association with the ilio-psoas; it occasionally receives an additional nerve from the obturator, or from the accessory obturator nerve, when that nerve is present.

Femoral Triangle.—The femoral triangle is a large triangular space, in the upper third of the front of the thigh, which contains the femoral vessels in the first part of their course and the femoral nerve. It is bounded above by the inguinal ligament, laterally by the sartorius, and medially by the medial border of the adductor longus muscle. Its floor is formed laterally by the ilio-psoas, and medially by the pectineus, adductor longus, and, occasionally, a small part of the adductor brevis.

Subsartorial Canal (Hunter's Canal).—The subsartorial canal is in the middle third of the medial part of the thigh; it contains the femoral vessels (in the distal half of their course) and the saphenous nerve. It is bounded *antero-laterally* by the vastus medialis; *postero-medially* by the adductor longus and magnus; *antero-medially* (or superficially) by the sartorius; deep to the sartorius, a dense membrane, derived from the fascia lata, binds the other two boundaries together and bridges across the femoral vessels.

Action of Muscles in Movements at the Hip Joint.—In considering the muscles that move the joints of the lower limb we have to remember that they act from one end when the trunk is moved upon the limb and from the other when the limb is moved upon the trunk—conditions illustrated respectively in the supporting side and the advancing side during walking. Again, the line of the body-weight transmitted through the supporting limb must be observed, for its position, say, in front of the axis of movement of a joint, will call the antagonists of that movement into action. Though the muscles may be arranged in flexor, extensor, adductor, abductor, and rotator groups, individual muscle action is not always wholly in agreement with these terms, but may merge into the action of other groups. Action of the muscles that move the hip is usually associated with action at the other joints of the limb, for the hip is seldom flexed without accompanying, automatic flexion of the knee: indeed, if the knee is voluntarily kept extended, the flexors of the hip will be limited in their action by the inability of the hamstrings to relax unless trained to do so—as in the high kick. It is, therefore, largely a theoretical practice to consider the action at one joint alone: the muscular activity at all the joints must be reviewed when any one is considered. The extensors of the hip are stronger than the flexors in Man; and the adductors and lateral rotators are far more powerful than the abductors and medial rotators.

The **gluteus maximus** is mainly an extensor of the thigh, and has a powerful action in straightening the lower limb, as in climbing or running. Its lower fibres also adduct the thigh and rotate it laterally. Acting from its insertion the muscle (assisted by the hamstring group) is a powerful extensor of the trunk on the lower limbs and is called into play when the body is being raised from the sitting or stooping position; when these attitudes are being assumed from the erect position, its relaxation under tension is the main factor. The action of this muscle is all the more important in view of the fact that when the body is bent forwards, as in stooping to touch the floor, the vertebral column plays but a small part in the movement, which is mainly secured by relaxation of the gluteus maximus (and **hamstrings**) permitting flexion at the hip joint (Pl. XXXI, p. 346, Fig. 1). The **tensor fasciæ latæ** assists in flexion, abduction and medial rotation of the thigh, but its most important action is exerted in counteracting the backward pull of the gluteus maximus on the ilio-tibial tract; by this action it assists in maintaining extension of the knee, and it has, therefore, been found a suitable muscle to transplant as substitute for a paralysed quadriceps femoris (Dunn & Stuart, 1924). The **gluteus medius** is a powerful abductor of the thigh for all positions of the limb, and a medial rotator of the extended thigh. The **gluteus minimus** is primarily an abductor of the thigh, but its anterior fibres, in addition, produce medial rotation, and its posterior fibres lateral rotation of the extended limb. Both the gluteus medius and gluteus minimus take an active part in the movements of the pelvis associated with walking, and their paralysis (much more serious than that of gluteus maximus) severely alters the gait, causing a peculiar

lurching style of walk. When one limb leaves the ground, the centre of gravity of the body no longer falls within the area of support, but the action of gravity is successfully opposed by the abductors of the opposite side. Further, as one limb advances, the pelvis is rotated to the opposite side by the gluteus medius and minimus of that side (see pp. 408 and 549). In this connection, the muscular control of gravitational movement is highly important. The moment the abductors, acting against gravity, have poised the trunk upon, say, the right limb, any further inclination to the right (which would be assisted by gravity) results in immediate flaccidity of the abductors, and powerful action of the adductors, which permit the desired inclination by relaxing under tension. There is a position of equilibrium in which the two sets of muscles have little action; but the alternate contraction of one or other group is readily seen in varied movements of the trunk poised on one limb.

The lateral rotators of the thigh are the **piriformis**, the **obturator internus** with the **gemelli**, the **quadratus femoris**, and the **obturator externus**. The piriformis and obturator internus act as lateral rotators of the extended thigh, and as abductors when the limb is flexed; the quadratus femoris and obturator externus, in addition to their action as lateral rotators, are adductors. These short muscles probably have more important actions in restraining movements at the hip joint, *i.e.*, ligamentous action, and they act as postural and articular muscles like those of the shoulder (p. 487) in facilitating movement effected by the more powerful muscles.

The chief flexors of the hip joint are the **psoas major** and the **iliacus**; their action is accompanied by a slight degree of medial rotation. (*N.B.*—The axis of rotation does *not* correspond to the shaft of the femur but to a line drawn from the middle of its head to the centre of the intercondylar notch when the limb is extended.) The ilio-psoas advances the limb in walking, and its paralysis interferes with the normal gait. In addition, acting from their insertions, the ilio-psoas muscles can flex the trunk on the lower limbs against resistance, and the psoas major can produce lateral flexion of the vertebral column. The **psoas minor** assists in the latter movement, and in flexing the pelvis on the vertebral column, or the vertebral column on the pelvis. When the knee is extended the **rectus femoris** is a powerful assistant of the ilio-psoas as a flexor of the hip joint; it has indeed been maintained that flexion of the hip joint is the chief action of that part of the quadriceps. The straight head of the rectus is taut when the movement begins, but it becomes a little relaxed and the reflected head is tightened when the thigh becomes flexed. When the body is recumbent, with the knees extended, the two recti assist the ilio-psoas muscles to flex the trunk on the hips.

In addition to their chief action, the muscles of the adductor group assist in other movements at the hip joint. The **pectineus,** while mainly an adductor, is also a flexor of the hip; the **adductors longus** and **brevis** assist in flexion and lateral rotation; the proximal part of the **adductor magnus** has a similar action, while the distal fibres, acting with the hamstrings, take part in extension of the femur and may assist in medial rotation.

The hamstring muscles (**long head of the biceps, semitendinosus,** and **semimembranosus**), in virtue of their attachment to the ischial tuberosity, assist the gluteus maximus in extension of the thigh.

Action of Muscles in Movements at the Knee Joint.—In addition to the flexor and extensor groups of the thigh, the muscles of the leg which take origin from the femur are concerned in movements at the knee joint. The greater power of the flexors compared with the extensors (in contrast with the hip joint) is again a human characteristic.

The **quadriceps femoris** is the great extensor of the limb at the knee joint; it can be felt in action both when one rises from the sitting position and when one assumes that position—taking active part in the first movement and controlling the other. The tendency for the patella to be pulled laterally as well as upwards is counteracted by the distal, horizontal fibres of the vastus medialis. The **articularis genu** draws the synovial membrane of the joint upwards during this movement.

The hamstring muscles are essentially flexors of the leg at the knee joint. When the knee is flexed the **biceps** is, in addition, a lateral rotator of the leg, and the **semitendinosus** and **semimembranosus** are additional medial rotators.

The **sartorius** —"the tailor's muscle"—is a feeble flexor of both the hip joint and the knee joint. It also adducts the thigh and rotates it laterally, and it assists in medial rotation of the tibia. The **gracilis** muscle has a similar flexing and rotating action at the knee joint.

Three muscles of the leg also act upon the knee joint. The **gastrocnemius,** assisted by the feeble action of the **plantaris,** takes part in flexing the leg upon the thigh when resistance is encountered as in Pl. XLIV, p. 529, Fig. 2. The **popliteus**

has a special action as a medial rotator of the tibia and a flexor of the knee. It is believed that the popliteus muscle is responsible for the unlocking movement of medial rotation of the tibia which occurs immediately before, or synchronous with, the initial stage of flexion of the fully extended knee joint. The popliteus and the short head of the biceps are the only two flexors of the knee confined in their action to that joint. As the hip and knee are usually both flexed or both extended together, their flexors and extensors work in unison. Some muscles, *e.g.*, the rectus femoris and the long head of the biceps, act upon both joints, as extensors of one and flexors of the other, and they may be unable, individually, to secure at the same time the maximum movement at both, *e.g.*, the rectus femoris having extended the knee may not be able to secure full flexion of the hip, even if the hamstrings are relaxed as in the high kick. The last stage of flexion of the hip in this exercise may be due to the momentum imparted to the limb in the initial stage of the movement. Again, the long head of the biceps (the muscular fibres of which are shorter than those of the short head), cannot flex the knee so far when the hip is extended. Quite apart from this point, the flexors of the knee do not, in the average person, secure the full flexion at this joint even when the hip is flexed, though the momentum of a slight backward kick can carry the heel into contact with the thigh, and the weight of the body may secure the full movement, as in sitting upon the heels. The main point is that the muscles are efficient for all natural movements, that their abilities are remarkably increased by training, and that contortionist movements are executed either by the aid of gravity or by pulling the limbs into place while appropriate muscles are stretched or relaxed. For postural action, see pp. 409, 543, 549. (See Pl. XLIII, p. 528, and Pl. XLV, Figs. 1 & 2, p. 546.)

FASCIÆ OF THIGH AND GLUTEAL REGION

The **superficial fascia** of the thigh and gluteal region is continuous above with the fascia of the abdomen and back, medially with that of the perineum, and below with that of the leg. It presents noticeable features in the gluteal region and the groin.

In the gluteal region the superficial fascia is of considerable thickness, and is usually loaded with fat, thereby contributing to the contour of the buttock and the formation of the fold of the buttock.

In the groin it is divisible into *two layers*, separated from each other by the superficial inguinal lymph-glands and subcutaneous vessels: a superficial **fatty layer**, continuous with the similar layer on the anterior surface of the abdominal wall and in the perineum, and a deeper **membranous layer**. The deeper layer is attached medially to the pubic arch, where it is continuous with the membranous layer of the superficial fascia of the perineum (p. 468); lateral to the arch it blends with the deep fascia of the thigh a short distance below the inguinal ligament; superiorly, it is continuous with the similar layer in the abdominal wall. Its attachments cut off the more superficial tissues of the thigh from the perineum and the abdominal wall, preventing the passage into the thigh of fluid collected in the perineum or beneath the fascia of the abdominal wall.

The **deep fascia** forms a tubular investment for the muscles and vessels of the thigh and extends upwards over the muscles of the gluteal region. It is firmly attached above to the iliac crest, the sacro-tuberous ligament, the ischium, the pubic arch, the pubic symphysis and crest, and the inguinal ligament. In the distal part of the thigh the intermuscular septa are connected with its deep surface; and, in the region of the knee, it is continuous with the deep fascia of the leg and gains attachment to the condyles of the tibia, the head of the fibula, and the patella—forming the medial and lateral retinacula of the patella. The portion that invests the thigh is called the **fascia lata**.

The immediate relations of the fascia lata in its descent from the inguinal ligament will be appreciated best if we consider first of all the disposition of structures as they cross the inguinal border between abdomen and thigh (Figs. 456, 457).

The **transversalis fascia** and **fascia iliaca** (different names for different parts of the same fascial sheath, p. 465) are prolonged in an oval, funnel-like tube—the **femoral sheath**—upon the front and back respectively of the vessels that pass

behind the inguinal ligament from the abdomen into the thigh. At the lateral side of the lip of the funnel these two layers are confluent; lateral to this point they are blended in their attachment to the inguinal ligament, and therefore are not prolonged into the thigh. At the medial side of the lip the two layers, again confluent, course past the lateral edge of the pectineal part of the inguinal ligament. Behind the inguinal ligament there are, therefore, two large compartments—a medial and a lateral. The medial compartment transmits the femoral sheath (itself divided into three compartments); the lateral transmits the ilio-psoas muscle, the femoral nerve, and the lateral cutaneous nerve of the thigh.

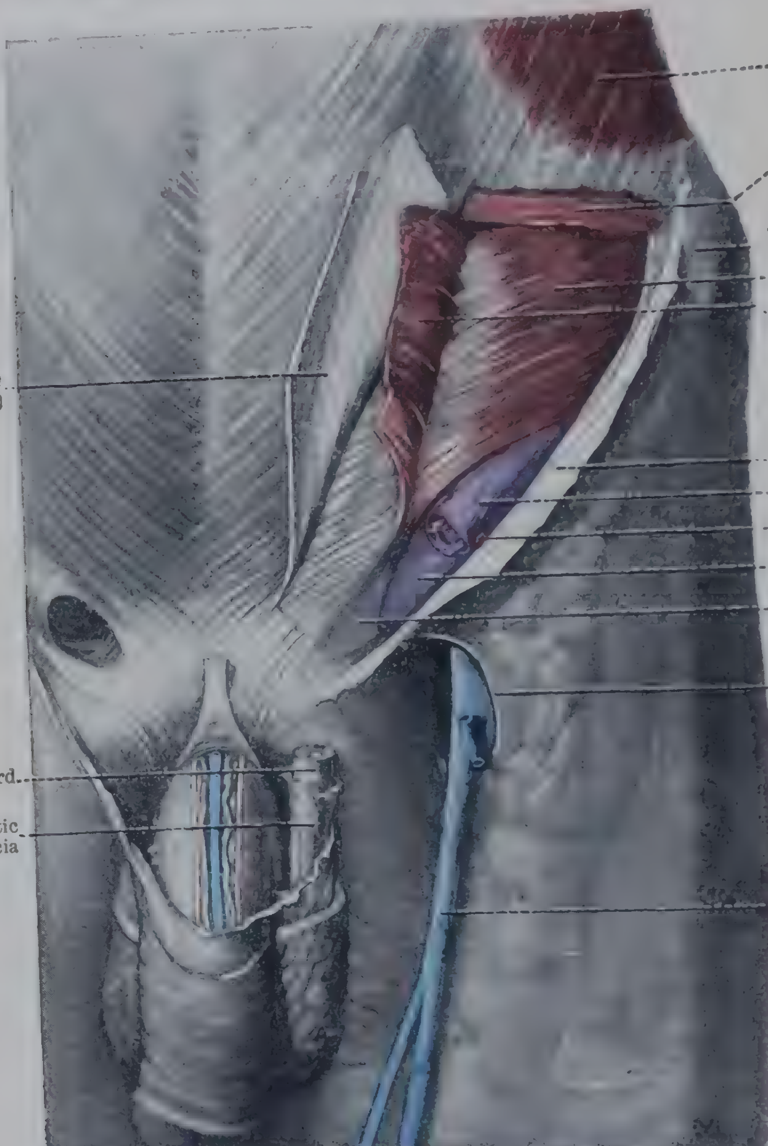

Fig. 455.—Dissection of Left Saphenous Opening.

(Bearing in mind the fact that the fascia iliaca, stretching from the iliac crest to the brim of the pelvis, thus strapping down the ilio-psoas in the iliac fossa, is continued upwards over the surface of the psoas major, it will be readily understood that inflammatory exudates from disease of the 'psoas' vertebræ track down on the surface of the muscle, behind the fascia iliaca and run behind the inguinal ligament in the muscular compartment to enter the thigh behind the fascia lata, lateral to the femoral sheath.) The femoral sheath, then, has a cover of fascia lata in front, while its bed is a muscular furrow formed by the ilio-psoas muscle and the pectineus, both covered with deep fascia—the fascia on the pectineus being tucked in behind the sheath to fuse with the capsule of the hip joint and with the fascia of the ilio-psoas in the thigh. The femoral sheath, itself, is divided by septa into three tubes—a lateral for the artery, an intermediate for the vein, and a medial named the femoral canal. The **femoral canal** contains some fat and a few lymph-vessels; its upper end—named the **femoral ring**—covered with

peritoneum and possibly occupied by a lymph-gland, is situated between the femoral vein and the lateral margin of the pectineal part of the inguinal ligament. The sheath is about an inch and a half long and terminates in the region of the saphenous opening, becoming lost upon the coats of the vessels. Its lateral wall is pierced by the femoral branch of the genito-femoral nerve and its anterior wall by the long saphenous vein.

On the front of the thigh, then, the fascia lata, continued from the inguinal ligament, is immediately applied to the femoral sheath in the intermediate area, to the ilio-psoas and sartorius laterally, and to the pectineus and adductor longus medially. But in this region—opposite the contiguous margins of the pectineus and psoas and the medial part of the femoral sheath—it presents an oval gap, named the saphenous opening. The **saphenous opening** is immediately below the medial part of the inguinal ligament; it is about an inch and a half long and half an inch wide, and its centre is an inch and a half below and lateral to the pubic tubercle. Medially, it is bounded by the sloping, anterior surface of the pectineus, covered with fascia extending laterally posterior to the femoral sheath. Its upper, lateral, and lower boundaries form one sharp, curved edge called the **falciform margin** of the opening, over whose lower part the long saphenous vein dips backwards to pierce the femoral sheath and enter the femoral vein—which is opposite the opening, while the artery is overlapped by the lateral boundary. The opening is closed by a layer of fibrous and fatty tissue which is perforated by the long saphenous vein, small arteries and lymph-vessels, and is therefore termed the **cribriform fascia**.

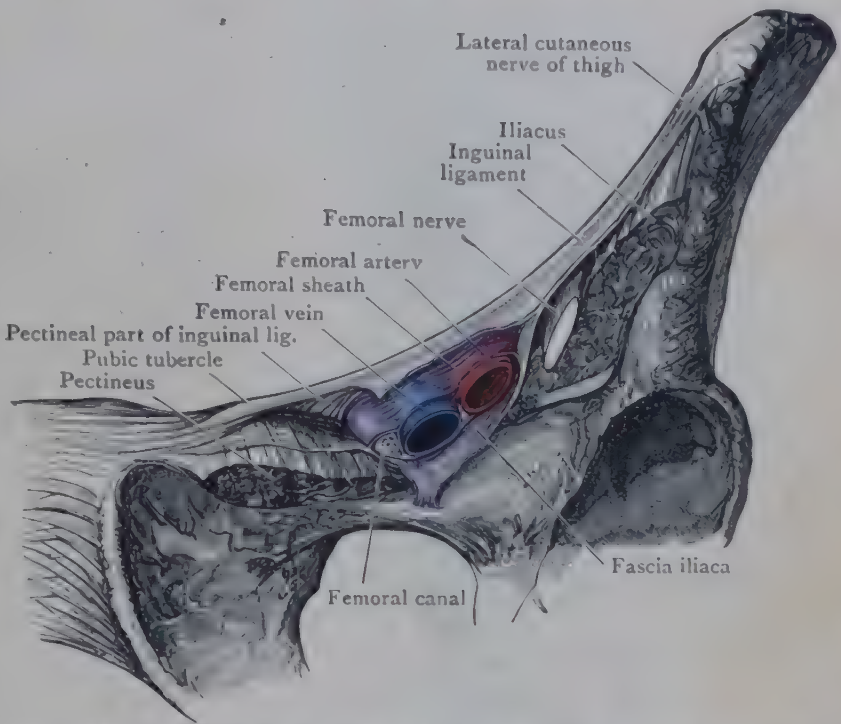

FIG. 456.—DISSECTION TO SHOW FEMORAL SHEATH AND STRUCTURES WHICH PASS BETWEEN INGUINAL LIGAMENT AND HIP-BONE.

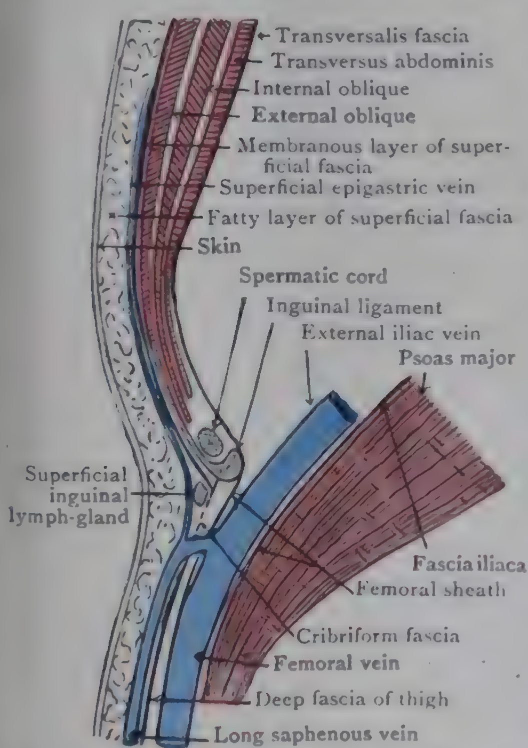

FIG. 457.—DIAGRAM OF FASCIÆ AND MUSCLES OF INGUINAL AND SUBINGUINAL REGIONS IN THE LINE OF THE SAPHENOUS OPENING.

When herniation occurs down through the femoral ring, femoral canal, and saphenous opening, the condition is termed a *femoral hernia*. This, subsequently rising up on to the abdominal wall, may be mistaken for an inguinal hernia; the successful reduction of both types depends upon their being made to retrace their different anatomical routes. The coverings of a femoral hernia, in addition to extra-peritoneal tissue, are the femoral sheath, cribriform fascia, superficial fascia and skin.

The fascia lata is pierced by numerous vessels and nerves, but the largest and most important aperture is the saphenous opening just described (Fig. 455).

On the medial side of the thigh, where it covers the adductor muscles, the fascia lata is thin. At the knee it is associated with the tendons of the vasti muscles, and forms the medial and lateral **retinacula of the patella**, attached to the borders of the patella and to the condyles of the tibia. On the lateral side of the thigh it is thickened by longitudinal fibres to form the **ilio-tibial tract**. This wide, strong band extends from the tubercle of the iliac crest to the lateral condyle of the tibia and the capsule of the knee joint. It receives the insertion of three-quarters of the gluteus maximus and the whole of the tensor fasciæ latæ, and it is continuous with both of the layers of fascia that enclose the tensor.

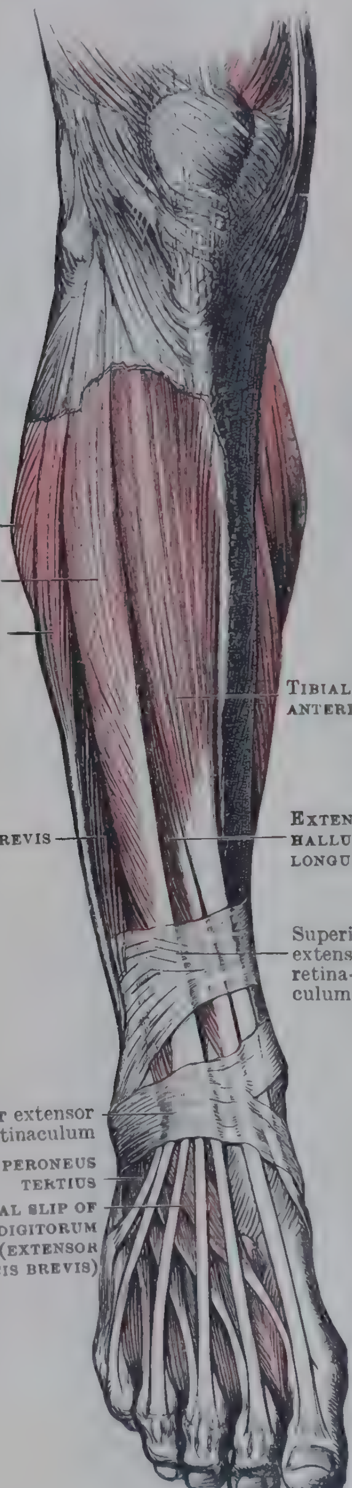

FIG. 458.—MUSCLES OF FRONT OF LEG AND DORSUM OF FOOT OF RIGHT SIDE.

On each side of the thigh above the knee an intermuscular septum is formed. The **lateral intermuscular septum** extends from the ilio-tibial tract to the lateral supracondylar line and the linea aspera of the femur, giving attachment to the vastus lateralis and intermedius anteriorly, and the short head of the biceps posteriorly. The **medial intermuscular septum,** in the distal third of the thigh, is associated with, and to a large extent represented by, the tendon of insertion of the adductor magnus muscle. It is related also to the fascia which envelops the adductor muscles and forms the sheaths of the sartorius and gracilis. In the middle third of the thigh the fascia under the sartorius is greatly thickened by transverse fibres and binds the vastus medialis to the adductor longus and magnus. That layer of fascia roofs over the femoral vessels in their course through the *subsartorial canal.*

On the **back of the thigh** and over the **popliteal fossa** the fascia is strengthened by transverse fibres. The fascia forming the roof of the popliteal fossa is specially thick, and is usually pierced by the short saphenous vein and the posterior cutaneous nerve of the thigh.

The **fascia of the gluteal region** is thick anteriorly, where it covers and gives origin to the gluteus medius, but is much thinner posteriorly, where it splits to enclose the gluteus maximus. Over the greater trochanter it becomes continuous with that part of the ilio-tibial tract into which most of the fibres of the gluteus maximus gain insertion.

MUSCLES AND FASCIÆ OF LEG AND FOOT

The muscles of the leg and foot are divisible into three series: (1) the extensor muscles on the front of the leg and dorsum of the foot; (2) the peroneal muscles on the lateral side of the leg; and (3) the flexor muscles on the back of the leg and in the sole of the foot.

Muscles on Front of Leg and Dorsum of Foot

These muscles are the tibialis anterior, the extensor hallucis longus, the extensor digitorum longus and peroneus tertius, and the extensor digitorum brevs.

On the front of the leg the tibialis anterior, extensor digitorum longus and peroneus tertius are superficially placed, and conceal the extensor hallucis longus muscle. On the dorsum of the foot, the extensor digitorum brevis is deep to the tendons of the extensor digitorum longus and peroneus tertius.

Tibialis Anterior.—The tibialis anterior **arises** from the lateral condyle and the upper two-thirds of the lateral surface of the shaft of the tibia, from the interosseous membrane, from the deep fascia, and from an intermuscular septum laterally. The muscle ends in a strong tendon which becomes free in the lower third of the leg and passes downwards and medially over the front of the distal end of the tibia, the ankle joint, and the dorsum of the foot, to be **inserted** into the medial sides of the medial cuneiform and base of the first metatarsal bone near the sole (Fig. 294, p. 319). Special compartments, lined with a separate synovial sheath, are provided for the tendon in both the superior and inferior extensor retinacula.

The double insertion recalls the double muscle in pronograde apes.

The **tibio-fascialis anterior** is a separated portion of the muscle occasionally present, inserted into the fascia on the dorsum of the foot.

Extensor Digitorum Longus.—This is a pennate muscle which **arises**, by fleshy fibres, from the lateral side of the lateral condyle of the tibia, from the upper two-thirds or more of the anterior surface of the shaft of the fibula, from the deep fascia and intermuscular septa, and from the upper part of the interosseous membrane.

It gives rise to a tendon which passes deep to the superior

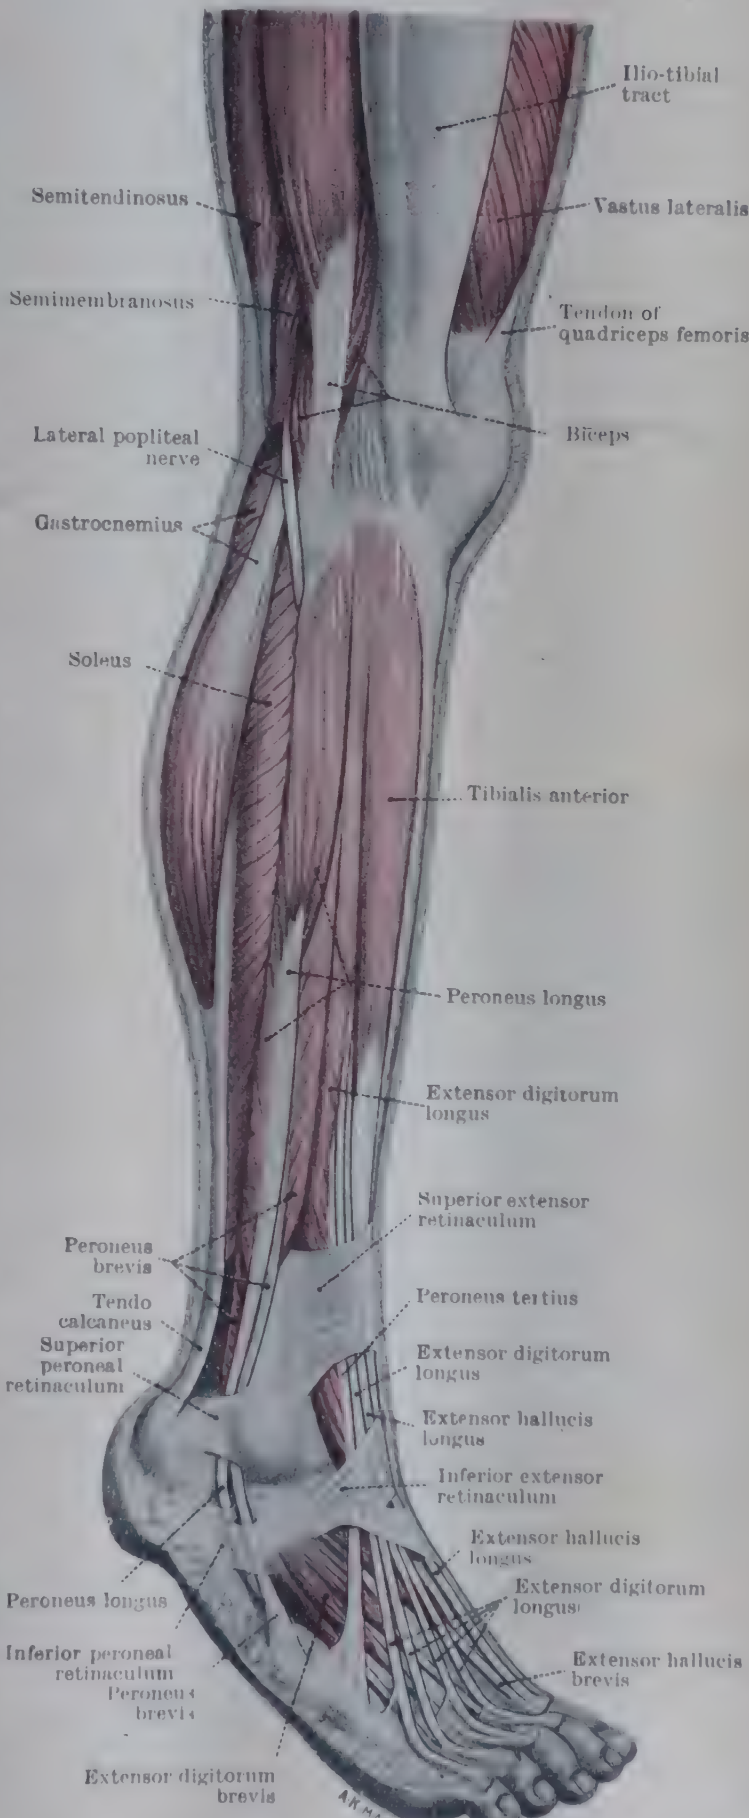

FIG. 459.—MUSCLES OF KNEE, LEG, AND DORSUM OF FOOT SEEN FROM LATERAL SIDE.

extensor retinaculum, and divides into four tendons on the front of the ankle, under cover of the inferior extensor retinaculum; these tendons, together with the tendon of the peroneus tertius, are enclosed in a single synovial sheath as they lie in the most lateral compartment of this retinaculum. They are **inserted** into the lateral four toes, exactly in the same way as the corresponding tendons in the hand (see p. 502), and form membranous expansions on the dorsum of the proximal phalanx, joined by the tendons of the extensor digitorum brevis, lumbricales, and interossei, and each then separates into one middle and two collateral slips, attached respectively to the middle and distal phalanges.

Peroneus Tertius.—The peroneus tertius, very variable in its size and sometimes absent, is a partially separated portion of the extensor digitorum longus. It **arises** (inseparably from the extensor) from the lower part of the anterior surface of the fibula, and from the intermuscular septum on its lateral side. Its tendon is **inserted** into the dorsum of the fifth metatarsal bone near its base.

Extensor Hallucis Longus.—The extensor hallucis longus **arises** from the anterior surface of the fibula in its middle three-fifths, medial to the origin of the extensor digitorum longus, and for a corresponding extent from the interosseous membrane. Its tendon passes over the dorsum of the foot, to be **inserted** into the base of the distal phalanx of the big toe. As the tendon lies under cover of the superior extensor retinaculum, it occupies the same compartment as the extensor digitorum longus and the peroneus tertius, but, in the inferior extensor retinaculum, it is provided with a special compartment, lined with a separate synovial sheath.

It is occasionally inserted also by separate slips into the proximal phalanx and the metatarsal bone.

Extensor Digitorum Brevis.—The extensor digitorum brevis **arises** from the fore part of the upper surface of the calcaneum and from the deep surface of the inferior extensor retinaculum. It usually divides into four fleshy bellies from which narrow tendons are directed forwards and medially to be **inserted** into the medial four toes. The lateral three tendons join those of the long extensor muscle to form the membranous expansions on the dorsum of the toes. The *most medial tendon* (**extensor hallucis brevis**), after crossing the dorsalis pedis artery, is inserted separately into the base of the proximal phalanx of the big toe.

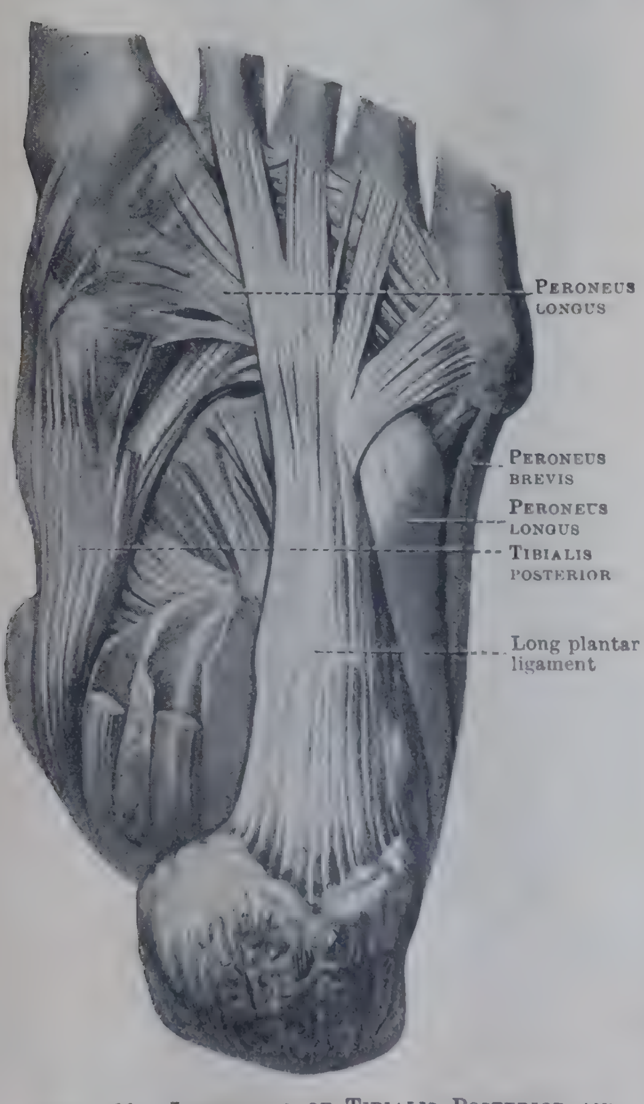

FIG. 460.—INSERTIONS OF TIBIALIS POSTERIOR AND PERONEUS LONGUS IN SOLE OF LEFT FOOT.

Muscles on Lateral Side of Leg

The peroneal muscles—longus and brevis—occupy a special osteo-fascial compartment on the lateral side of the leg where they are placed between the extensor digitorum longus in front and the soleus and flexor hallucis longus behind.

Peroneus Longus.—The peroneus longus **arises** from the lateral condyle of the tibia, from the head and the upper two-thirds of the lateral surface of the shaft of the fibula, from intermuscular septa at its sides, and from the fascia covering the muscle.

It forms a stout tendon, which lies superficial to the peroneus brevis,

and hooks round the lateral malleolus deep to the superior peroneal retinaculum, where it is invested by a synovial sheath common to it and the peroneus brevis (p. 553). Then, crossing the lateral side of the calcaneum under cover of the inferior peroneal retinaculum, it diverges from the peroneus brevis tendon, passes below the peroneal tubercle, and, finally, crosses the sole of the foot obliquely to be **inserted** into the lateral sides of the medial cuneiform and base of the first metatarsal bones (Fig. 294, p. 319). As it enters the sole of the foot a *sesamoid fibro-cartilage* (occasionally a bone) is formed in the tendon where it plays over the smooth surface of the tuberosity of the cuboid bone. In its passage across the foot the tendon traverses the groove on the cuboid and is enclosed in a fibrous sheath derived from the long plantar ligament and the tibialis posterior tendon. A synovial sheath also invests this part of the peroneal tendon.

Peroneus Brevis.—The peroneus brevis **arises** by fleshy fibres from the lower two-thirds of the lateral surface of the shaft of the fibula (its upper half arising anterior to peroneus longus), and from intermuscular septa at its sides. Its tendon grooves the back of the lateral malleolus, invested by the synovial sheath common to it and the peroneus longus (p. 553). Farther forwards it passes above the peroneal tubercle and is **inserted** into the dorsal surface of the base of the fifth metatarsal bone.

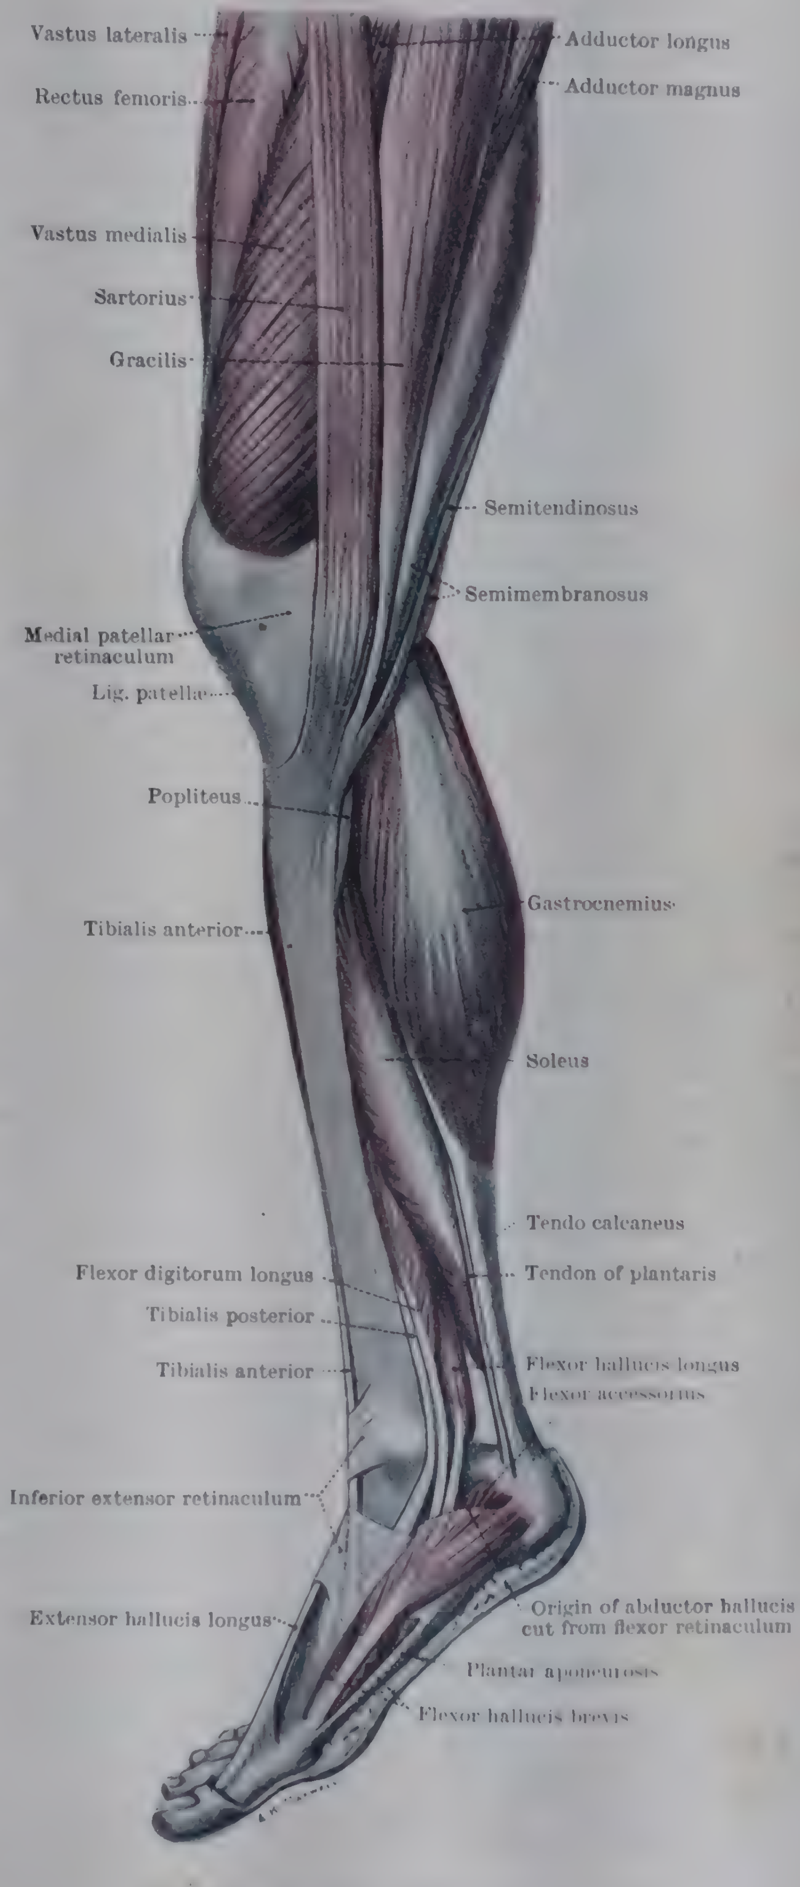

Fig. 461.—Muscles of Knee, Leg, and Foot seen from Medial Side.

The peroneus longus and brevis may be fused together, or additional slips may be present which either join the tendon of the peroneus longus (**peroneus accessorius**) or are inserted into the calcaneum or the cuboid ; an occasional tendinous slip of the peroneus brevis which joins the long extensor tendon of the little toe is known as the **peroneus digiti minimi.**

Muscles on Back of Leg

The muscles on the back of the leg are in two groups—superficial and deep.

The **superficial muscles** are the gastrocnemius, soleus, and the plantaris. The gastrocnemius and the soleus, by their bulk, form the calf of the leg, the massiveness of which is peculiar to Man and is associated with his ability to maintain the erect position while walking and running. The gastrocnemius is superficial except at its origin, where two bellies, forming the boundaries of the popliteal fossa, are overlapped by the tendons of the hamstring muscles. The soleus muscle is partially concealed by the gastrocnemius and plantaris, and becomes superficial in the distal part of the leg on each side of the common tendon (tendo calcaneus).

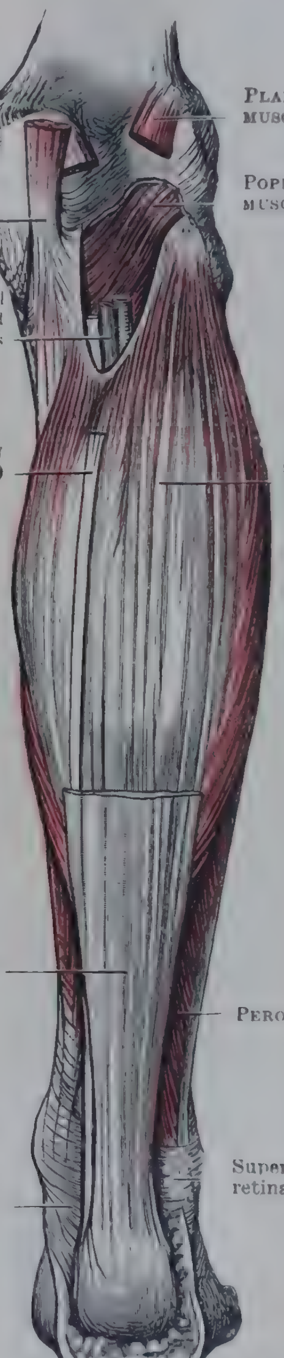

FIG. 462.—RIGHT SOLEUS MUSCLE.

Gastrocnemius [γαστήρ (gaster) = belly ; κνήμη (knēmē) = leg].—The gastrocnemius **arises** by *two heads*, medial and lateral, by strong tendons which are prolonged over the surface of the muscle. The **lateral head** arises from an impression on the upper and posterior part of the lateral surface of the lateral condyle of the femur, and from the distal end of the lateral supracondylar line ; at its origin it may contain a sesamoid bone. The **medial head** arises from a rough mark on the popliteal surface of the femur above the medial condyle. Each head has an additional origin from the back of the capsule of the knee joint. A *bursa* lies deep to each tendon of origin. The bursa of the medial head frequently communicates with the cavity of the knee joint and also with a *bursa* which intervenes between the medial head and the tendon of the semimembranosus. The bursa of the lateral head is smaller, and rarely communicates with the knee joint.

The two fleshy bellies, of which the medial is the larger, remain separate (Pl. XLIV, p. 529, Fig. 1) and are inserted into the posterior surface of a broad, membranous tendon which narrows distally and fuses with the tendon of the soleus to constitute the tendo calcaneus.

The **tendo calcaneus**, about half a foot long, the strongest tendon in the body, narrows and thickens as it descends to the heel, where it again spreads out to be **inserted** into the middle part of the posterior surface of the calcaneum. A bursa intervenes between the tendon and the bone immediately above the insertion.

Plantaris.—The plantaris—a narrow fleshy slip, not more than four inches in

length—**arises** from the lateral supracondylar line of the femur for about an inch at its distal end, from the adjacent part of the popliteal surface of the femur, and from the oblique posterior ligament of the knee joint. It ends in a remarkably long, slender tendon which descends obliquely between the gastrocnemius and soleus, and then along the medial border of the tendo calcaneus to be **inserted** into the medial side of the posterior surface of the calcaneum, or the tendo calcaneus, or the flexor retinaculum. The tendon of the muscle, although apparently a narrow bundle, can be drawn out into a fine, aponeurotic sheet, two or three inches in width.

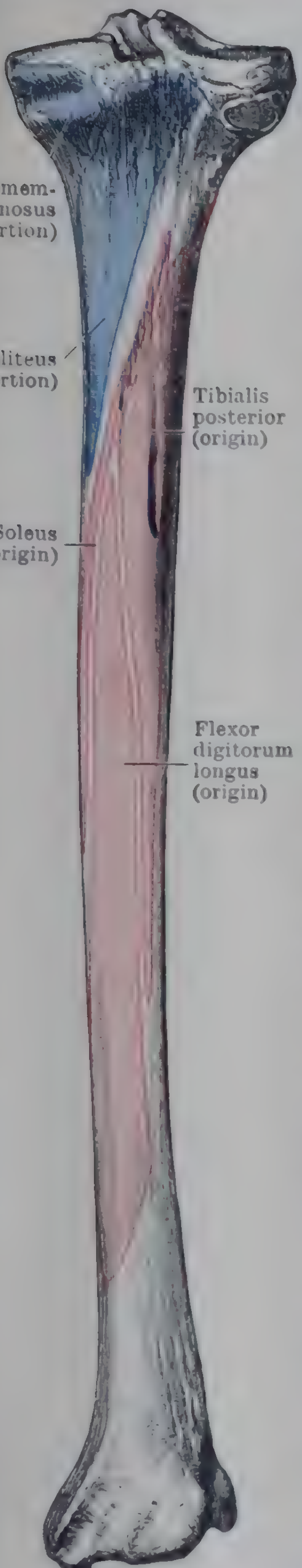

FIG. 463.—MUSCLE-ATTACHMENTS TO POSTERIOR SURFACE OF RIGHT TIBIA.

Like the palmaris longus in the forearm, the plantaris is a variable muscle and may be absent. Each of these muscles is the remains of a superficial layer of the primitive common flexor of the digits; and they are represented in the palm and in the sole by an aponeurosis.

Soleus.—The soleus, as its name implies, is a thick flat plate; it has a triple **origin** from—(1) the posterior surfaces of the head and the upper third of the shaft of the fibula; (2) a fibrous arch (*tendinous arch of soleus*) that stretches between the tibia and fibula across the popliteal vessels and medial popliteal nerve; and (3) the soleal line of the tibia and the middle third of its medial border (Fig. 463).

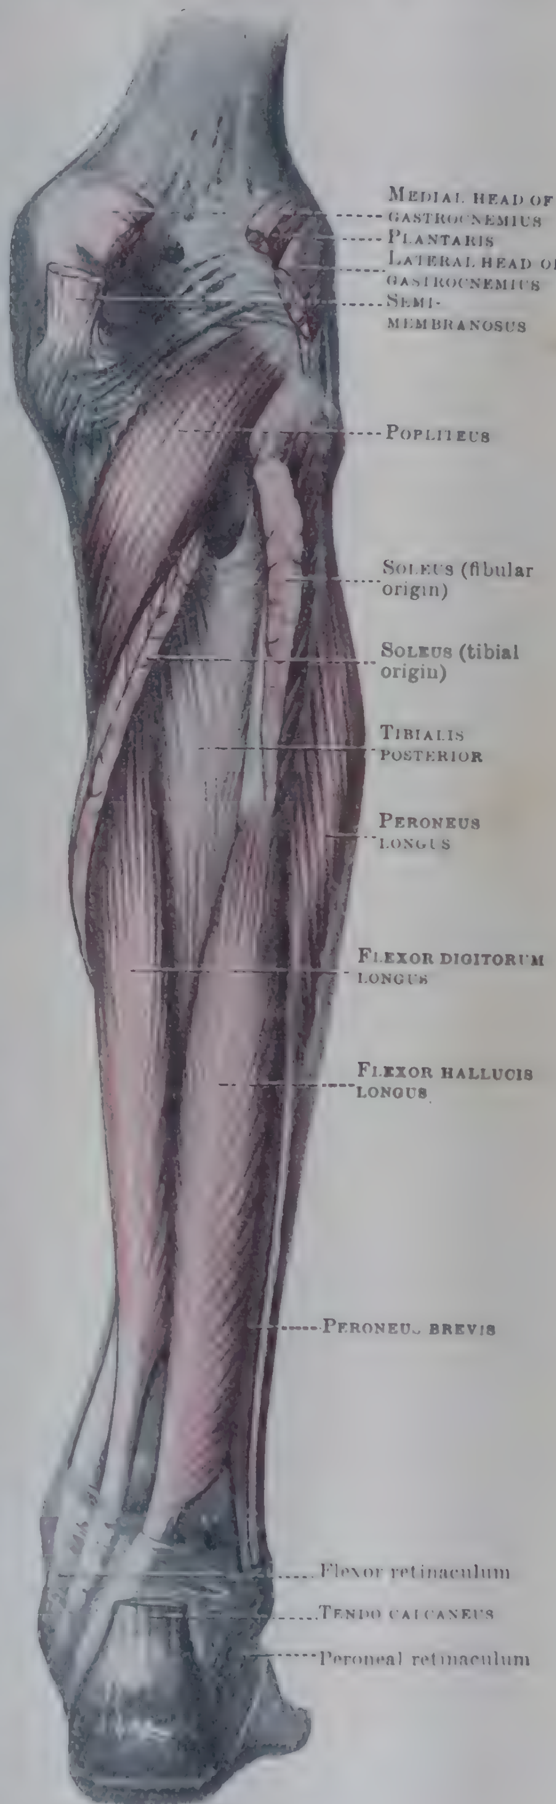

FIG. 464.—DEEP MUSCLES ON BACK OF RIGHT LEG.

From their origin the upper muscular fibres descend to join the deep (anterior) surface of a broad membranous tendon which is applied to the deep surface of the similar tendon of the gastrocnemius—the two gliding upon each other above but fused below to obtain a common

insertion through the tendo calcaneus; the lower fibres are inserted directly into the tendo calcaneus to within one or two inches of the calcaneum. The muscle is related to the lower border of the popliteus above, and is separated anteriorly by a transverse fascial septum from the posterior tibial vessels and nerve and the muscles of the following group.

The **deep muscles** of the back of the leg are the popliteus, flexor digitorum longus, flexor hallucis longus, and tibialis posterior.

The popliteus muscle is deeply placed in the distal part of the floor of the popliteal fossa, and is crossed by the popliteal vessels and medial popliteal nerve. The flexor digitorum longus lies on the tibia, the flexor hallucis longus on the fibula, and the tibialis posterior, lying between them, is related to the interosseous membrane and both bones of the leg. The four muscles are concealed by the superficial group, and are bound down to the bones by layers of the deep fascia.

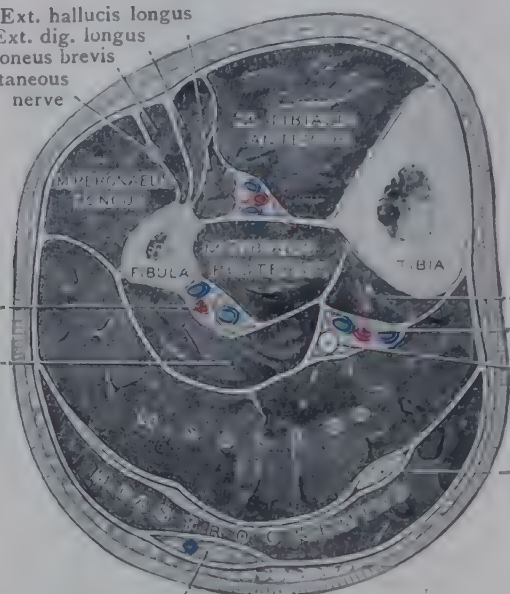

Fig. 465.—Transverse Section through Middle of Leg.

Popliteus.—The popliteus **arises**, by a stout tendon, from a rough pit on the lateral surface of the lateral condyle of the femur, below the attachment of the lateral ligament of the knee and close to the articular margin. The tendon, grooving the lateral semilunar cartilage, passes between it and the capsule of the knee joint and emerges from under the arcuate ligament of the knee, from which it takes an additional fleshy origin (Fig. 339, p. 383). It is **inserted**, by fleshy fibres, (1) into a triangular surface on the back of the tibia above the soleal line (Fig. 463), and (2) into the fascia which covers it.

Intracapsular at its origin, the tendon is partially invested by the synovial membrane, which protrudes along it for a short distance after it has pierced the capsule.

The pit of origin lies at the antero-inferior end of a groove on the lateral surface of the condyle; in that groove the upper margin of the tendon lies when the knee joint is flexed, but in extension the tendon slips over the articular edge of the condyle and rests in a shallow notch on the bone.

Flexor Digitorum Longus.—The flexor digitorum longus takes **origin** by fleshy fibres from the posterior surface of the shaft of the tibia in its middle three-fifths below the soleal line and medial to the vertical line, from the overlying fascia and from an intermuscular septum on each side (Fig. 463).

Its tendon, crossed obliquely in front by the tendon of the tibialis posterior, lies along its lateral side on the back of the lower end of the tibia, and then passes deep to the flexor retinaculum, where it is invested in a special synovial sheath. Escaping from the retinaculum, it passes forward over the medial margin of the sustentaculum tali and enters the sole above the abductor hallucis. As it extends forward in the sole it is above the flexor digitorum brevis and crosses below the tendon of the flexor hallucis longus, which separates it from the plantar calcaneonavicular or "spring" ligament; and, as the tendons cross, the flexor hallucis gives to the flexor digitorum a slip that passes into the medial two of the four subordinate tendons into which the tendon of the flexor digitorum longus finally divides. These four tendons are **inserted** into the lateral four toes in precisely the same manner as the flexor digitorum profundus is inserted in the hand (p. 497). Each

tendon enters the fibrous flexor sheath of the toe, perforates the tendon of the flexor digitorum brevis, and is inserted into the base of the distal phalanx. **Vincula tendinum (longa and brevia)** are present as in the hand.

Associated with the tendons of the flexor digitorum longus in the sole of the foot are the lumbrical muscles and the flexor digitorum accessorius.

Lumbricals. — The lumbricals are four slender muscles which are inserted into the lateral four toes; they **arise** from the tendons of the flexor digitorum longus—the *first muscle* by a single origin from the tibial side of the tendon for the second toe, and each of the *other three* by two heads from the adjacent sides of two tendons. Each passes forwards on to the tibial side of its toe, below a deep transverse ligament of the sole, to be **inserted** by tendinous fibres into the dorsal expansion of the extensor tendon; it is also bound to the metatarso-phalangeal capsule and the base of the proximal phalanx.

Flexor Digitorum Accessorius. —The flexor digitorum accessorius **arises** by two heads (Fig. 294, p. 319): (1) the lateral, tendinous head, sometimes absent, springs from the lateral border of the plantar surface of the calcaneum and from the lateral border of the long plantar ligament; (2) the medial head, which is fleshy, arises from the medial surface of the calcaneum in its whole extent, and from the medial border of the long plantar ligament — a portion of the long plantar ligament being exposed between the two origins. The two heads unite to form a flattened band which is **inserted** into the tendons of the flexor digitorum longus—usually into those destined for the second, third, and fourth toes.

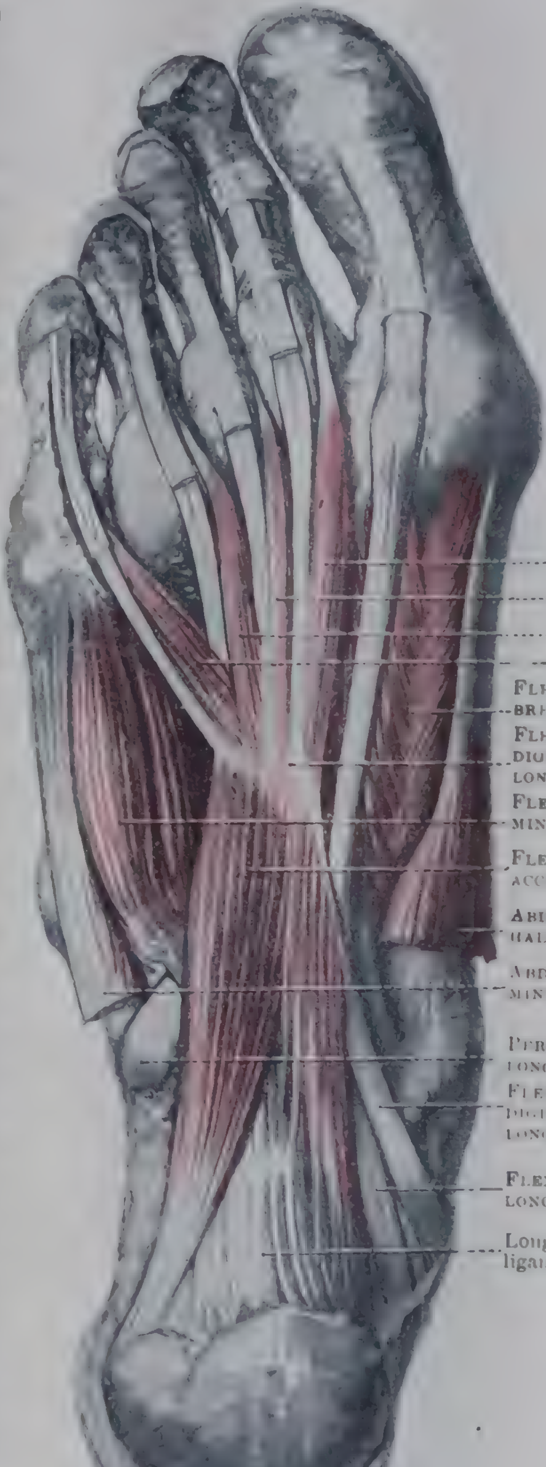

FIG. 466.—MUSCLES OF RIGHT FOOT (Second Layer).

In the sole of the foot the tendons of the flexor digitorum longus, along with the lumbricals and flexor accessorius and the flexor hallucis longus tendon, constitute the second layer of muscles, which lies between the abductors of the big and little toes and the flexor digitorum brevis superficially and the flexor brevis and adductor of the big toe more deeply.

Flexor Hallucis Longus.—The flexor hallucis longus **arises** from the lower two-thirds of the posterior surface of the shaft of the fibula, from the covering fascia and from intermuscular septa at its sides, overlapping the tibialis posterior considerably. Its tendon, passing deep to the flexor retinaculum, enclosed in a

special synovial sheath, grooves the posterior surface of the distal end of the tibia, the talus, and the plantar surface of the sustentaculum tali (to which it is strapped by a fibrous sheath lined with the synovial sheath), and is directed forwards in the sole of the foot, passing above the tendon of flexor digitorum longus, to be **inserted** into the base of the distal phalanx of the big toe after traversing a fibrous sheath under the proximal phalanx.

Tibialis Posterior.—The tibialis posterior, the deepest muscle on the back of the leg, has a fourfold fleshy origin. It **arises**—(1) from the posterior surface of the shaft of the fibula between the medial crest and the interosseous border; (2) from the lower part of the lateral condyle of the tibia, and from the upper two-thirds of its shaft below the soleal line and between the vertical line and the interosseous border; (3) from the interosseous membrane; and (4) from the covering fascia and the septum on each side. The muscle ends in a strong tendon which is invested with a special synovial sheath. The tendon grooves the back of the medial malleolus, and then, turning forwards below the malleolus between the flexor retinaculum and the deltoid ligament, it passes below the plantar calcaneo-navicular ("spring") ligament and spreads out to be **inserted** by three bands into (1) the tuberosity of the navicular bone and the plantar surface of the medial cuneiform bone, (2) the plantar surfaces of the bases of the second, third, fourth (and sometimes fifth) metatarsal bones, the intermediate and lateral cuneiform bones and the floor of the groove on the cuboid, and (3) into the medial border of the sustentaculum tali of the calcaneum (Fig. 294, p. 319). As it crosses the spring ligament, a sesamoid cartilage or bone is developed in its substance.

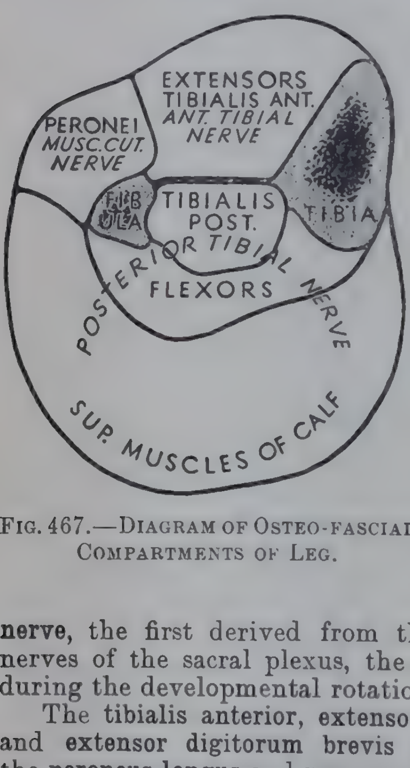

Fig. 467.—Diagram of Osteo-fascial Compartments of Leg.

An occasional separate slip (**peroneo-calcaneus**) **arises** from the lower end of the fibula, and is **inserted** into the calcaneum, or may join the tendon of the flexor hallucis longus.

Nerve-Supply.—The muscles of the front and lateral side of the leg and those on the back of the leg are all supplied by nerves derived respectively from the lateral popliteal and medial popliteal divisions of the **sciatic nerve**, the first derived from the dorsal offsets, the second from the ventral offsets of the nerves of the sacral plexus, the extensor and flexor aspects of the leg having been reversed during the developmental rotation of the limb.

The **tibialis anterior, extensor digitorum longus, peroneus tertius, extensor hallucis longus,** and **extensor digitorum brevis** are all supplied by the *anterior tibial nerve* (L. 4, 5, S. 1); the **peroneus longus** and **peroneus brevis** by the *musculo-cutaneous nerve* (L. 4, 5, S. 1).

The following muscles are all supplied by branches of the *medial popliteal* or its continuation—the *posterior tibial nerve*:—**Gastrocnemius**, by two branches, one to each head (S. 1, 2); **plantaris** (L. 4, 5, S. 1); **soleus**, by two branches, one arising in the popliteal fossa and entering its superficial surface (S. 1, 2), the other in the back of the leg and entering its deep surface (L. 5, S. 1, 2); **popliteus** (L. 4, 5, S. 1), by a branch which winds round the lower border of the muscle and enters its deep surface; **flexor digitorum longus** (L. 5, S. 1); **flexor hallucis longus** (L. 5, S. 1, 2); and **tibialis posterior** (L. 5, S. 1). The *posterior tibial nerve*, through its plantar branches, supplies also the muscles associated with the tendons of the flexor digitorum longus in the sole of the foot; the **first lumbrical** is supplied by the *medial plantar nerve* (L. (4), 5, S. 1), the **other three** by the *lateral plantar nerve* (S. 1, 2), which supplies the **flexor digitorum accessorius** also.

Action of Muscles in Movements at Ankle and Intertarsal Joints.—

The terms which are least liable to be misunderstood in the description of movements at the ankle joint are **dorsi-flexion** (produced by muscles on the anterior (extensor) aspect of the leg), and **plantar-flexion** (produced by muscles on the posterior (flexor) aspect of the leg). In addition, important movements of **inversion** and **eversion** of the foot take place at the subtalar joints (p. 398). (See Pl. XLV, Figs. 2 and 3, p. 546.)

The dorsi-flexors of the ankle are: the **tibialis anterior, extensor digitorum longus, peroneus tertius,** and **extensor hallucis longus**. The plantar-flexors of the ankle are: the **gastrocnemius** and **soleus** with the feeble **plantaris**; the **flexor digitorum longus, flexor hallucis longus** and **tibialis posterior**; and the **peroneus longus** and **brevis**.

Most of these muscles have some action also at the intertarsal joints; but the

invertors of the foot, in the order of their strength, are first the tibialis posterior and then the tibialis anterior, acting together (Pl. XXXVI, p. 383, Fig. 1), while the chief **evertors** are the two **peroneal** muscles, **longus** and **brevis**. The **peroneus tertius** also is associated with the movement of eversion, which is a characteristic movement of the human foot (it raises the lateral border of the foot, for example, in the action of skating or dancing).

It is to be noted that the muscles whose tendons pass into the sole have the additional, important postural function of maintaining the arches of the foot. The tibialis posterior is perhaps the most important muscle in that respect because of the direct relation of its tendon to the plantar calcaneo-navicular ("spring") ligament and of its numerous secondary insertions. The flexor hallucis longus also has an important share in this function because of its position in relation to the tarsus and the spring ligament. The peroneus longus, by its passage across the sole, keeps the transverse arch of the foot up, as a taut string maintains the bend of a bow. The arches of the foot are girders constructed of mobile segments which interplay as the muscles lever them into position (Pl. XLVI, p. 547; Fig. 468); and the phrase "supporting the arch" may refer to a direct pull upon its segments, such as is exerted by the tibialis anterior, or an indirect effect upon these segments by the approximation of the pliable pillars as in the action of the flexor hallucis longus.

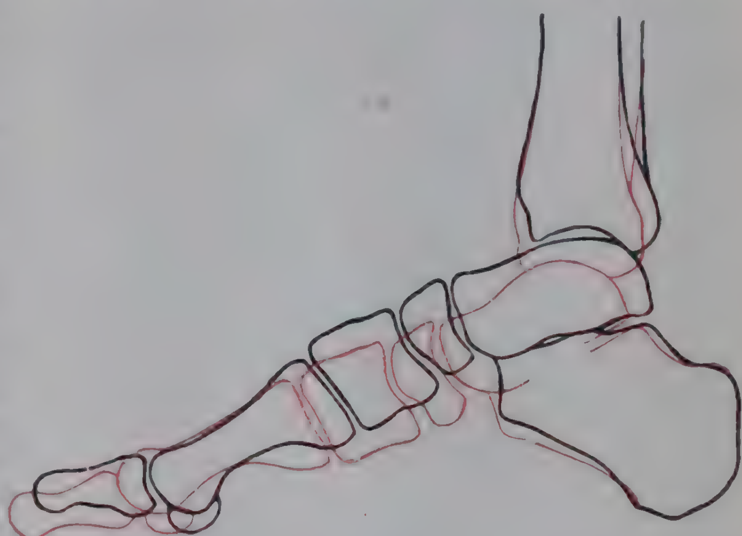

FIG. 468.—TRACINGS OF RADIOGRAPHS (Pl. XLVI, p. 547, Figs. 2 and 3), superimposed to show the position of the Longitudinal Arch of the Foot during Relaxation (red), and Contraction (black) of the Muscles. (See also Fig. 472, footprints 2 and 3.)

As the line of the body-weight in the erect attitude lies in front of the axis of the ankle joint, the plantar flexors are required to be far more powerful than the dorsi-flexors—again, a feature distinctive of Man.

As the function of the limb is to support and propel the body in movement, it is essential to consider the **reversed action** of the muscles in pulling from the foot firmly applied to the ground as well as in pulling upon the free foot from the leg. In the **standing position** the muscles of the tendo calcaneus pull from the heel, but **in walking** they pull up the heel. Again, in standing on one foot the **tibialis anterior** and **posterior** pull the leg medially while the **peroneal** muscles pull it laterally to secure a balance. Now, the movement induced by any one muscle at the joints is never pure flexion, extension or version, and accordingly the synergic action of all groups is necessary. One can readily feel this in all the muscles of the leg in poising the body on the toes of one foot, when the tibialis anterior, though a dorsi-flexor, must act as an invertor to counteract the everting pull of the peroneal muscles. The student will appreciate that such direct antagonists as the tibialis posterior (flexor) and the tibialis anterior (extensor) nevertheless co-operate in producing inversion.

The **gastrocnemius** requires special consideration, not only because it is a powerful plantar-flexor, but also because of the necessity for its relaxation during dorsi-flexion of the ankle in walking. The condition of this muscle varies considerably, and a slight shortening is so common that it can hardly be considered abnormal. Its "ligamentous action" (see p. 408) thus hampers dorsi-flexion at the ankle joint, and an endeavour is made to supplement the ankle joint in that movement during walking by the use of the "transverse tarsal joint" (p. 397). Now, at this joint, dorsi-flexion does not take place in the sagittal plane: the fore part of the foot is moved laterally as well as upwards; the walk becomes "out-toed" and the medial longitudinal arch is depressed—predisposing to flat foot. The muscles of the calf are concerned also in keeping the posture erect, the slowly acting soleus being more important in this respect than the quickly acting gastrocnemius, which is used in more active movements. (See also Cyriax, 1917; Haines, 1934.)

The power of the flexor muscles in their tie-beam action on the foot is well illustrated when the tibialis anterior is paralysed and the gastrocnemius and soleus are weak. In using the flexors powerfully to overcome the drooping of the heel caused by the weakness of their companions, the fore part of the foot is gradually pulled towards the heel, until a marked concavity is produced.

Muscles in Sole of Foot

The muscles in the sole of the foot are arranged in four layers:—
First layer: the abductor hallucis, flexor digitorum brevis, and abductor digiti minimi. *Second layer*: the lumbricals and flexor digitorum accessorius, together with the tendons of the flexor hallucis longus and flexor digitorum longus. *Third layer*: the flexor hallucis brevis, adductor hallucis, and flexor digiti minimi brevis. *Fourth layer*: the interossei (plantar and dorsal), placed between the metatarsal bones; and the tendons of insertion of the tibialis posterior and peroneus longus.

Fig. 469.—Superficial Muscles of Sole of Foot.

FIRST LAYER

Abductor Hallucis.—The abductor hallucis **arises** by a short tendon from the medial side of the medial tubercle of the calcaneum and by fleshy fibres from the flexor retinaculum, the plantar aponeurosis and the intermuscular septum between it and the flexor digitorum brevis. The muscle lies superficially along the medial border of the sole, and its tendon is **inserted** into the medial side of the base of the proximal phalanx of the big toe and partly with the medial head of flexor hallucis brevis into the medial sesamoid bone.

Flexor Digitorum Brevis.—The flexor digitorum brevis is situated above (deep to) the plantar aponeurosis, between the two abductors, and is separated from the second layer of muscles by their fascia and the lateral plantar vessels and nerve. It **arises** from the medial tubercle of the calcaneum, the plantar aponeurosis, and the intermuscular septa at its sides. Passing forwards, it gives rise to four slender tendons which are **inserted** into the middle phalanges of the lateral four toes, after having been perforated by the long flexor tendons, just as in the case of the tendons of the flexor digitorum sublimis of the hand (p. 496).

Abductor Digiti Minimi.—The abductor digiti minimi **arises** by fleshy and tendinous fibres from both tubercles of the calcaneum (partly concealed by the flexor digitorum brevis) and by fleshy fibres from the fascia on its surface and the intermuscular septum between it and the flexor digitorum brevis. Its tendon

glides over a smooth depression on the inferior surface of the base of the fifth metatarsal bone and runs along the bone to be **inserted** into the lateral side of the base of the proximal phalanx of the little toe. The most lateral fibres usually obtain an additional insertion into the lateral part of the plantar surface of the fifth metatarsal bone and may constitute a small separate muscle called the **abductor ossis metatarsi quinti.**

SECOND LAYER

The muscles and tendons of this layer have been described already (pp. 540, 541).

THIRD LAYER

Flexor Hallucis Brevis.—The flexor hallucis brevis **arises** by tendinous fibres from (1) the medial part of the plantar surface of the cuboid bone (behind the groove for the peroneus longus), and from the adjacent part of the lateral cuneiform bone and (2) from the expansions of the tendon of the tibialis posterior in this area. Directed forwards over the first metatarsal bone, the muscle separates into two parts which escort the tendon of the flexor hallucis longus. Each portion gives rise to a tendon which is **inserted** into the corresponding side of the base of the proximal phalanx of the big toe; in each tendon, under the metatarso-phalangeal joint, a *sesamoid bone* is developed to play the part of a roller-bearing (Fig. 468 and Pl. XLVI, p. 547). The tibial tendon is united with the insertion of the abductor muscle of the big toe, the fibular tendon with the insertion of the adductor.

An occasional insertion of some fibres into the shaft of the metatarsal bone represents an **opponens hallucis.**

FIG. 470.—DEEP MUSCLES OF SOLE OF FOOT.

Adductor Hallucis.—The adductor hallucis has two heads. The *oblique head* **arises** (1) from the sheath of the peroneus longus, and (2) from the plantar surfaces of the bases of the second, third, and fourth metatarsal bones (Fig. 294, p. 319). It lies in the hollow of the foot, on a deeper plane than the long flexor tendons and lumbricals, and on the fibular side of the flexor hallucis brevis, with which it is frequently fused; and it runs obliquely, medially and forwards, to be **inserted** on the fibular side of the base of the proximal phalanx of the big toe along with the transverse head and the flexor brevis.

The *transverse head* **arises** from the capsules of the lateral four metatarso-phalangeal joints and the deep transverse ligaments of the sole. Running transversely medially under cover of the flexor tendons and lumbricals and crossed by

the digital nerves, it is **inserted**, along with the oblique head, into the fibular side of the base of the proximal phalanx of the big toe.

Flexor Digiti Minimi Brevis.—The flexor digiti minimi brevis **arises** from the sheath of the peroneus longus and the base of the fifth metatarsal bone. Partially concealed by the abductor digiti minimi, the muscle passes along the fifth metatarsal bone to be **inserted**, in common with that muscle, into the fibular side of the base of the proximal phalanx of the little toe.

A frequent insertion of some fibres into the metatarsal bone represents an **opponens digiti minimi.**

FOURTH LAYER

Interosseous Muscles.—The interosseous muscles of the foot resemble those of the hand except in one respect. In the hand the line from and to which they

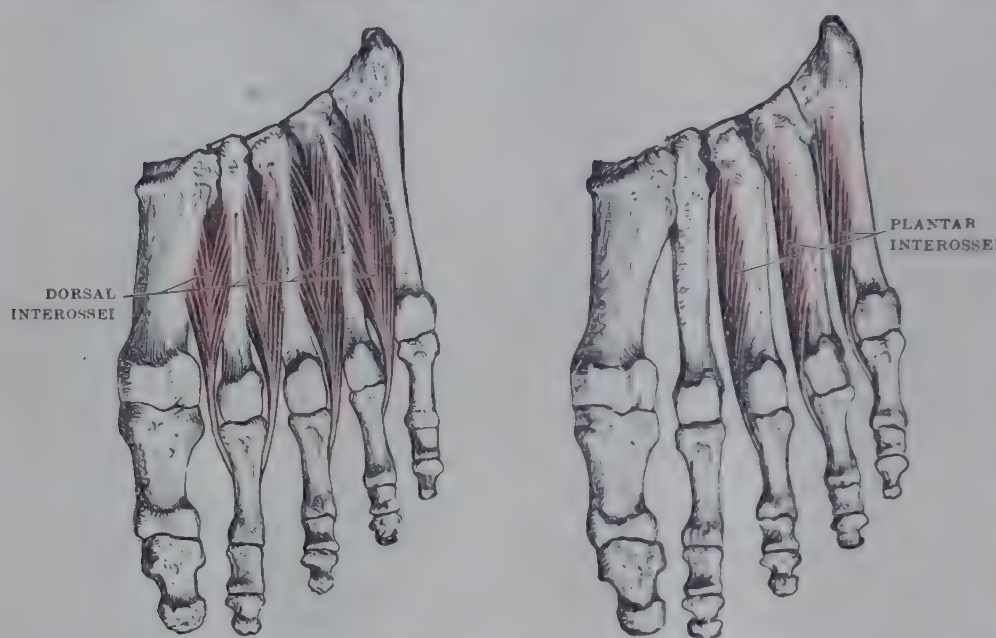

FIG. 471.—INTEROSSEOUS MUSCLES OF RIGHT FOOT.

move the digits is the middle line of the middle digit, whereas, in the foot, it is the middle line of the second digit.

There are four dorsal and three plantar muscles; they occupy the four interosseous spaces, and bulge into the hollow of the foot.

The **four dorsal muscles** lie in the intermetatarsal spaces, and as each **arises** by two heads from the adjacent bones their fibres have a bipennate arrangement. Their tendons pass forwards above the deep transverse ligaments of the sole, and each is **inserted**, on the dorsum of the foot, into the side of the proximal phalanx, the metatarso-phalangeal capsule, and the dorsal expansion of the extensor tendon. The *first* and *second muscles* are inserted respectively into the tibial and fibular sides of the proximal end of the proximal phalanx of the second toe. The *third* and *fourth muscles* are inserted into the fibular sides of the third and fourth toes. The dorsalis pedis artery enters the sole of the foot through the cleft between the heads of the first muscle; the perforating arteries gain the dorsum of the foot through the corresponding intervals in the other three muscles.

The **three plantar muscles** lie in the lateral three interosseous spaces. They **arise**, each by a single head, from the medial side of the third, fourth, and fifth metatarsal bones respectively. Their tendons pass forwards above the deep transverse ligaments, and each is **inserted**, in the same manner as the dorsal muscles, into the tibial sides of the third. fourth, and fifth toes.

Nerve-Supply.—The muscles of the sole of the foot are supplied by the two *plantar nerves*; the **abductor hallucis, flexor hallucis brevis, flexor digitorum brevis,** and the **first lumbrical** by the *medial plantar nerve* (L. (4.) 5. S. 1.); the **adductor hallucis,** the **abductor digiti minimi,** the **flexor digiti minimi brevis,** the **lateral three lumbricals,** the **flexor digitorum accessorius,** and *all* **interossei** by the *lateral plantar nerve* (S. 1. 2.). (Branches from the anterior tibial nerve to the **drosal interossei are probably afferent.**)

Plate XLIV.—Photographic and Radiographic Illustrations of the Weight-Bearing Areas of the Foot

Action of Muscles in Movements of the Toes.—The **extensor hallucis longus** extends the big toe, the **extensor digitorum brevis** extends the medial four toes, and the **extensor digitorum longus** the lateral four toes. The **flexor digitorum longus** flexes the lateral four toes: the **lumbrical muscles** have a similar action to those of the hand; they flex the metatarso-phalangeal joints of the lateral four toes and extend their interphalangeal joints. The muscles are capable of performing these actions when the foot is off the ground; but it is more important to consider the action in walking, when the long flexors and the lumbricals act together and the lumbricals, by endeavouring to keep the interphalangeal joints extended, enable the long flexors to "push off" more effectively. The chief action of the flexors and lumbricals in the "push off" is, however, an endeavour to bend the dorsi-flexed metatarso-phalangeal joints while extension of the interphalangeal joints is maintained; and it should be noted that the muscles, though exerted powerfully in this action, do not in fact shorten (cf. Pl. XLVI, Fig. 1 and p. 548.

The attitude of the toes in the "push off" varies even in the same foot according to the balance and the pressure exerted. When all the toes and metatarsal pads are firmly pressed to the ground, there is extension at the metatarso-phalangeal and distal interphalangeal joints, while the interphalangeal joint of the great toe and the proximal interphalangeal joints of the other toes are flexed. If the inner toes are exerting the greater pressure, then both interphalangeal joints of the outer toes tend to flex. By altering his balance and the pressure on his own feet, the student will quickly acquire the best appreciation of the slight differences produced by various attitudes. When the lumbricals are weak, they allow the long flexors to bend the interphalangeal joints; but, when the foot is on the ground, the toes cannot be depressed, and accordingly dorsi-flexion occurs at the metatarso-phalangeal joints and the toes become "clawed". The backs of the toes then press on the shoe, and to mitigate that the flexors curl the toes still more. The surgeon corrects this by straightening the toes and fixing the proximal interphalangeal joints in the extended position so that the long flexors cannot act on these joints and must attempt to flex at the metatarso-phalangeal joints just as normal lumbricals do.

The **flexor digitorum accessorius**, as its name implies, is an accessory flexor of the toes, assisting the long flexor, and tending to draw the tendons into which it is inserted into the middle of the sole of the foot. The **flexor digitorum brevis**, corresponding to

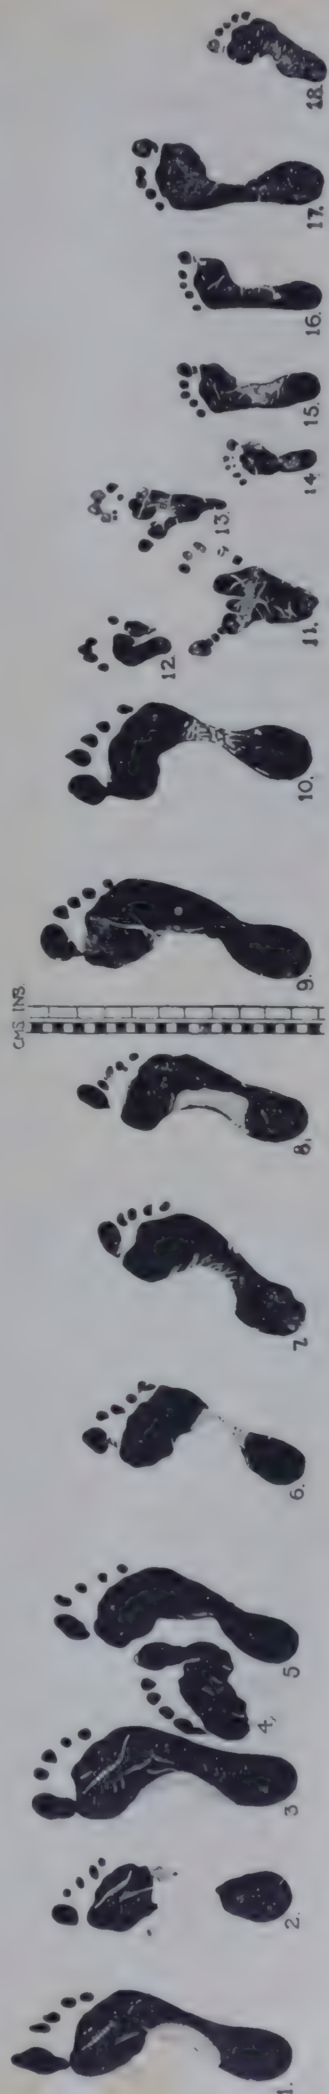

FIG. 472.—COMPARATIVE SERIES OF FOOTPRINTS. 1, 2, 3, 4. Footprints of a Man: (1) Walking-print; (2) Stationary, foot highly arched; (3) With the Muscles relaxed as much as possible (see Pl. XLVI, Figs. 2 and 3); (4) Walking on the Toes. Note the prominence of the bar between the ball and phalangeal pad of the big toe. 5. Footprint of Male Athlete. 6. Athletic Girl. 7. Ballet Dancer in Attention Attitude. 8. The same showing the difference between the arched and relaxed state of the foot, the increased area of contact indicated by the dotted area. 9. Negro, Male. 10. Australian Aboriginal Woman. 11. Chimpanzee, Female, 3½ years of age, walking-print. 12. Hamadryas Baboon, Female. 13. Rhesus Macacus Monkey. (Observe the narrow heel, 11, 12, and 13.) 14. Infant before walking, at 3 months old. 15. The same child after walking at 2 years, 9 months old. 16. The same child at 3 years, 7 months old. 17. The same child at 7¼ years old. 18. This infant, after beginning to walk, was confined to bed through illness, and lost the art. The footprint is taken from a series while the art of walking is being learned anew. The eminence in front of the heel on the medial side is caused by the impression of the area under the head of the navicular bone.

the flexor sublimis of the fingers, acts on the metatarso-phalangeal and proximal interphalangeal joints of the lateral four toes.

The **abductor** and **adductor hallucis** abduct and adduct the big toe, and both assist the **flexor hallucis brevis** and the **flexor hallucis longus** (at the metatarso-phalangeal joint) in flexion of the big toe. The importance of the big toe in walking may be estimated from the fact that the flexor hallucis longus exerts three times more force upon it than is exerted upon any other toe (cf. weight-bearing areas of foot and Fig. 472). The **abductor digiti minimi** abducts, and assists the **flexor digiti minimi brevis** (at the metatarso-phalangeal joint) in flexion of the little toe.

The **interossei** are flexors of the metatarso-phalangeal joints and extensors of the interphalangeal joints of the lateral four toes (but the opinion is also held that they do not extend these joints). The dorsal interossei **abduct** the toes into which they are inserted from the middle line of the *second toe*; the plantar interossei **adduct** the lateral three toes towards the *second toe*. The small muscles of the foot also have an important tie-beam action in maintaining the arches of the foot. (For further discussion of the actions of the muscles of the foot, see Wood Jones, 1944.)

Weight-Bearing Areas of the Foot.—The function of the arches of the foot and the activity of the muscles of the leg and foot in maintaining these arches (pp. 543 and 549) are indicated in some measure by the footprints, which vary considerably in different people and alter remarkably in the early years of life. In the average person (Fig. 472, **1**), the weight of the posterior pillar is taken by the heel pad, that of the anterior pillar by the metatarsal pad—particularly in the region of the ball of the big toe—while under the lateral longitudinal arch there is an area of contact (very frequently absent, Fig. 472, **6**, **10**), and not usually a weight-bearing area. (It has been said that the feet of primitive races are broad and flat, but this is not borne out in Fig. 472, **10**, which shows the foot of an Australian aboriginal woman). The weight-bearing areas are merely roughly and not adequately represented by footprints; a well-worn shoe is one of the best and readiest sources of information. **In the usual method of walking,** as (say) the left heel comes down, pressure is light, for the weight is still borne mainly by the right foot; but pressure on the left heel increases as the weight is transferred, and the left heel rolls forward until the ball of the foot now makes contact. In the forward movement, the heel-pressure decreases as the ball-pressure increases; then the ball-pressure decreases as the toe-pressure increases, and this diminishes as the right foot comes forward—the left toes alone exerting pressure as the weight is being transferred to the right foot. In the last part of the movement it will be noted that there is metatarso-phalangeal dorsi-flexion (Pl. XLVI, p. 547, Fig. **1**) and it should be appreciated that while the toes are thus extended their flexors are exerting their full power of propulsion. The bar between the metatarsal pad and the phalangeal pad is evident in the case of the big toe (Fig. 472, **1**, **4**), but is prevented by the metatarsal pad from appearing, though the toes are extended, in the case of the others. **Most people walk slightly "toeing-out"**—the pressure being marked on the lateral side of the heel, and then transferred to the medial side of the ball of the foot. In those who walk "**toeing-in**", the medial side of the heel bears the greater pressure, and this is transferred to the lateral side of the ball. The net result in both cases is that the line between the areas of pressure is parallel to the line of progress (Elftman, 1934). The angle of gait, usually about 15 degrees between the two feet, varies individually and becomes less the quicker the walk (Morton, 1935). The footprint at birth is flat and the heel narrow (Fig. 472, **14**) (cf. Fig. 472, **17**), and is very variable as the child begins to learn to walk, as is seen by the impression in front of the heel caused by the area under the navicular bone in Fig. 472, **18**. As the child grows the heel broadens out and the raising of the longitudinal arch begins (see pp. 393 and 400).

Movements of Lower Limb as a Whole

The characteristic features of the lower limb are stability and strength, and its muscles and joints are subservient to the functions both of transmission of weight and of locomotion. In the standing position the centre of gravity of the trunk falls between the heads of the femora, and is located about the middle of the body of the last lumbar vertebra. The weight of the body is transmitted from the sacrum through the sacro-iliac joints to the hip bone, and through the femur and tibia to the arch of the foot, where the talus distributes it backwards through the calcaneum to the heel, and forwards through the tarsus and metatarsus to the ball of the foot.

Locomotion.—The three chief means of progression are walking, running, and leaping.

In **walking**, the body and its centre of gravity are inclined forwards, and the trunk oscillates from side to side as it is supported alternately by each foot. As one foot leaves the ground the sacro-spinalis of that side and the gluteus medius and minimus of the opposite side can be felt contracting to maintain the balance of the body. The upper limb swings alternately with the corresponding lower limb, and one foot or the other is always on the ground. The act of progression is performed by the lower limb aided by gravity. The movements of the lower limb occur in the following way. At the beginning of a step, one lower limb, so to speak, " shoves off " ; the heel is raised and the limb is extended. The limb passes forwards by the action of gravity aided by the impetus from the extensor muscles, and it is raised sufficiently to clear the ground by the action of the muscles that flex the hip and knee joints and dorsi-flex the ankle joint and toes. After passing the line of the centre of gravity the flexion of the joints ceases, the muscles relax, and the limb gradually returns to the ground. The other limb then passes through the same cycle, the weight of the body now resting on the limb which is in contact with the ground.

In **running**, the movements are all exaggerated. The time of each movement is diminished, and the force and distance are increased. Both feet are off the ground at one time ; the action of flexors and extensors alternately is much more powerful, so that, on the one hand, the knees are drawn upwards to a greater extent in the forward movement, and not the whole foot but only the toes reach the ground in the extension of the limb. The attempt is made to bring the foot to the ground in front of the line of the centre of gravity. At the same time the trunk is sloped forwards much more than in walking.

In **leaping**, the actions of the limbs are still more exaggerated. The movements of flexion of the limb are still more marked, and the foot reaches the ground still farther in front of the line of the centre of gravity.

The importance of postural action in the muscles of the lower limb in maintaining the posture erect must again be emphasized : and it is an interesting exercise, as the subject leans slightly forwards, to feel the flexor groups of the hip, knee and ankle joints contract to retain the balance, while their opponents relax, and then feel the reverse effects as the model inclines backwards. The muscles and tendons traversing the sole of the foot have a highly important postural function in safeguarding the arches during standing and also during vigorous movement. (For further discussion of the mechanics of locomotion, see Steindler, 1935.)

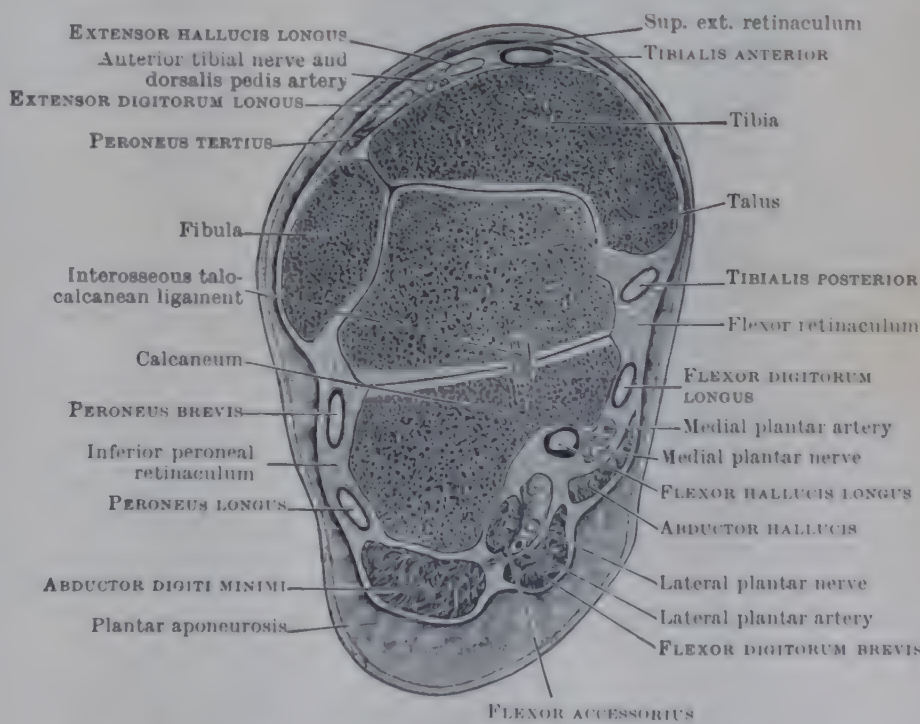

Fig. 473.—Frontal Section through Left Ankle Joint, Talus, and Calcaneum.

FASCIÆ OF LEG AND FOOT

The **superficial fascia** of the leg and foot presents no special features except in the sole, where it is greatly thickened by pads of fat, particularly at the heel and in the ball of the foot and the pads of the toes. These pads are important in weight - bearing, and they protect deeper structures. Their distribution and the flexure-lines of the sole show characteristic changes during the evolution of the arches of the foot (cf. p. 548 and Fig. 472, 3, 9, 11, 15). In the webs of the toes it contains some

transverse fibres that form a weak band called the *superficial transverse ligament of the sole.*

The **deep fascia** is continuous with the fascia lata and is strengthened around the knee by expansions from the tendons of the sartorius, gracilis, semitendinosus, and biceps femoris. Anteriorly, it is attached to the patella, the ligamentum patellæ, and the tubercle of the tibia; medially and laterally, it is connected to the condyles of the tibia and the head of the fibula, and helps to form the **patellar retinacula**—broad membranous bands which pass obliquely from the sides of the patella to the condyles of the tibia and are joined by fibres of the vasti muscles.

In the leg, the fascia blends with the periosteum of the medial surface of the tibia, and extends round the lateral side of the leg from the anterior border of the tibia to its medial border, binding the muscles together and giving origin to them, and gaining an attachment to the lower part of the shaft of the fibula. Two septa pass from its deep surface—anterior and posterior. The **anterior intermuscular septum** is attached to the anterior border of the fibula; it encloses the musculocutaneous nerve, and separates the peroneal muscles from the extensors; the **posterior intermuscular septum** is attached to the posterior border of the fibula, and separates the peroneal muscles from the flexors. The muscles are thus partitioned into three functional groups—extensors anteriorly, flexors posteriorly, and evertors laterally. From the posterior septum another septum extends across the back of the leg, forming a partition between the superficial and deep flexor muscles, and enclosing the posterior tibial vessels and nerve. This septum gives rise to subordinate septa which are attached to the vertical line of the tibia and the medial crest of the fibula, and separate the tibialis posterior from the flexors of the toes. It is attached above to the soleal line, whence a strong fascia is prolonged over the popliteus muscle, reinforced by an expansion from the semimembranosus.

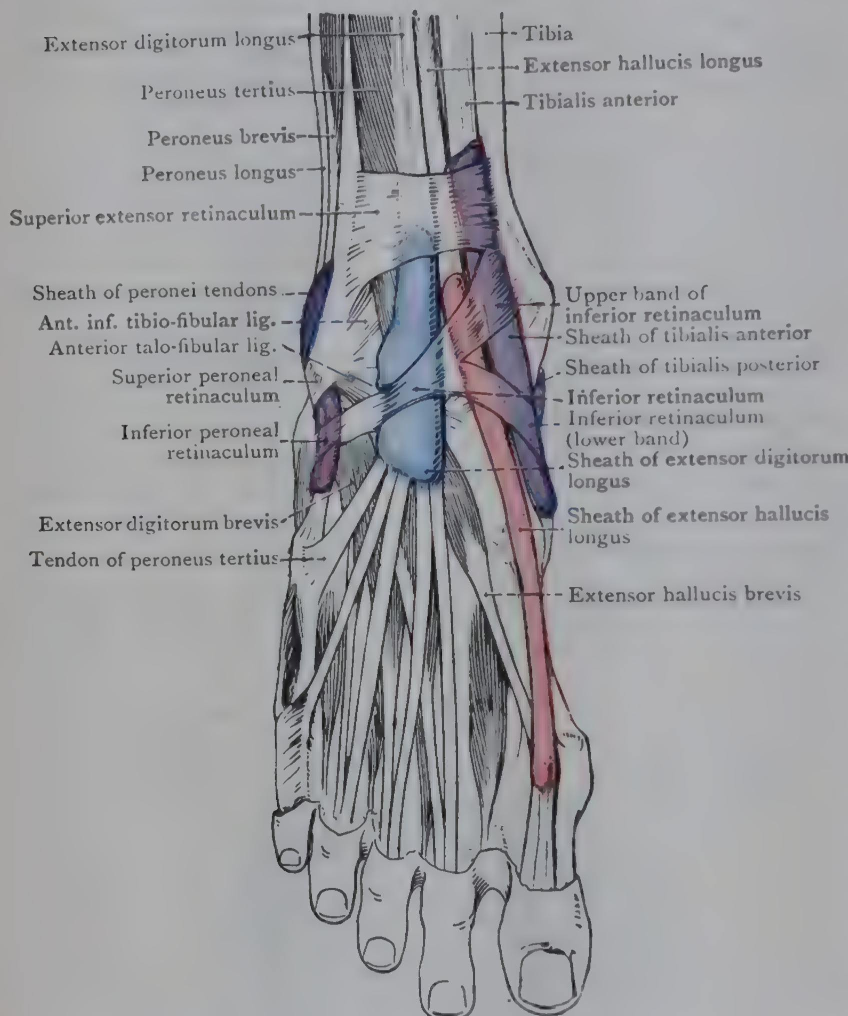

FIG. 474.—SYNOVIAL SHEATHS OF DORSUM OF FOOT.

At the ankle the deep fascia is strengthened by additional transverse fibres, and forms thickened bands named the flexor retinaculum, extensor retinacula, and peroneal retinacula.

The **flexor retinaculum** stretches between the medial malleolus and the medial tubercle of the calcaneum. The space which it bridges is divided into four tunnels by fibrous septa that pass from its deep surface to the back of the lower end of the tibia and to the capsule of the ankle joint. Its upper border is continuous partly with the investing deep fascia of the leg, but chiefly with the septum that covers

the deep muscles of the calf. Its lower border is continuous with the deep fascia of the sole and gives origin to the abductor hallucis muscle. It is pierced by the calcanean vessels and nerve. The four tunnels, enumerated from the medial malleolus laterally, contain (1) the tendon of the tibialis posterior, (2) the flexor digitorum longus, (3) the posterior tibial vessels and nerve, and (4) the flexor hallucis longus; and each of the tendons is enclosed in a separate synovial sheath.

The **superior peroneal retinaculum**, binds down the tendons of the peroneus longus and brevis as they pass together, invested by a single synovial sheath, behind the malleolus; the **inferior peroneal retinaculum**, attached by a septum to the peroneal tubercle, holds them separately to the lateral surface of the calcaneum, each with its own prolongation from their common synovial sheath.

The **superior extensor retinaculum**, broad and undefined at its proximal and distal borders, stretches across between the shafts of the tibia and fibula just above the ankle. It binds down the tendons of the tibialis anterior and the extensor muscles—of which only the tibialis has a synovial sheath at that level.

The **inferior extensor retinaculum** is a better-defined, thickened band of deep fascia that binds down the tendons as they enter the dorsum of the foot. In shape it resembles the letter Y laid on its side. The stem is attached to the anterior part of the upper surface of the calcaneum and to the floor of the tarsal canal (Fig. 347, p. 394); extending medially, it forks into two bands, the upper of which is attached to the medial malleolus, while the lower arches over the medial side of the foot and is lost in the deep fascia near the sole.

Deep to the stem of the Y, the peroneus tertius and extensor digitorum longus occupy one compartment, in a common synovial sheath. The upper limb runs superficial to the anterior tibial vessels and nerve, splits to enclose the tendon of the extensor hallucis longus, and then runs deep to the tibialis anterior, though it may sometimes split to enclose that tendon; the lower limb crosses superficial to the tendons of the extensor hallucis longus and tibialis anterior, the dorsalis pedis artery, and the terminal branches of the anterior tibial nerve. There are three synovial sheaths related to the retinaculum—one for the peroneus tertius and extensor digitorum longus, and one each for the extensor hallucis longus and tibialis anterior. A band of fibres from the deep surface of the stem loops the extensor digitorum longus to become attached to

FIG. 475.—LEFT PLANTAR FASCIA.

adjoining parts of the calcaneum and the neck of the talus; occasionally an additional band connects the upper border of the stem with the lateral malleolus.

In the sole the deep fascia is an unbroken layer which joins the fascia of the dorsum at the borders of the foot; it is greatly thickened in the middle part

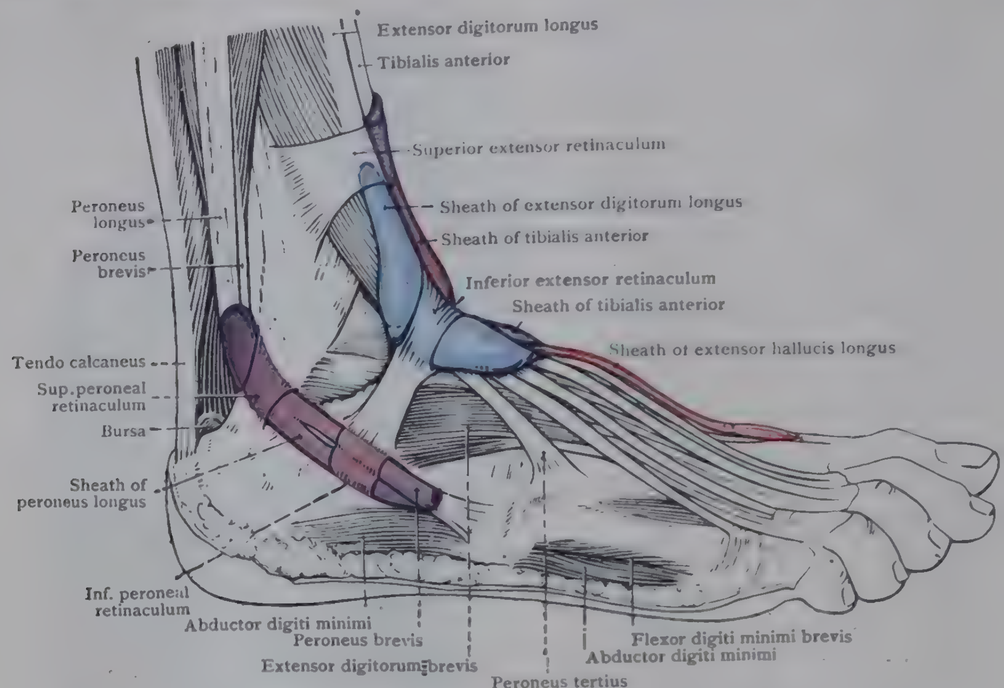

FIG. 476.—DISSECTION SHOWING SYNOVIAL SHEATHS OF TENDONS OF FOOT.

and also on the surface of the abductor digiti minimi between the lateral tubercle of the calcaneum and the base of the fifth metatarsal bone. The thick portion in the middle is called the **plantar aponeurosis**, whose thickness and strength is due chiefly to densely arranged longitudinal fibres.

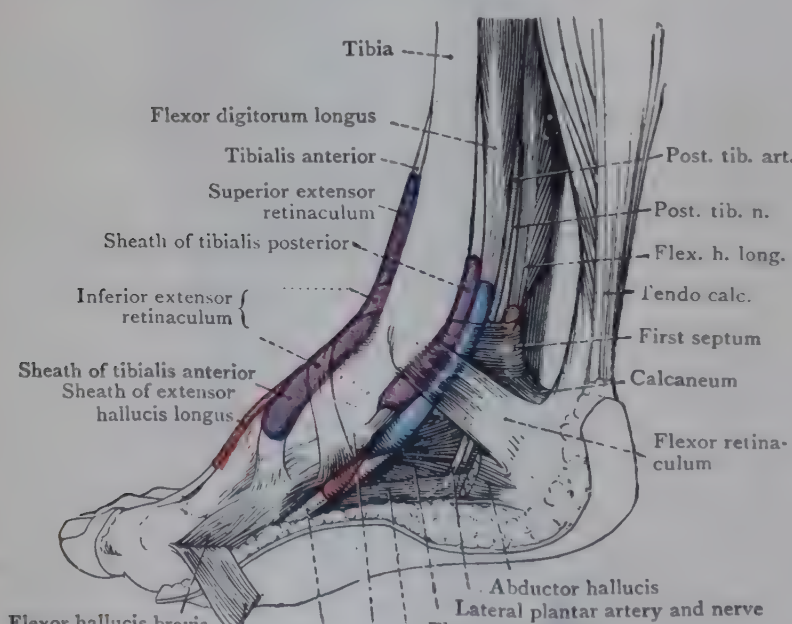

FIG. 477.—DISSECTION OF LEG AND FOOT SHOWING SYNOVIAL SHEATHS.

It is attached to the medial tubercle of the calcaneum and spreads out anteriorly to separate into *five slips* which are directed forwards to the bases of the toes and are united at their origin by ill-defined bands of transverse fibres. The slip for each toe straddles the flexor tendons and is attached on each side to the deep transverse ligaments of the sole and the base of the proximal phalanx. Distally it is continuous with the fibrous flexor sheath. Superficial fibres from the slips are inserted into the skin of the furrow between the toes and the sole. From the margins of the plantar aponeurosis strong septa are sent upwards between the flexor digitorum brevis and the two abductors; they give origin to the muscles between which they lie, and they fuse with the fascia on the deep surface of the flexor brevis, thus enclosing it in a separate sheath.

On the toes, the deep fascia is thickened to form the **fibrous flexor sheaths**, which, though smaller, are similar to those of the fingers (p. 514).

Synovial Sheaths.—The synovial sheaths facilitate the play of the tendons upon the ankle and tarsal regions. They are not so numerous as those at the wrist and in the hand, nor are they so liable to injury; and they do not communicate with the synovial sheaths in the fibrous flexor sheaths, as do those of the thumb and little finger. **On the front of the ankle and dorsum of the foot** there are three separate sheaths: one for the tendon of the tibialis anterior, one for that of the extensor hallucis longus, and a third which is common to the tendons of the extensor digitorum longus and peroneus tertius.

1. The sheath of the **tibialis anterior** begins near the upper border of the superior retinaculum and reaches almost to the insertion of the tendon.

2. The sheath of the **extensor hallucis** begins between the extensor retinacula and extends to the proximal phalanx of the big toe.

3. The sheath of the **extensor digitorum longus and peroneus tertius**, narrow above and wider below, begins at the lower border of the superior retinaculum and ends about the middle of the dorsum of the foot.

On the lateral side of the ankle and foot, the common sheath of the **peroneus longus and brevis** begins at the back of the lateral malleolus and bifurcates as it approaches the peroneal tubercle; one part is prolonged on the peroneus brevis almost to its insertion; the other ensheaths the peroneus longus (with or without interruption at the lateral side of the foot) across the sole to its attachment.

On the medial side of the ankle and foot there are three synovial sheaths.

1. The sheath of the **tibialis posterior** begins about 2 inches (50 mm.) above the tip of the medial malleolus, and ends at the insertion into the navicular bone.

2. The sheath of the **flexor digitorum longus** begins immediately below the previous one, but extends farther forwards—reaching the middle of the foot.

3. The sheath of the **flexor hallucis longus** begins immediately below the last one, and may extend to the middle of the first metatarsal bone.

Within the fibrous flexor sheaths the tendons, as in the fingers, are accompanied by short synovial sheaths—that of the big toe running backwards as far as the shaft of its metatarsal bone, while the others do not extend backwards farther than the heads of the metatarsal bones.

DEVELOPMENT AND MORPHOLOGY OF SKELETAL MUSCLES

The mesoderm on each side of the neural tube separates primarily into mesodermal somites, intermediate cell-mass (nephrotome), and the lateral plate. Afterwards each mesodermal somite divides into two parts—a medial portion called the **scleratogenous segment**, and a lateral portion called the **muscle-plate** (myotome). The lateral plate divides into an outer layer called the **somatic mesoderm** and an inner layer called the **splanchnic mesoderm** (p. 50).

The skeletal muscles are derived from the muscle-plates of the mesodermal somites. The limb-muscles, however, appear to be formed in the mesenchymal core of the limb-bud, probably from cells that have migrated from the muscle-plates into the core; and the visceral muscles of the head and neck are derived from the mesoderm of the pharyngeal arches. Each **mesodermal somite** is at first a quadrilateral mass which rests against the neural tube and notochord. Its cavity represents a diverticulum of the cœlomic cavity. In the early stages of embryonic life the growth of the mesodermal somite is rapid. From its scleratogenous segment, masses of cells arise which grow medially and surround the neural tube and notochord to form the rudiment of the vertebral column. On its lateral side, cells appear to be given off which participate in the formation of the corium of the skin. At the same time the dorsal and ventral borders of the muscle-plate continue to extend, and present extremities (growing points) which have an epithelial structure for a considerable period. *On the dorsal side*, it overlies the neural tube as the "dorso-lateral sheet", which gives rise to the muscles of the back; its *ventral extension* traverses the somatic mesoderm in the body-wall, and produces the "ventro-lateral sheet", which gives rise to the lateral and ventral muscles of the body-wall and, by a medial prolongation, the prevertebral muscles of the neck. The cells of the medial layer of the muscle-plates are responsible for the formation of the muscle-fibres. The innervation of a muscle-plate or of a pre-muscle mass is determined at a very early stage of development, and the nerve-supply of a muscle is consequently the best guide to its morphology. The dorso-lateral sheet is innervated by the posterior primary rami of the spinal nerves, the ventro-lateral by the anterior primary rami.

Portions of two or more neighbouring muscle-plates may fuse to form a skeletal muscle, and that is the common mode of origin, as it is only in a few groups that the individual muscles can be referred to single muscle-plates.

In the course of growth and development a muscle may become widely separated from the skeletal elements which are derived from the same somites as its myotomic constituents. The diaphragm (C. 3, 4, and 5) is an excellent example of "muscle migration". In the same way muscles derived from the mesodermal core of the limb-buds may spread to the trunk and there obtain attachments to skeletal elements at a considerable distance. The latissimus dorsi is an outstanding example of such "migration".

Musculature of the Trunk.—The **dorsal portion** of each muscle-plate becomes separated off and becomes continuous with the corresponding portions of neighbouring myotomes; a longitudinal pre-muscle column is thus formed, to which the posterior primary rami of the spinal nerves are distributed. That column gives rise to the muscles of the back of the neck and the

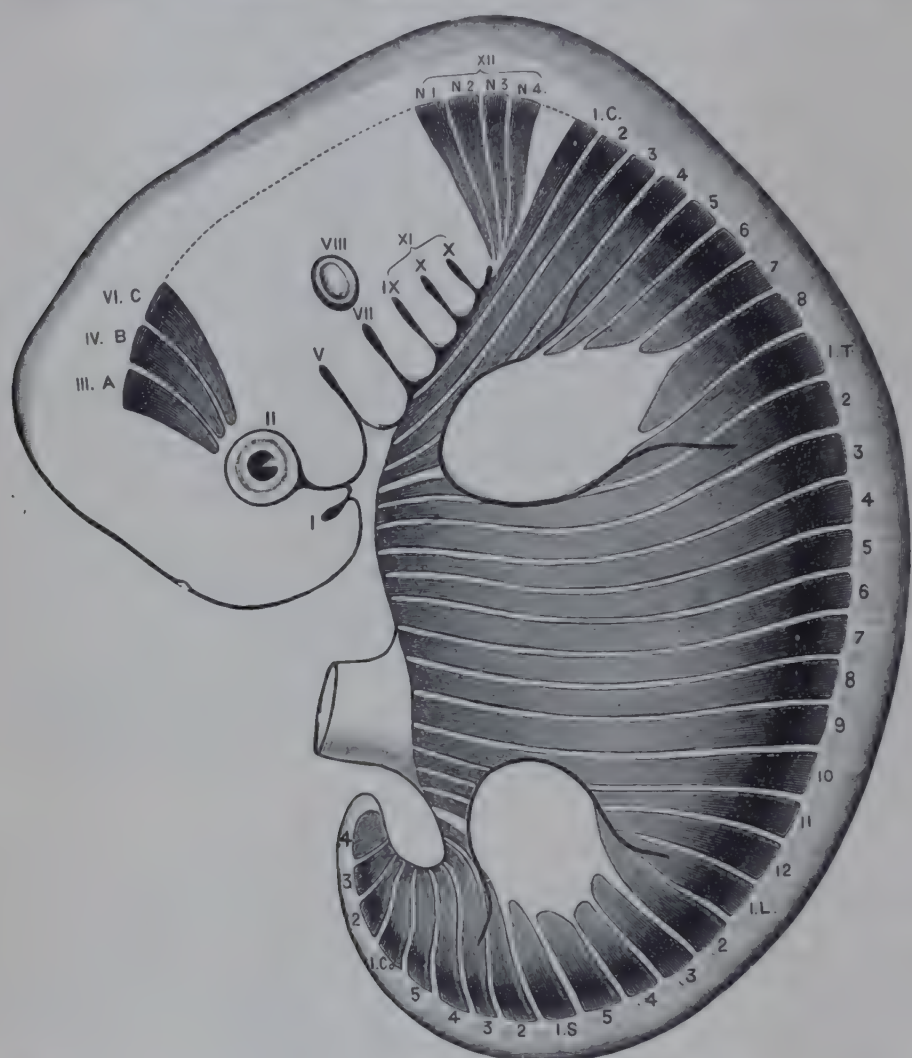

FIG. 478.—SCHEME TO ILLUSTRATE THE DISPOSITION OF THE MYOTOMES IN THE EMBRYO IN RELATION TO THE HEAD, TRUNK, AND LIMBS.

A, B, C, First three cephalic myotomes; N, 1, 2, 3, Occipital myotomes (it is probable that three only are represented in the human embryo); C., T., L., S., Co., The myotomes of the cervical, thoracic, lumbar, sacral, and caudal regions; I, II, III, IV, V, VI, VII, VIII, IX, X, XI, XII, refer to the cranial nerves and the structures with which they may be embryologically associated.

back of the trunk, and they become differentiated from one another by the formation of longitudinal fibrous septa. The deeper parts of the dorsal portions of the muscle-plates remain separate in certain regions and constitute the rotatores and interspinales.

The **ventral portion** of each muscle-plate carries off the anterior primary ramus of the corresponding nerve and spreads ventrally into the somatic mesoderm dorso-lateral to the derivatives of the intermediate cell-mass. (*a*) The dorsal portion of this strip separates off from the rest and fuses with the corresponding portions of neighbouring segments. In the human embryo the column so formed persists only in the cervical region, where it gives rise to the longus cervicis, longus capitis, and the crura of the diaphragm. (*b*) The ventral ends of this extension into the somatic mesoderm behave in a similar way—giving rise, in Man, to the rectus abdominis, the pyramidalis, the sterno-costal portions of the diaphragm, and, probably, the infra-hyoid group of muscles. (*c*) The intermediate portions of these strip-like extensions into the somatic mesoderm become fused and then, in some vertebrates, are delaminated into as many as five layers. In Man, only three such layers are formed, viz., the obliquus externus, the obliquus internus, and the transversus abdominis. Dorsally, the quadratus lumborum, with its enclosing layers of the lumbar fascia, is derived from the same source. In the thoracic region, however, the fusion of the individual myotomic derivatives is carried out only in the case of the transversus thoracis.

The more superficial derivatives constitute the external and internal intercostal muscles, which retain their segmental characters. It appears probable that in the cervical region the corresponding myotomic derivatives in part disappear and in part form the scalene muscles and the remaining portion of the diaphragm.

The ventral portions of the lumbar myotomes (with the exception of the first) and the upper sacral myotomes disappear in Man; but they persist in the third and fourth sacral somites and give rise to the levator ani and the coccygeus.

The occipital myotomes form the muscles of the tongue.

The diaphragm, which may justly be termed the most essential of all the skeletal muscles in Man, is derived to a very large extent, if not entirely, from the ventral portion of the fourth cervical muscle-plate. The crura are on the same morphological plane as the longus cervicis, the sterno-costal portions as the rectus and transversus abdominis. The phylogenetic history of the diaphragm shows that it represents the detached cervical portion of the transversus sheet. In Amphibia and Reptilia there is no separation of the pleural and peritoneal cavities, and the whole transversus sheet functions as a compressor of the cœlom and so as a muscle of expiration. In Mammalia, on the other hand, the diaphragm intervenes between the pleural and the peritoneal cavities, and its action as a cœlomic compressor is restricted to the latter. At the same time, its new position makes it a powerful inspiratory muscle, and in Man it is of very much greater importance than all the other muscles which, primarily or secondarily, help to increase the capacity of the thorax. In pronograde mammals, on the other hand, inspiration depends much more on elevation of the ribs by the external respiratory muscles, and the principal action of the diaphragm in those animals would seem to be its primitive action as a compressor of the cœlom.

The **branchial musculature** is formed in the mesoderm of the pharyngeal arches and is quite distinct from the musculature derived from the occipital and cervical myotomes, not only in its source but also in its innervation, which is obtained from certain of the cranial nerves. Although laid down in the substance of the arches, the branchial muscles may undergo extensive "migration". This change of position is best exemplified by the muscles of the second arch (*vide infra*).

The sterno-mastoid and trapezius have a special morphological history, as is clearly indicated by the peculiarity of their supply from the accessory nerve. They arise from a special common rudiment, believed to be branchial in origin, situated in the embryo over the hinder part of the branchial region ventral to the last two occipital myotomes and first two cervical myotomes, from which situation they spread to their attachments to the head and shoulder-girdle. The accessory part of the vagal complex which supplies these muscles extends into the cervical part of the spinal cord, and this extension is perhaps to be associated with their afferent supply from that region (C. 2, 3, 4); if any motor fibres reach the muscles through these cervical nerves, this is to be looked upon as a secondary supply from the same source by an alternative route and not as an indication of myotomic origin.

The accompanying table indicates the muscles derived from the individual pharyngeal arches with their nerves of supply :—

Arch	Nerve	Muscles
First (mandibular)	Trigeminal (mandibular division)	Muscles of mastication Tensor tympani Tensor palati
Second (hyoid)	Facial	Muscles of facial expression (including muscles of scalp and platysma) Stylo-hyoid Posterior belly of digastric Stapedius
Third	Glosso-pharyngeal	Stylo-pharyngeus (Constrictors of pharynx ?)
Fourth Fifth ? Sixth	Vagus-Accessory	Constrictors of pharynx Muscles of soft palate Muscles of larynx Sterno-mastoid and trapezius

Muscles of the Orbit.—It has not been possible to identify cephalic muscle-plates in the human embryo. The muscles of the orbit can be distinguished in the embryo as a single pre-muscle mass, closely related to the optic vesicle, and receiving the terminations of the third, fourth, and sixth cranial nerves. Muscle-plates have been demonstrated in the head-region of elasmobranch fishes: the precise number is uncertain, but probably there are at least nine, of which the last four are occipital. The first three cephalic muscle-plates form the muscles of the orbit—the first giving rise to the group supplied by the oculomotor nerve, the second to the superior oblique, and the third to the lateral rectus muscle. The fourth and subsequent myotomes disappear, but three occipital muscle-plates persist to form the muscles of the tongue.

Musculature of the Limbs.—The developing limb-bud consists of an ectodermal envelope enclosing a mass of mesoderm from which both the skeletal elements and the musculature of the limb are derived. Ventral and dorsal sheets of muscle are laid down, and they are at first continuous with each other along the pre-axial and post-axial borders of the bud. The anterior primary rami of the spinal nerves which eventually enter into the formation of the limb-plexus are at first arranged segmentally in the developing limb, and each gives ventral and dorsal branches to exactly corresponding portions of the muscle-sheets. It will therefore be found that the muscles which develop along the pre-axial border, whether ventral or dorsal, are innervated by the highest nerve of the plexus, while those which develop along the post-axial border are innervated by the lowest nerve of the plexus. The early subdivision of the limb-musculature into ventral and dorsal sheets, and the innervation of portions of both sheets by every nerve of the limb-plexus, are indicated in the fully formed upper limb by the division of the trunks of the brachial plexus into anterior and posterior divisions before the formation of the cords; and, in the case of the lower limb, by the similar division of the nerves that enter the lumbar and sacral plexuses.

The proximal portions of the two muscle-sheets extend towards the trunk and eventually constitute the muscles which connect the limb or its girdle to the trunk (with the exception of the trapezius). Those muscles are much more numerous in the upper limb than they are in the lower limb, where their chief representative is the psoas major.

FIG. 1.—LATERAL RADIOGRAPH OF LEFT HALF OF JAWS OF MALE SKULL WITH COMPLETE SET OF TEETH.

Note the details of the Tooth Cavities and Root Canals, and of the structure of the bone around the Tooth Sockets (for periodontal membrane and lamina dura, see p. 574). The usual relation of the Roots of the Upper Teeth to the Maxillary Sinus (see p. 197) is well shown; see also Plate VII, p. 154.

FIG. 2.—RADIOGRAPH OF RIGHT HALF OF MANDIBLE OF CHILD AGED TWO YEARS, SHOWING THE STATE OF ERUPTION OF THE TEETH.

Note the situation of the developing first permanent molar behind the full set of deciduous teeth. In Figs. 2 and 3, the deciduous teeth are indicated by small letters, the permanent teeth by capitals.

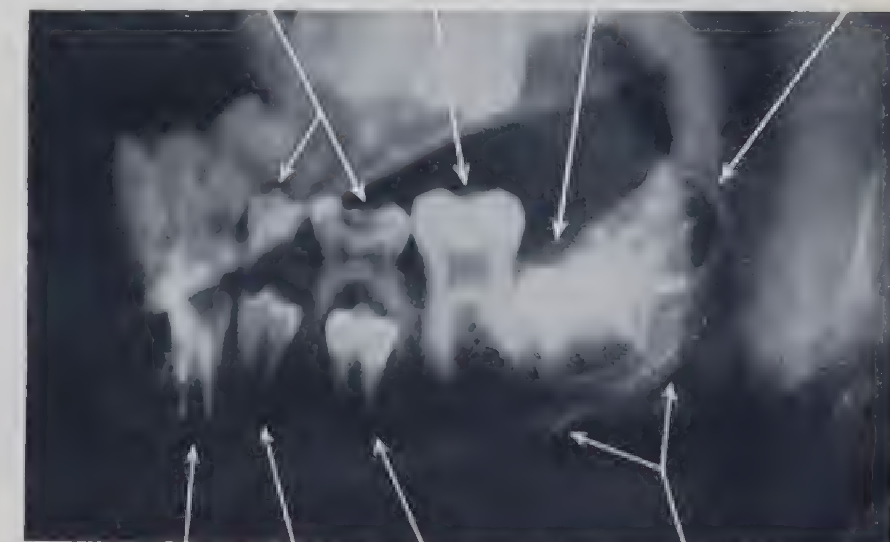

FIG. 3.—RADIOGRAPH OF MANDIBLE OF CHILD AGED NINE YEARS, SHOWING THE STATE OF ERUPTION OF THE TEETH.

Note the situation of the second and third permanent molars, behind the fully-erupted first permanent molar, and the stage of their development. The roots of the permanent canine and premolars are not fully calcified at their apices.

PLATE XLVIII

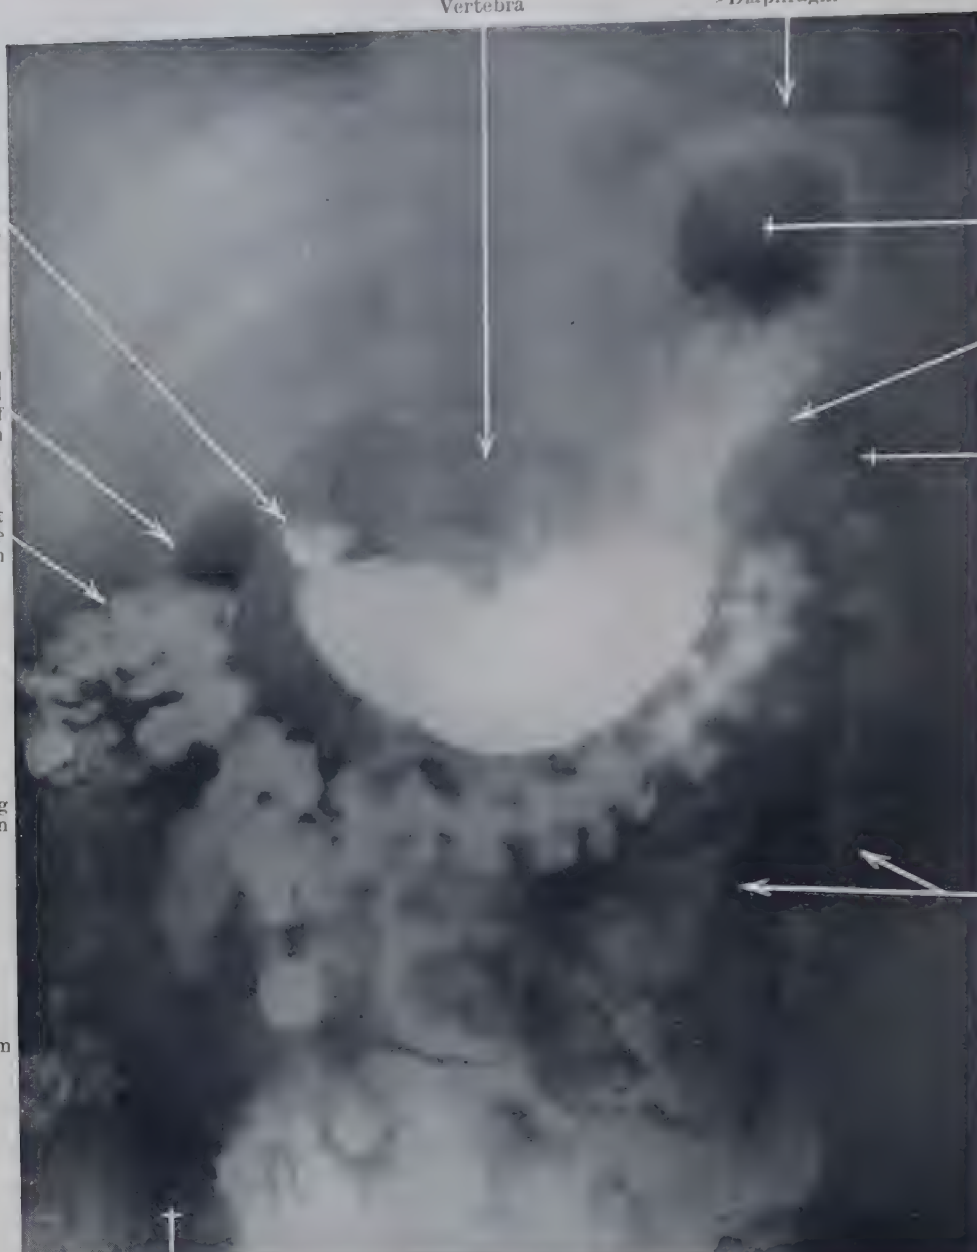

PLATE XLVIII.—RADIOGRAPH OF ABDOMEN OF MAN AGED 28 IN THE ERECT POSTURE, SHOWING THE APPEARANCE OF THE ALIMENTARY CANAL AFTER ADMINISTRATION OF OPAQUE MEALS AT INTERVALS.

The contents of the Stomach and Duodenum and of the Ileum seen in Plate LIII, p. 612 (given respectively 45 and 48 hours previously) are now in the Large Intestine. The first half of a third opaque meal (given one hour before the radiograph was taken) is in the Jejunum and Ileum, and the Stomach is half-filled by the second half. Note the Duodenal Cap (see p. 621) and the residue of radio-opaque material in the Cæcum and Ascending Colon. For further stage in the filling of the Large Intestine, see Plate LVII, p. 648.

DIGESTIVE SYSTEM

By M. R. Drennan, M.A., M.B., Ch.B., F.R.C.S.Ed.

Professor of Anatomy, University of Cape Town

The physical characters and chemical composition of food taken into the body are such that much of it cannot be utilized at once by the organism. Before it is absorbed and used in nutrition, it is acted upon both chemically and mechanically. The process of performing these mechanical and chemical changes is called *digestion*.

The term **Digestive System** is applied collectively to the organs which are concerned in this process, in the reception of food into the body, and in the excretion of the unabsorbed residue.

A simple form of digestive system, found in many of the lower animals, consists of a tube that passes through the interior of the body from an anterior aperture or mouth to a posterior aperture or anus.

In Man, a tube of that kind forms the basis of the digestive system. It extends from the mouth, through the neck, thorax, abdomen, and pelvis, to the anal orifice. The wall and lining membrane act mechanically and chemically upon the food in its interior, absorb products of digestion and transmit them into the adjacent blood-vessels and lymph-vessels.

The successive parts of this tube are the *mouth, pharynx, œsophagus, stomach, small intestine,* and *large intestine.* The mouth and pharynx are used for respiration as well as for digestion, and the **alimentary canal** proper begins at the upper end of the œsophagus. In addition, there are several glandular organs whose ducts open into the mouth—the *salivary glands*—and into the small intestine—*liver* and *pancreas.* These also are included in the digestive system. The general arrangement, position, and size of these various parts are shown in Fig. 479.

MOUTH

The **mouth**, the first part of the digestive system, is bounded externally by the lips and cheeks, and is roofed in by the palate. Within it lie the teeth and greater part of the tongue; and the ducts of the salivary glands open into it.

The aperture of the mouth or **oral fissure** is the interval between the lips, which meet at the *angles of the mouth.* In a state of rest, with the lips in apposition, the aperture forms a slightly curved line which extends transversely between the first premolar teeth at a level immediately below the middle of the upper incisor crowns. The shape of the aperture varies with every movement of the lips, from the resting linear form, curved like the conventional bow, to a circular or oval shape when the mouth is widely open, or the "pursed-up" condition produced by the contraction of the orbicularis oris muscle.

The **cavity of the mouth** is divisible into two portions—the *vestibule* and the *cavity proper.*

The **vestibule of the mouth** is the interval between the lips and cheeks externally and the teeth and gums of the upper and lower jaws internally.

When the oral fissure is closed and the lips and the teeth are in contact, the vestibule is merely a slit whose roof and floor are formed by the reflexion of the mucous membrane from the lips and cheeks to the maxillæ and mandible.

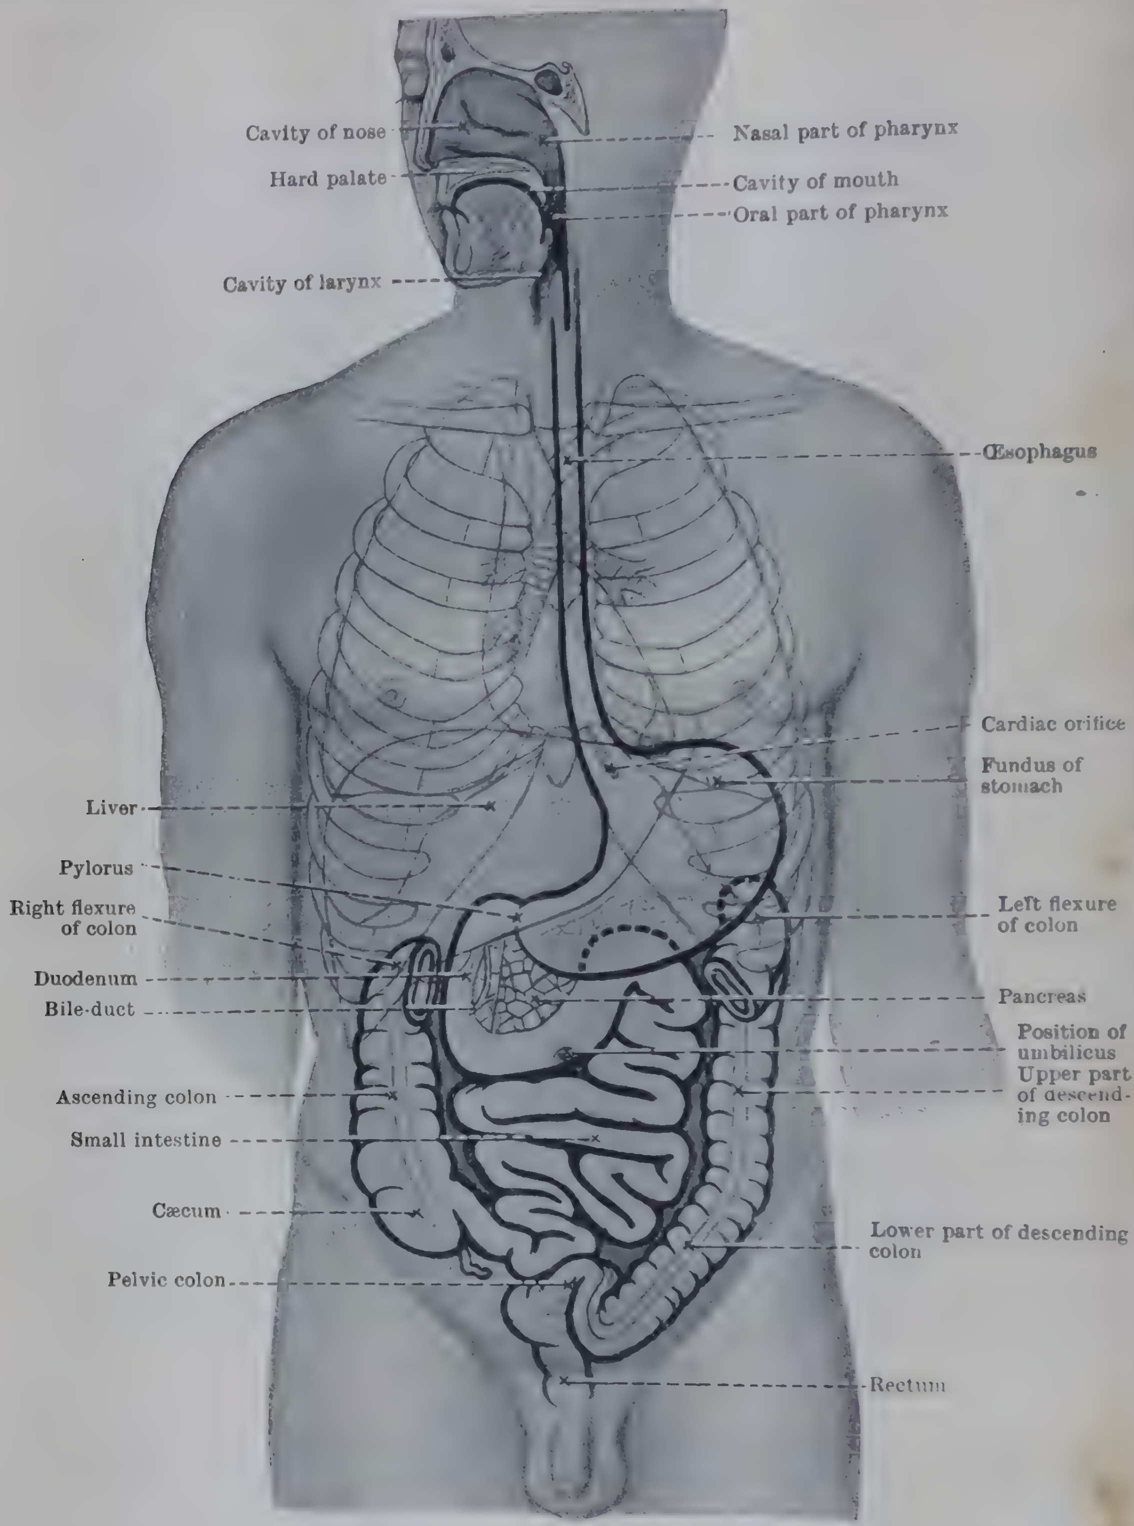

FIG. 479.—DIAGRAM OF GENERAL ARRANGEMENT OF DIGESTIVE SYSTEM.

The transverse colon is not represented, in order that the duodenum and pancreas, which lie behind it, may be seen.

From the back of each lip in the median plane projects a small vertical fold of mucous membrane—the **frenulum**—which connects the lip to the front of the corresponding gum. The *frenulum of the upper lip* is the larger, and is brought into view when the lip is everted. The *frenulum of the lower lip* is not always obvious.

On the outer wall of the vestibule, opposite the crown of the second upper molar tooth, there is a slight eminence, and on its summit is the small opening of the duct of the parotid salivary gland.

When the upper and lower teeth are in contact the vestibule communicates with the cavity of the mouth only through small and irregular spaces between opposing teeth, and, behind, by the wider but variable aperture between the last molars and the ramus of the mandible.

Advantage may be taken of that aperture for the introduction into the mouth of liquid food in certain cases—trismus, anchylosis, etc.—in which the jaws are rigidly closed.

If the finger is passed backwards in the vestibule, the anterior border of the masseter can be distinctly felt on the outer wall when the muscle is thrown into a state of contraction. Still farther back, the front of the coronoid process, bearing the insertion of the temporal muscle, can also be made out. The pterygo-mandibular ligament, which is felt along with the anterior border of the medial pterygoid muscle, is distinguishable as a pliant ridge when the finger is carried from the front of the coronoid process behind the last molar tooth into the cavity of the mouth.

In addition to the ducts of the parotid glands, those of numerous small glands, which are embedded in the lips and cheeks, open into the vestibule.

Under normal conditions the lips and cheeks lie against the teeth and gums, obliterating the cavity of the vestibule; and they help, with the aid of the tongue, to keep the food between the grinding surfaces of the molar teeth during mastication. In facial palsy, however, the lips and cheeks fall away from the dental arches, owing to the paralysis of their muscles, and particularly of the buccinator muscle, and food accumulates in the vestibule.

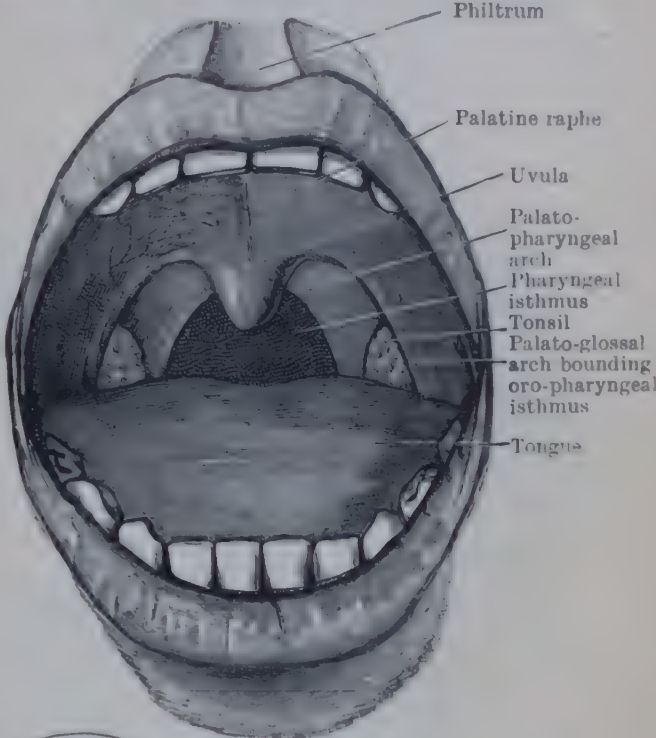

FIG. 480.—OPEN MOUTH SHOWING PALATE AND TONSILS.

It shows also the two palatine arches, the oro-pharyngeal isthmus, through which the mouth communicates with the oral part of the pharynx, and the pharyngeal isthmus or communication of the oral part of the pharynx with the nasal part.

The **cavity proper of the mouth** is within the arches of the teeth and gums and extends back to the palato-glossal arches. The *roof* is formed by the **hard palate** and the anterior portion of the **soft palate**, the *floor* by the anterior part of the tongue in the middle, and on each side by the reflexion of the mucous membrane from the side of the tongue to the mandible.

The term "floor of the mouth" indicates the muscular and other structures, especially the mylo-hyoid muscles, which fill in the interval between the two halves of the body of the mandible (from the symphysis menti to the body of the hyoid bone) and form the basis upon which the tongue and the mucous membrane of the sublingual space are supported.

When the tip of the tongue is raised the mucous membrane in the median plane forms a prominent fold, called the **frenulum of the tongue**, which stretches from the floor of the mouth to the inferior surface of the tongue. On each side of the frenulum, near its junction with the floor, there is a prominent soft projection, called the **sublingual papilla**, on which the **duct of the submandibular gland** opens (Fig. 481). Running laterally and backwards, on each side, from the frenulum, there is a well-marked ridge, called the **sublingual fold**, which is due to the bulging of the underlying sublingual gland. Most of the ducts of the gland open near the crest of this ridge. Another fold, called the **fimbriated fold**, lies lateral to the frenulum, on each side, on the inferior surface of the tongue (Fig. 481).

This fold represents the "sublingua" of Lemurs, a highly developed fringe situated under the tongue which functions as a cleanser of the incisor teeth (Wood Jones, 1918).

Lips.—The lips are the two mobile folds, covered externally with skin, and internally with mucous membrane, which surround the oral fissure and contain the orbicularis oris muscle. Laterally they are prolonged into the cheeks, and below into the chin. The junction of the lips and cheek is marked on the

surface by the **naso-labial sulcus**—a slight groove which passes downwards and laterally from the margin of the nose towards the angle of the mouth—and the **mento-labial sulcus** separates the lower lip from the chin. At the middle of the upper lip there is a shallow vertical groove—the **philtrum**—bounded by two distinct ridges that descend from the nasal septum (Fig. 481); inferiorly the groove widens out and ends opposite a slight projection on the free edge—the *labial tubercle*. This tubercle is particularly well developed in children and is chiefly responsible for the characteristic curve of the oral fissure. The lower lip is usually longer and more movable than the upper lip.

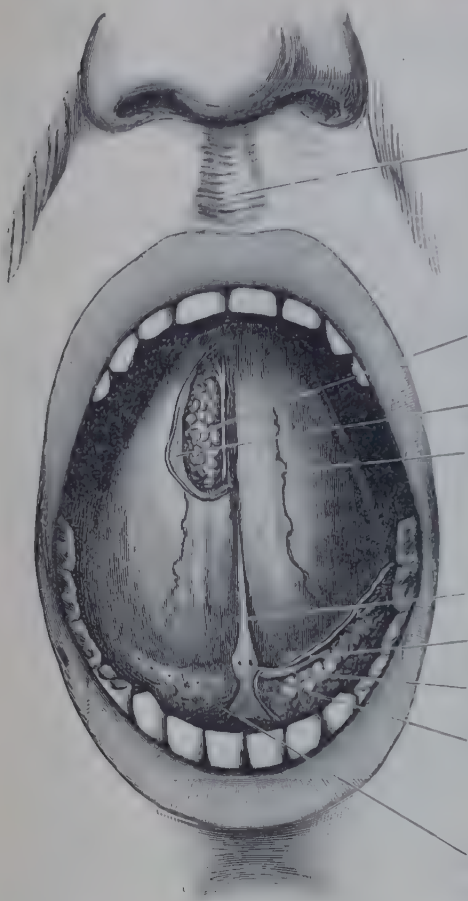

Fig. 481.—Open Mouth with Tongue raised, and the Sublingual and Anterior Lingual Glands exposed.

The sublingual gland of the left side has been laid bare by the removal of the mucous membrane; to expose the anterior lingual gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial side of the gland. The profunda vein also is faintly indicated on this side.

Between the inner and outer surface of each lip there is an intermediate area—the free margin—which bounds the oral fissure. It is covered with a modified mucous membrane similar to that of the mouth but devoid of mucous glands and dry. It is translucent and transmits the colour of the blood in the underlying capillaries, and hence in health it is reddish-pink in colour. Its size and shape vary greatly; it may be narrow and thin, occupying only a small area on the external surface of the lip, or it may be wide and pouting and, as in the negro, may occupy a wide surface externally. The surface is richly vascular and numerous nerve-terminals are present in it. It is limited externally by a sharply defined line where the skin and mucous membrane meet, but the internal boundary merges into the mucous membrane of the mouth. In the upper lip, the external bounding line follows a curve from near the angle of the mouth to the root of the labial tubercle and there turns sharply downwards, forming with its fellow a bow-shaped figure. In the lower lip the line runs in a more uniform curve from one angle of the mouth to the other. In the child the free margin is transversely grooved and is also divided by a longitudinal groove into two zones—the outer villous, the inner smooth.

In each lip the following structures are present from the external to the internal surface:—(1) **Skin**, closely studded with hairs, small and fine in children and women, long and stout in men. (2) A layer of fatty **superficial fascia** continuous with the fascia of the face. (3) The **orbicularis oris muscle**, a number of whose fibres, or those of the muscles which join it, pass through the superficial fascia and are attached to the skin. (4) **Submucous tissue**, which is occupied by an almost continuous layer of glands—the **labial glands**; they are small, nodular glands, each about the size of a grape-seed, closely packed together, and lie immediately external to the mucous membrane of the upper and lower lips; each nodule is a small, racemose gland lined with mucous secretory cells, with a short duct which pierces the mucous membrane. (5) **Mucous membrane** of the mouth, covered with stratified squamous epithelium.

For the various muscles which enter into the formation of the lip, see the Section on Myology (pp. 424-426).

Vessels and Nerves.—The lips receive a free **arterial** supply from the labial branches of the *facial artery*.

The sensory **nerve-supply** of the lips is derived from the *trigeminal nerve*—that of the upper through the *infra-orbital branch* of the maxillary nerve, and that of the lower from the

mental branch of the inferior dental branch of the mandibular nerve, while the *buccal* branch of the mandibular nerve supplies the region of the angle. The **lymph-vessels** of the upper lip pass with the facial artery to the *submandibular lymph-glands*, while those from the lower lip pass in part to the same glands, and in part to the *submental glands.*

Movements of Lips.—Opening and closing of the oral fissure are usually associated with elevation and depression of the mandible. Finer movements are effected by contraction of the orbicularis oris muscle as a whole or of its parts, and by those muscles of expression which are inserted into the upper and lower lips.

Ability to perform finer movements of the lips in speech or in whistling constitutes a test of the integrity of the nerve-supply of these muscles.

Cheeks.—The cheeks resemble the lips in structure, and have corresponding layers, but the buccinator muscle takes the place of the orbicularis oris. Under the skin lies the fatty superficial fascia of the face, through which the **parotid duct** runs inwards to pierce the buccinator; it is much looser in texture than in the lips. Near the end of the duct are found four or five mucous glands, as large as hemp-seeds, known as the **molar glands**; their ducts pierce the cheek and open into the vestibule. Beneath the superficial fascia lies the *buccinator muscle,* covered by the bucco-pharyngeal fascia. Deeper still is the submucosa, which, like that of the lips, contains numerous mucous glands—the **buccal glands**—and finally the mucous membrane.

The **buccal pad of fat** is an encapsuled mass of fat which lies on the outer side of the buccinator, and in the recess between that muscle and the overlying part of the masseter and ramus of the mandible. It gives to the cheeks their rounded contour. It is relatively larger in the child than in the adult, and it strengthens the cheek to resist the effects of atmospheric pressure during the act of sucking.

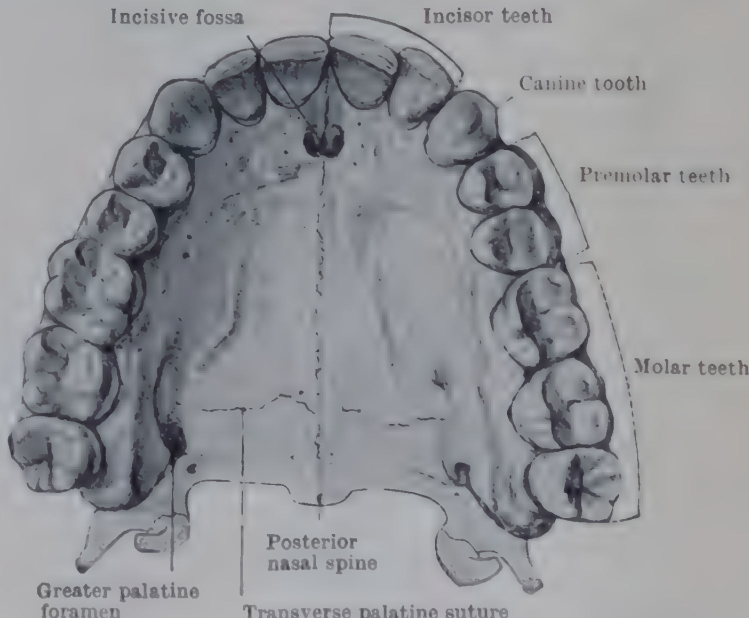

FIG. 482.—HARD PALATE AND UPPER PERMANENT TEETH.

Movements of Cheeks.—The cheeks are of great importance in mastication. By their movements the cavity of the vestibule of the mouth can be obliterated, and food in the vestibule forced into the cavity of the mouth proper. Movements of the cheeks are also required in playing wind-instruments. The principal agent is the buccinator muscle, but the orbicularis oris muscle and the muscles inserted into the lips also participate.

Palate.—The palate forms the roof of the mouth. It separates the mouth from the nasal cavities and nasal part of the pharynx, and it extends backwards into the cavity of the pharynx, forming a partial division between the oral and the nasal parts of the pharynx.

It consists of two portions—an anterior two-thirds, with a bony foundation, termed the *hard palate,* and a posterior third, with a fibro-muscular basis, termed the *soft palate.* The palate is arched antero-posteriorly and also transversely. The transverse curvature is the more pronounced in the hard palate.

The **hard palate** is a horizontal plate formed by the palatine processes of the maxillæ and the horizontal plates of the palatine bones, covered on each surface, superior and inferior, with muco-periosteum. The muco-periosteum of the inferior surface is very thick, and contains in its posterior part a large number of mucous glands and the larger nerves and blood-vessels of the palate (Fig. 483). The epithelium of the muco-periosteum which covers the superior surface forms the floor of the nasal cavity and is largely ciliated in character, while that on the inferior surface is covered with stratified squamous epithelium.

The **soft palate** is attached to the posterior margin of the hard palate. Its lower or posterior margin is free and forms an arch which extends from one side of the pharynx to the other; but the arch is interrupted in the middle by a conical projection, called the **uvula**, which shows great variation in length; in some persons it is short and blunt; in others it is long and thin and its tip may extend downwards to the dorsum of the tongue. On each side, the soft palate is connected with two folds of mucous membrane which are separated

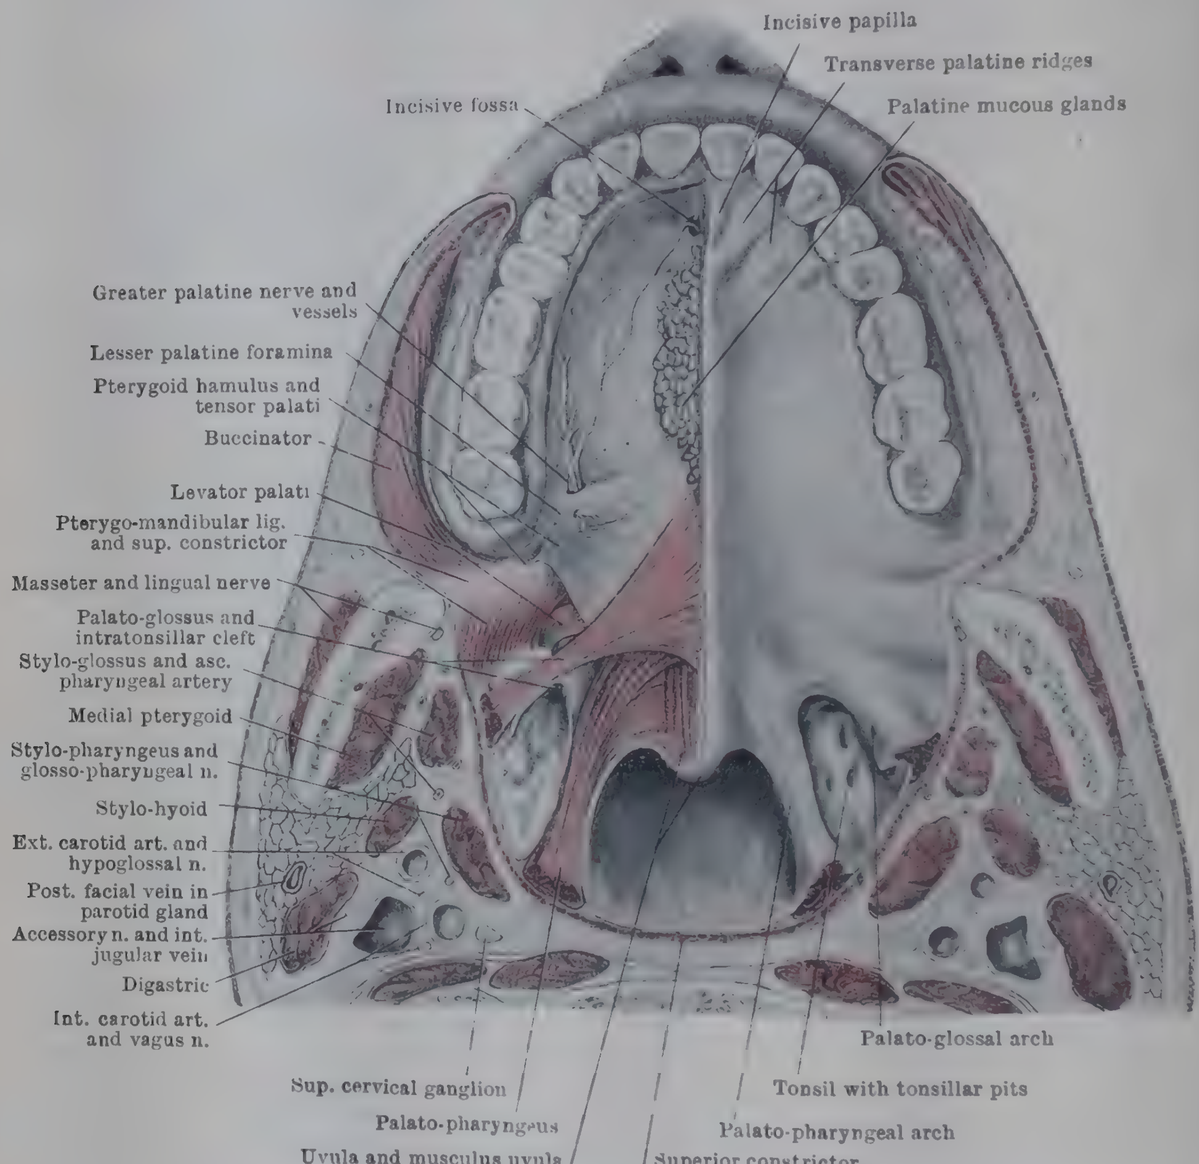

FIG. 483.—HORIZONTAL SECTION AT LEVEL OF ORAL FISSURE SHOWING PALATE FROM BELOW.
The right half of the palate has been dissected to show the palatine glands, arteries and nerves and the muscles of the soft palate.

by a triangular interval occupied by the tonsil. The anterior fold is called the *palato-glossal arch* (p. 566), and it descends to the side of the tongue. The posterior fold descends from the posterior edge of the soft palate and is lost on the side-wall of the pharynx; it is called the *palato-pharyngeal arch* (p. 590).

The superior surface of the soft palate continues the floor of the nasal cavity backwards and downwards and forms the floor of the nasal part of the pharynx.

Along the middle of the oral surface of the palate, a faint median ridge—the **palatine raphe** (Figs. 480, 483)—indicates its original development from two halves; it begins behind at the root of the uvula, and in front it ends in a slight elevation called the **incisive papilla**; in the fœtus, and even at birth, the papilla is continued over the edge of the gum into the frenulum of the upper lip. From the anterior part of the raphe a series of transverse ridges of mucous membrane, about six in number, run laterally

immediately behind the incisor teeth; they are known as the *transverse palatine ridges*, and are composed of dense fibrous tissue adherent to the periosteum. These ridges correspond to the strongly marked ridges seen in the roof of the mouth of lower animals; they are very distinct in a fœtus of five or six months, are less distinct in a child, and become more or less obliterated in old age. Sometimes a small pit which will admit the point of a pin is seen on each side immediately behind the central incisor teeth and about 2 mm. from the median plane. These pits correspond to the inferior openings of the incisive canals, with which they are occasionally continuous.

The soft palate, during rest, as for instance in quiet nasal breathing, is very oblique in direction. When, however, the soft palate is raised, as in swallowing, it continues the plane of the hard palate backwards, and projects across the cavity of the pharynx, forming a nearly complete partition between its oral and nasal parts. In that position it prevents food from passing upwards into the nasal part of the pharynx and the nose.

Structure.—The framework of the soft palate is a strong, thin, flat, fibrous sheet, called the *palatine aponeurosis*, which is confined to the anterior part of the soft palate, and is formed by the expanded tendons of the tensor palati muscles. Its anterior margin is united to the posterior edge of the horizontal plates of the palatine bones. The tensor palati is continuous with its lateral part, but the other muscles occupy chiefly the posterior two-thirds of the soft palate.

The anterior part of the soft palate contains the anterior fibres of the palato-glossus (Fig. 483), and the origins of the musculi uvulæ, but it consists essentially of the palatine aponeurosis, covered by an extremely thick layer of glands on the inferior surface and by mucous membrane on both surfaces. The anterior portion is much less movable than the rest of the soft palate, and forms a relatively horizontal continuation backwards of the hard palate, stretching across between the two medial pterygoid plates. Upon that portion chiefly the tensor palati muscles act. The posterior and larger part contains muscular fibres in abundance, slopes strongly downwards, and is freely movable, and upon it the other palatine muscles act. The muscles of the soft palate (palato-pharyngeus, palato-glossus, levator palati, tensor palati and musculus uvulæ) are described on pp. 441-443.

The mucous membrane of the oral surface of the soft palate is covered with stratified squamous epithelium. In the fœtus the whole of the epithelium on the upper surface is ciliated, but after birth the ciliated epithelium is largely replaced by stratified squamous epithelium, except at the margins.

Mucous glands, the orifices of which can be seen as dots with the naked eye, are extremely abundant in the soft palate and in the posterior half of the hard palate, except near the raphe. The position and limits of these glands are usually clearly indicated by the smooth area of the hard palate. The glands usually extend forward as far as a transverse line drawn behind the canine teeth.

The **uvula** is composed of a mass of mucous glands and areolar tissue covered with mucous membrane, and it contains a slender prolongation of the uvular muscle.

Vessels and Nerves of Palate.—The principal **arteries** are the palatine branches of the maxillary artery. The largest and most important of these is the *greater palatine artery*, which reaches the palate through the greater palatine foramen and runs forward along the lateral margin of the hard palate, near the alveolar margin, towards the incisive fossa, where it anastomoses with a minute terminal branch of the spheno-palatine artery. Some smaller *lesser palatine branches* from the maxillary artery emerge through the lesser palatine foramina and supply the soft palate and anastomose with the ascending palatine branch of the facial artery. The soft palate shares in the blood-supply of neighbouring structures, and so receives a blood-supply from the tonsillar branch of the facial artery, the ascending pharyngeal artery, and the dorsal lingual branches of the lingual artery.

The **sensory nerves** of the palate are all branches from the spheno-palatine ganglion. The largest of these—the *greater palatine nerve*—emerges through the greater palatine foramen and divides in the roof of the mouth into branches which run in grooves in the hard palate and extend forward nearly to the incisor teeth. Some of them join with a small branch of the *long spheno-palatine nerve*, which reaches the palate through the median incisive foramen. The *lesser palatine nerves* emerge through the lesser palatine foramina and are distributed to the hard and soft palate. For the **motor** nerves to the muscles of the soft palate, see p. 444.

The **lymph-vessels** of the palate pass lateral to the tonsil and the palato-glossal arch to the *upper deep cervical lymph-glands*.

Movements of Soft Palate.—The hinder part of the soft palate is freely mobile, moving like a door on its hinge near its junction with the hard palate. It can be raised so that its dorsal surface comes into contact with the posterior wall of the pharynx, where it meets a ridge formed by the contraction of the upper fibres of the superior constrictor muscle of the pharynx, known to surgeons as Passavant's ridge. By means of this mechanism, which has been compared to a sphincter, the oral part of the pharynx is separated from the nasal part. The elevation of the soft palate is effected by the levator

and tensor palati muscles, and the resulting closure of the pharyngeal isthmus takes place in swallowing, in vomiting, and in speech, except with the consonants *m*, *n*, and *ng*, which require nasal resonance for their correct pronunciation. The soft palate can also be lowered and its under surface brought into contact with the posterior part of the upper surface of the tongue through the agency of the palato-glossus and palato-pharyngeus muscles. (See also p. 444.)

Oro-Pharyngeal Isthmus.—The oro-pharyngeal isthmus is the aperture through which the mouth communicates with the oral part of the pharynx (Fig. 480). It is bounded at the sides by the palato-glossal arches, above by the inferior surface of the soft palate, and below by the dorsum of the tongue; in width it corresponds pretty closely to the cavity of the mouth.

Each **palato-glossal arch** is a fold of mucous membrane which contains a palato-glossus muscle in its interior. It begins on the lower surface of the soft palate about one-third of an inch (8 mm.) in front of its posterior edge, near the root of the uvula, and it arches laterally and downwards to blend with the mucous membrane of the side of the tongue a little behind its middle.

Gums.—The gums (gingivæ) are composed of firm fibrous tissue united with mucous membrane. They are attached to the alveolar borders of the maxillæ and mandible and surround the necks of the teeth. They are richly supplied with blood-vessels but sparsely with nerves, and they are covered with stratified squamous epithelium. Around the neck of each tooth the gum forms a free overlapping collar, and at that part particularly it is closely studded with small papillæ, visible to the naked eye. In thickness it usually measures from 1 to 2 mm.

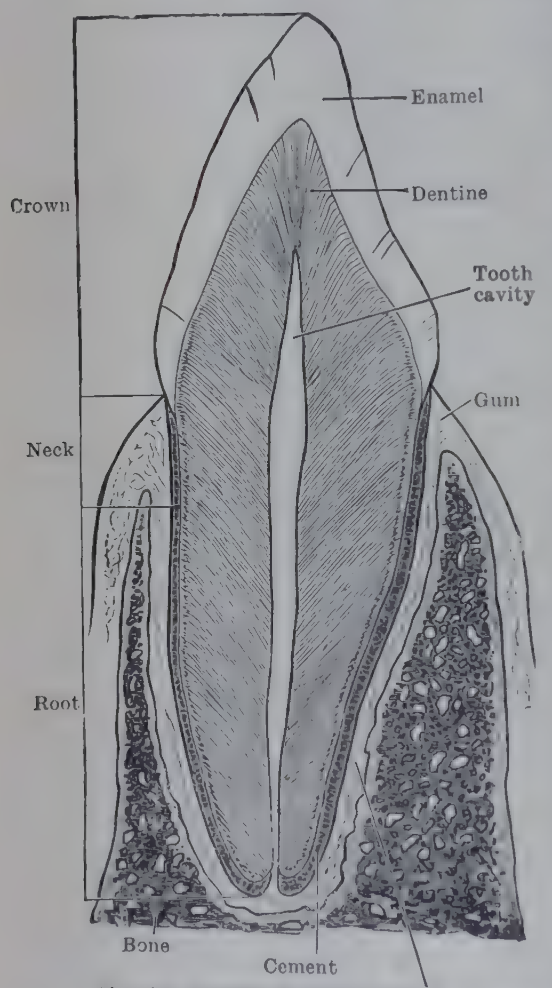

Fig. 484.—Vertical Section of Canine Tooth to illustrate its Parts and Structure.

TEETH

The teeth, rooted in the tooth-sockets of the upper and lower jaws, are of different form and shape, and appear in two sets—a deciduous (milk-teeth) and a permanent.

The deciduous teeth appear through the gums from about the sixth month of childhood. They are gradually shed and are succeeded by the permanent teeth.

General Form and Structure.—Each tooth has a crown, a neck, and a root (Fig. 484). The **crown** is the portion above the gum. It is of different form in the different teeth, being chisel-shaped, conical, or flattened and broad with tubercles on its masticating surface. The surface of the crown which faces outwards is termed its *labial* (or *buccal*) *surface*, that on the opposite side its *lingual surface*. The terminal surface of molars and premolars is termed the *masticating surface*. The **neck** is the faintly constricted part which connects the crown with the **root**, which is the portion of the tooth embedded in the socket. In the majority of teeth, the root is single or nearly so, and it is long, tapering, conical, or flattened—accurately fitting the socket. In the molar teeth (and in some of the others occasionally) the root is divided into two or three tapering or flattened roots or fangs. At the apex of each root there is a minute opening, called the **root-foramen**, through which the vessels and nerves enter the cavity of the tooth.

The **cavity of the tooth** is a space of some size, which is filled in the natural

state by loose areolar tissue, capillaries, nerves, and lymph-vessels; these structures collectively constitute the **pulp of the tooth**. The cavity is prolonged into each root as a slender tapering passage, called the **root-canal**, which opens at the root-foramen.

Short diverticula of the cavity are prolonged into the bases of the tubercles in the molar and premolar teeth, and in the incisors also there are similar slight prolongations towards the angles of the crown.

The root of a tooth, embedded in the **socket** (alveolus), is firmly united to the wall of the socket (Fig. 484) by a layer of vascular fibrous tissue—the **alveolar periosteum**—which is attached to the wall and to the root of the tooth, and above is continuous with the periosteum and with the fibrous tissue of the gum. It is known in dentistry as the *periodontal membrane.*
